Abstract: A Watt-level continuous and single frequency blue laser at 461 nm is obtained by frequency-doubling an amplified diode laser operating at 922 nm via a LBO crystal in a resonant Fabry-Pérot cavity. We achieved a best optical conversion efficiency equal to 87% with more than 1 W output power in the blue, and limited by the available input power. The frequency-converted beam is characterized in terms of long term power stability, residual intensity noise, and geometrical shape. The blue beam has a linewidth of the order of 1 MHz, and we used it to magneto-optically trap $^{88}$Sr atoms on the $5s^2 1S_0 - 5s5p 1P_1$ transition. The low-finesse, linear-cavity doubling system is very robust, insensitive to vibrations, and is compatible with a tenfold increase of the power levels which could be obtained with fully-fibered amplifiers and large mode area fibers.

1. Introduction

Blue and violet laser light is increasingly adopted for both scientific and technical purposes, like in underwater communication [1], medical science [2], and quantum information [3]. In the specific context of timekeeping, driven in the last years by the unrelenting improvements of optical lattice clocks, laser light in this band is typically required for the laser cooling of alkaline-earth and alkaline-earth-like atoms, e.g. for Yb at 399 nm, Ca at 422 nm, and Sr at 461 nm.

Different approaches are adopted to obtain the few hundreds of mW typically required for such cooling: laser diodes, a technologically simple solution, which can combine moderate power and narrow linewidth but requires optical injection of one or more slave modules [4]; single-pass second-harmonic (SH) generation with a bulk crystal [5], which can achieve high power, while doubling the source linewidth but only with large input power; SH generation exploiting a travelling-wave cavity [6, 7], commonly folded in a bow-tie configuration for compactness. The latter configuration, which is widely adopted commercially [8, 9], offers high power and narrow linewidth at the price of a complex alignment procedure and a high sensitivity to vibration noise and optical losses.

2. Frequency-doubling system

In this article, we demonstrate high power CW operation at 461 nm. Our system exploits frequency doubling of an amplified infrared laser in a linear cavity [10] via a lithium triborate (LBO) crystal. Our solution combines low linear losses, ease of alignment, and high mechanical...
stability thanks to the reduced number of optical elements. Notably, we obtain an output power of 1 W, competitive with the state-of-the-art, and yet limited only by the available level of input power; the figure could be widely increased as soon as higher power will be available for the fundamental wavelength [11].

The scheme of our frequency doubler is shown in Fig. 1. The seed laser light at $\lambda=922$ nm and with a linewidth <200 kHz is generated by an ECDL (DL pro, Toptica) fiber coupled to a Tapered Amplifier (TA pro, Toptica). The system delivers a maximum output power of 2.2 W in free space, reduced to 1.36 W after coupling it to a single-mode fiber (P1-780PM-FC-1, Thorlabs) to clean the geometrical mode and ease its alignment on the doubling cavity (position A in Fig. 1).

Two $\approx 60$ dB double-stage Faraday isolators (FI1 and FI2) decouple the TA from the seed laser and from the doubling cavity respectively, thus protecting the system and avoiding frequency and intensity noise due to optical feedback.

We tested different kinds of non-linear crystals for the SH generation, as resumed in Tab. 1. Periodically-poled crystals operating at quasi-phase matching condition have been dismissed, despite a promising high conversion efficiency ($d_{\text{eff}}$), because of their major limitations at high power induced by the photo-refractive beam distortion, the blue-induced infrared absorption [12], and thermal effects [13]. $\beta$-barium borate (BBO) [14] and bismuth triborate (BIBO) [15] crystals were discarded because of their large walk off angle (see Tab. 1). We opted for a LBO crystal from Crystal Laser characterised by a small walk off angle, high thermal conductivity, and an overall good long-term stability; its much smaller second-order non-linearity compared to periodically-poled crystals is compensated by a much higher damage threshold and crystal quality, a greater transparency at the operating wavelengths, and lower thermal lensing [16,17].

Table 1. Key parameters for different kinds of crystals suitable to generate blue light by SH generation.

The LBO crystal is tightly fixed on the cavity axis; it has a length of 15 mm and a cross section of $3\times3$ mm$^2$. The crystal is cut for normal incidence $\theta = 90^\circ$, $\phi = 21^\circ$ at the phase matching at 48 $^\circ$C and has a two layer antireflective coating working at 922 nm (reflectivity R<0.1%) and 461 nm (R<0.3%). The temperature of the LBO crystal is stabilized to the optimal phase-matching temperature of 48$^\circ$C with a long term stability at the mK level, by controlling the temperature of the copper holder where it is fixed. The input mirror of the cavity is concave and has a nominal reflectivity at 922 nm equal to 98.8%; the output coupler is a flat mirror coated for high reflection at 922 nm and antireflection at 461 nm. The cavity is 17 mm long, which results in a waist of $\sim 40 \mu$m on the output mirror; the single-pass nonlinear conversion efficiency is evaluated to $\sim 1.0 \times 10^{-4}$ W$^{-1}$ [20].

The amplified seed laser beam before the doubling cavity is mode-matched to the fundamental transverse mode of the cavity with a pair of lenses (L1 and L2), whose positions are precisely adjusted by means of micrometric translational stages. The polarization axis of the input beam is controlled with a $\lambda/2$ waveplate. To further protect the TA from optical feedback – particularly
Fig. 1. (a) Frequency doubling setup. The laser power at 922 nm injected to the cavity is measured at position A, the output power at 461 nm at position B. TA: tapered amplifier; FI1, FI2, FI3: Faraday isolators; BS: beam splitter; PBS: polarizing beam splitter; PD: photodetector; LPF: low-pass filter; L1, L2: aspherical lenses; L3, L4: cylindrical lenses; PM: prism mirror; WM: wavelength meter. strong when the cavity unlocks – we placed an additional 30 dB optical isolator (FI3) resulting in an extra 12% insertion loss at the input of the resonator.

