We introduce a one-dimensional lattice model whose hopping amplitudes are modulated for equally spaced sites. Such mosaic lattice exhibits many interesting topological and localization phenomena that do not exist in the regular off-diagonal lattices. When the mosaic modulation is commensurate with the underlying lattice, topologically nontrivial phases with zero- and nonzero-energy edge modes are observed as we tune the modulation, where the nontrivial regimes are characterized by quantized Berry phases. If the modulation becomes incommensurate, Anderson localization will emerge. The eigenstate is found to be localized on two neighboring sites connected by the quasiperiodic hopping terms. This is in sharp contrast with the conventional localization process where the state is localized only on a single site, indicating a new mechanism for Anderson localization. Furthermore, both the commensurate and incommensurate off-diagonal mosaic lattices can host Chern insulators in their two-dimensional generalizations. Our work provides a new platform for exploring topological phases and Anderson localization in low-dimensional systems.

Introduction.—During the past two decades, topological phases have drawn considerable attention from almost every research field of physics [1–4]. To get a better understanding and description of the topological phases, various tight-binding models, or lattice models, have been constructed, for instance, the Haldane model for quantum Hall effect [5], the Kane-Mele model for quantum spin Hall effect [6], the one-dimensional (1D) Kitaev model for topological superconductors [7] and so on. Among all these models, modulations present in the on-site potentials and hopping amplitudes, which are called diagonal and off-diagonal modulations accordingly, play a decisive role in determining the systems’ properties. Apart from the spacial modulations varying in configuration space, there are also temporal modulations which are applied to systems periodically, e.g. Floquet systems [8, 9]. With the presence of appropriate symmetries, many exotic topological phases can be realized by tuning the modulations, such as topological insulators [10], Weyl/Dirac semimetals [11–13], nodal-line semimetals [14], and more recently, higher-order topological insulators [15–17] and non-Hermitian topological phases [18].

In addition to topological phases, different types of modulation can also influence the systems’ localization properties significantly [19–21]. One paradigmatic example is the 1D Aubry-André-Harper (AAH) model with on-site quasiperiodic modulations, where Anderson localization phase transition emerges as the modulation becomes stronger than a critical value [22, 23]. Various generalizations of the AAH model have been introduced to study the Anderson localization in 1D quasicrystals[24–33]. Besides, the AAH model also exhibits interesting topological properties [34–37]. Recently, the 1D mosaic lattice is introduced, where quasiperiodic modulations are added to the sites with equally spaced distance and Anderson localization phenomenon with multiple mobility edges are observed [38]. By further including such diagonal mosaic modulations to the 1D topological superconductors model, robust nontrivial phases are reported [39]. However, the effect of off-diagonal mosaic modulations on the topological phases and Anderson localization has been ignored and remains illusive so far.

In this paper, we propose a 1D lattice model with modulations purely added to the hopping amplitudes for equally spaced sites, which is called off-diagonal mosaic lattice and exhibits many novel properties in topological phases and Anderson localization. When the modulation is commensurate, zero- as well as non-zero energy topological edge modes can be observed at the two ends of the lattice by tuning the modulation amplitude. The topologically nontrivial phases are characterized by quantized Berry phases which are obtained from the summation of the phase for every occupied energy band. On the other hand, if the mosaic modulation becomes incommensurate with the underlying lattice, Anderson localization phenomenon emerges. Most interestingly, the eigenstate is found to be localized on two neighboring sites with (un)equal distribution weight, which are connected by the mosaic modulated hopping terms and acts as impurities in the lattice. This is a new mechanism for inducting Anderson localization and is totally different from the conventional localization process where the state is expected to be localized only on a single site. Furthermore, we find that by generalizing the model into a 2D system, Chern insulators can be obtained in both the commensurate and incommensurate cases. Our model provides a rich playground for studying topological phases and
Anderson localization by varying the off-diagonal modulations in the model.