The optical cavity is locked to the input seed laser using the modulation-free Hänsch-Couillaud stabilization technique [21]; the cavity length is controlled by a piezo-electric device which translates one of the two mirrors defining the resonator with a 1 kHz bandwidth. The doubling efficiency is critically dependent on the mechanical and thermal stability of the system, hence great care was devoted to the design of the doubling cavity. Notably, mechanical robustness has been obtained by gluing the components of the doubling system to a Zerodur plate and enclosing it in an aluminum box to passively improve its temperature stability.

Fig. 2. Measured output power at 461 nm from the SH module (blue filled circles) and optical conversion efficiency versus incident fundamental laser power (red open squares). The solid lines result by fitting the experimental points with the theoretical curves.

3. Characterization

We measured the doubling cavity conversion efficiency $\epsilon \equiv P_{\text{out}}/P_{\text{in}}$, the power ratio between the SH output component at 461 nm and the fundamental input one at 922 nm, respectively measured at position B and A in Fig. 1. The power of the SH component at 461 nm increases almost linearly with the fundamental laser power (blue circles in Fig. 2). The frequency conversion efficiency also increases, reaching a maximum value equal to 87% with 1.05 W of blue light at 461 nm generated with 1.19 W at 922 nm (red squares in Fig. 2). By fitting the experimental points with the expected theoretical behavior [20, 22] we: i.) confirm that thermal effects are negligible in our setup; ii.) obtain an input mirror reflectivity at 922 nm of 1.16(1)%, which is very close to the nominal one, and estimate the linear losses in the cavity equal to 0.170(3)%. From these values we infer a cavity finesse of ~ 490. Remarkably, the system performances in terms of both output power and conversion efficiency are presently limited by the available input laser power, which could be up-scaled for example exploiting fully-fibered solutions [23].

The laser system can operate for a few days without any maintenance. The power stability of the frequency conversion system has been characterized by monitoring the SH power over several hours: the peak-to-peak fluctuations over 4 h are ~1.2% (see Fig. 3). However, most fluctuations are strongly correlated with the varying input power (see the inset of Fig. 3), and the uncorrelated relative fluctuations obtained after removing the linear dependence between $P_{\text{in}}$ and $P_{\text{out}}$ over the
same time interval show an Allan deviation of $5 \times 10^{-4}$ at 10 s decreasing to $7 \times 10^{-5}$ at 2500 s, with a standard deviation equal to $\sim 5.5 \times 10^{-4}$. This residual noise could be explained in terms of residual instabilities of the crystal temperature and of the cavity injection pointing.

We measured the relative intensity noise (RIN) of both the fundamental and frequency converted component (see Fig. 4). The spectrum of the fundamental light component starts at -120 dBc/Hz at 100 Hz, rolls-off as $f^{-1}$ till 20 kHz where the slope decreases to $f^{-1/3}$. The SH component shows an excess of noise in the acoustic band on a plateau at -105 dBc/Hz extending till 10 kHz, then it rolls off with a general $f^{-1}$ trend. The doubling process adds excess intensity noise in the whole Fourier frequency range, as already observed in previously published works based on resonant doubling cavities [24, 25] but not in single pass systems [26].
The strong focusing of the fundamental mode on the crystal, imposed to obtain a high conversion efficiency, produces as a side-effect the multi-lobe cross-section of the frequency doubled beam, whose intensity is well described by a sinc \(^2\) function; the central lobe of the output beam contains more than 90% of the power, and we correct its aspect ratio using two cylindrical lenses to improve the single mode fiber injection efficiency.

To demonstrate the system potential in cold atom physics, we use it to implement a 3 dimensional magneto-optical trap (MOT) for \(^{88}\)Sr atoms, capturing the pre-cooled atomic flux produced by a compact 2D MOT similar to that reported in [27, 28]. The frequency of the SH component is referenced to the Sr spectroscopy via a frequency-shift optical lock with a red detuning \(\Delta = 1.5 \Gamma\) with respect to the blue cooling transition \(5s^{2}1S_{0} - 5s5p^{1}P_{1}\) transition of \(^{88}\)Sr (\(\Gamma \sim 2\pi \times 30.5\) MHz is the transition linewidth) [29]. The resulting linewidth of the servo-controlled blue laser is of the order of one MHz, hence significantly below that of the cooling transition. We use the beam to produce the 6 cooling beams for the 3D MOT with integrated fiber splitters, and obtain in this way a stable operation of the trap with \(\sim 10^9\) atoms.

4. Conclusion

In conclusion, we realized a robust frequency doubled system based on a LBO crystal placed in a linear Fabry-Pérot cavity; the system delivers more than 1 W of power at 461 nm with an efficiency of 87%, limited by the available power on the fundamental mode. The drawback represented by the poor mode quality is significantly mitigated by exploiting the two main lobes of the output beam. A higher output power and more integrated setup could exploit a fully-fibered amplifier [23] and large mode area fibers [30] for the fundamental frequency.

*Note:* Another scheme to generate Watt-level blue light by frequency doubling in a cavity a vertical-external-cavity surface-emitting laser (VECSEL) has been reported recently [31].

5. Acknowledgments

We thank Hanyu Ye for splicing an optoisolator to the seed laser and Clément Dixneuf for helping with the data acquisition for the RIN measurement.