**Model Hamiltonian.**—The 1D off-diagonal mosaic lattice model is described by the following Hamiltonian

\[
H = \sum_{j=1}^{L-1} t_j c_j^\dagger c_{j+1} + H.c. \tag{1}
\]

This 1D chain has \( L \) sites and \( c_j^\dagger \) (\( c_j \)) is the creation (annihilation) operator of spinless fermion at site \( j \). The hopping amplitude between the nearest neighboring sites \( t_j \) is modulated as

\[
t_j = \begin{cases} 
  t + \lambda \cos(2\pi \alpha j + \phi), & j = s\kappa, \\
  t, & \text{otherwise}.
\end{cases} \tag{2}
\]

Throughout the paper, we will set \( t = 1 \) as the energy unit. \( \lambda \) denotes the strength of the modulation and \( s = 1, 2, 3, \ldots \). The modulation in the hopping term occurs with interval \( \kappa \). if \( \kappa = 1 \), the model reduces to the regular lattice with modulations applied to every hopping term, which is called off-diagonal AAH model. With nonzero \( \phi \), the model in Eq. (1) can also be generated from a 2D Hamiltonian which is a quantum Hall system with nonuniform magnetic flux [40]. In this work, we will investigate the influence of mosaic modulations on the topological phase and Anderson localization.

**Topological phases in commensurate lattices.**—If the mosaic modulation is commensurate, we can choose \( \alpha = p/q \) with \( p \) and \( q \) being coprime integers. When \( \kappa = 1 \), the model reduces to the commensurate off-diagonal AAH model [35], where topological zero-energy modes are observed in the gapless spectra, as shown in Fig. 1(a). The color bar in the figure indicates the inverse participation ratio (IPR) value of the eigenstate, which is defined as

\[
\text{IPR} = \sum_{j} |\psi_j|^4 / \sum_{j} |\psi_j|^2
\]

where \( \psi_j \) represent the \( j \)th component of eigenstate \( \psi \). The IPR values are of the order \( O(1/L) \) for extended states but become of order \( O(1) \) for localized states. In Fig. 1(b), we show the distribution of eigenstates in real space. States with small IPR are bulk states spread over the whole lattice (black lines), while those with large IPR values are localized at the two ends of the 1D chain (red and blue lines). These localized states are actually topological edge modes. For \( \kappa = 2 \) and 4, all the edge modes have constant energy, while for the system with \( \kappa = 3 \), some edge modes have non-constant energy. So by tuning the mosaic modulation, we can obtain topological edge modes in the commensurate lattices.

It should be noticed that in the case with \( \alpha = 1/2 \) and \( \kappa = 3 \), the band gap near zero energy decreases as we increase the value of \( \lambda \), as shown in Fig. 1(d). However, the gap will remain finite though small and the zero edge modes always exist for \( \lambda > 0 \). Besides, we also find that the non-constant energy edge modes in this case can exist in the continuous bulk band when \( \lambda \) becomes strong enough, see details in supplementary materials [41].

**Fig. 1.** (Color online)(a),(c)-(e) Energy spectra for the commensurate off-diagonal mosaic lattice model under open boundary conditions as a function of the mosaic modulation \( \lambda \). The color bar indicates the IPR value of the eigenstates, where states with large IPR values corresponds to topological edge modes. (b) The distribution of bulk states (black) and edge states (red and blue) in the lattice. In (a)-(e) we have set \( \alpha = 1/2, \phi = 0 \), and \( L = 300 \). (f) shows the energy spectrum for the system with \( \kappa = 2, \alpha = 1/3 \) and \( \lambda = 1 \) as a function of \( \phi \). Red numbers are the Chern numbers of the gapped bands.

If we generalize the model to 2D by taking \( \phi \) as the momentum along another direction, we can obtain Chern insulators under appropriate parameters, see Fig. 1(f). The gapped bands are characterized by Chern numbers defined as \( C_n = \frac{1}{4\pi} \int_0^{2\pi} \int_0^{2\pi} \Gamma \Omega_n(k,\phi) dk \Omega_n(k,\phi) \) with \( \Omega_n(k,\phi) = i \langle \partial_k \Psi_n \partial_\phi \Psi_n \rangle - k \leftrightarrow \phi \), where \( \Psi_n \) is the eigenstates of the Hamiltonian in momentum space. The Chern number for the lowest three bands are indicated by the red numbers in the figure, which are equal to the number of chiral edge states connected to the corresponding bands.

In all the commensurate off-diagonal mosaic models with \( (q \times \kappa) \) being even, zero-energy edge modes are observed due to the presence of chiral symmetry. These zero-energy edge modes can be characterized by winding numbers. However, if \( (q \times \kappa) \) is odd, there will be no chiral symmetry in the system and winding number cannot be well-defined. Besides, the characterization of topological edge modes with non-zero energy requires topological invariant other than winding numbers. Here we show that Berry phase can be used to characterize the non-trivial phases in a systematical way. The Berry phase for the \( n \)th band is defined as \( A_n = \int_{\mathbb{B}_n} dk \langle \Psi_n(k) \partial_k \Psi_n(k) \rangle \) where \( k \) is the momentum and \( \partial_k \Psi_n(k) \) is the eigenstate in momentum space. In Fig. 2, we show the numerical results of Berry phases for the lowest three bands with \( E < 0 \) of the system with \( \kappa = 3 \). For convenience, we label these bands in ascending order by numbers from 1 to 3. If only the lowest band is occupied, we have \( A = A_1 \mod(2\pi) \). The result shown
Anderson localization and topological phases in incommensurate lattices.—When the mosaic modulations are incommensurate, i.e. \( \alpha \) is irrational and we take \( \alpha = (\sqrt{5} - 1)/2 \) without loss of generality, Anderson localization will happen in the model with \( \kappa > 1 \). For a regular model with \( \kappa = 1 \), the incommensurate off-diagonal modulation cannot localize the states but only make them multifractal, see Fig. 3(a). The critical value for the transition from extended phase to multifractal phase is \( \lambda_c = \pm 1 \). If \( |\lambda| < 1 \), all the states are extended, while for \( |\lambda| > 1 \), they becomes multifractal. We also present the value of the mean inverse participation ratio (MIPR), which is defined as \( \text{MIPR} = \sum_{n=1}^{L} \text{IPR}(E_n)/L \). The MIPR is very close to zero and jumps to a finite but still very small value at \( \lambda_c \). These two regimes correspond to the extended and multifractal phase, respectively. However, there is no localized states under this situation. Now if we change the \( \kappa \) from 1 to 2, localized states show up. From Fig. 3(b), we find that MIPR is close to zero for \( |\lambda| < 0.55 \) and all the eigenstates are extended. So the regime for the extended phase shrinks comparing to the regular lattice with \( \kappa = 1 \). When \( |\lambda| > 0.55 \), some of the eigenstates will become localized. Notice that in order to get localized states, the off-diagonal modulation should be incommensurate as well as mosaic. If the modulation is commensurate, then the system is period and the eigenstates are extended. On the other hand, if the modulation is not mosaic but regular, namely, \( \kappa = 1 \), then the states can only be multifractal. The introduction of incommensurate mosaic modulations in the hopping amplitudes is a new mechanism for inducing Anderson localization phenomenon.

To get a better understanding of the localization properties, we plot the distribution of the localized states and the hopping amplitudes in Fig. 4. The hopping amplitudes are normalized as \( t_j = |t + \lambda \cos(2\pi \alpha j + \phi)/|t + \lambda| \) and shifted along the horizontal axis by 0.5. In Fig. 4(a), the gray square at 144.5 indicates the hopping between the 144th and 145th sites in the incommensurate lattice.
with $\kappa = 2$ and $\lambda = 2.5$, which is a modulated hopping amplitude and a local maximum in the lattice. One of the eigenstates (red dots) near the band edge is localized on these two sites with almost the same distribution weight. Such localized states also exist in the system with $\kappa = 20$, as shown in Fig. 4(c). For the states near the band center, however, they are more extended but the main peaks still center around the sites connected by the modulated hopping terms, which are local minimums or maximums, see Fig. 4(b). As $\lambda$ gets stronger, these states will be more localized on two neighboring sites though the distribution weights might be unequal, see supplementary for more details [41]. The modulated hopping terms can be taken as defect links in the lattice and the two sites connected by such terms play the role of impurities. An eigenstate will be stuck on them, leading to the two-site localized states. Since the mosaic modulation occurs periodically with interval $\kappa$, the number of defect links is determined by the number of quasi-cell which contains the nearest $\kappa$ sites. When $\kappa$ gets larger, the number of localized states will decrease since there are less impurities in the lattice, as compared in Fig. 3(b) and (c). However, in a regular incommensurate lattice with $\kappa = 1$, every hopping amplitude is different, the states can stay at many sites and thus become multifractal. This simple explanation gives us a physically intuitive way to understand the Anderson localization in the incommensurate off-diagonal lattices.

By zooming into the spectra for the lattice with $\kappa = 2$ in Fig. 3(b), we find there is a zero-energy mode across the whole parameter range when the lattice size is odd, see Fig. 5(a). However, if the number of the lattices sites is even (i.e. $L = 338$), the zero mode disappears (Fig. 5(b)). Such even-odd effect has been reported in the regular 1D off-diagonal AAH model [35], and also exists in the commensurate off-diagonal mosaic lattice model, where both the zero- and non-zero energy edge modes are influenced in a more complicated way depending on whether $L$ is a multiple of $(q \times \kappa)$ or not [41]. We further calculate the energy spectrum as a function of $\phi$, as presented in Fig. 5(c). Again, gapped Chern bands exist in the 2D generalization. The Chern band is characterized by Bott index [42], which is calculated in the real space and equivalent to the Chern number [43, 44]. The Bott indices for the gapped bands are shown by the blue numbers in the figure. So, in the incommensurate off-diagonal mosaic lattices, we can also obtain topological Chern insulators.

In summary, we have investigated the topological phases and Anderson localization in the one-dimensional off-diagonal mosaic lattices. When the lattice is commensurate, we find that topological edge modes with zero and non-zero energies can exist by tuning the modulations. The nontrivial regime are characterized by quantized Berry phases which are calculated by summing up the phases for all the occupied energy bands. If the lattice becomes incommensurate, Anderson localization phenomenon will show up. The eigenstate is found to be localized on two neighboring sites connected by the mosaic modulated hopping terms, which indicates a new mechanism for inducing Anderson localization in 1D lattices. In addition, we also find that our model can host Chern insulators when generalized to 2D.

In Ref. [34], Kraus et al. demonstrate that the 1D off-diagonal AAH model can be realized by using coupled optical waveguides. Such method can be readily adopted to realize the off-diagonal mosaic lattice model, and all the phenomena reported in this paper could be examined. In addition, as a new and versatile platform for simulating topological systems, electrical circuits have been extensively used to realize various lattice models recently [45, 46]. Our model can be constructed by using LC circuits, where the system’s properties are detectable from the impedance measurement.

In the supplementary material, we will first discuss the details of the energy spectra and the existence of topological edge modes for the one-dimensional (1D) off-diagonal mosaic lattices. Then we present the energy spectra for the systems with different lattice sizes, where the changing of the size results in the even-odd effect in the edge modes of the system.
A. ENERGY GAP AND EDGE MODES IN SYSTEMS WITH STRONG $\lambda$

In the main text, we have shown that for the system with $\alpha = 1/2$ and $\kappa = 3$, there are zero- as well as nonzero-energy edge modes. For the zero-energy modes, the gap near the zero energy decreases as $\lambda$ increases, but keeps finite even when $\lambda$ becomes very strong, as shown in Fig. 6(a). It seems that when $\lambda$ is strong enough, the gap will close and zero modes will disappear. However, we have calculated the spectrum for system with $\lambda$ up to 40, where the gap near zero energy is found to be finite though very small, see Fig. 6(b). And we can still observe two zero modes localized at the two ends of the system (Fig. 6(c)). So, the band gap near zero energy will remain finite and zero-energy edge modes will always exist in this case, which is consistent with the results obtained from the Berry phase, which shows that the system is nontrivial for $\lambda > 0$ when half-filling, see Fig.(3) in the main text.

Next we turn to the non-zero energy edge modes near the lowest energy band. As can be seen from Fig. 6(d), the energy of the edge modes are not constant. As $\lambda$ gets stronger, the edge modes will get closer and closer to the continuous bulk band, as shown in Fig. 6(e). However, the edge modes still exist in the continuum of extended bulk states and the system is nontrivial for $\lambda > 0$ for the lowest energy band. This is again consistent with the nontrivial regime revealed from the Berry phase discussed in the main text.

B. EVEN-ODD EFFECT IN THE EDGE MODES

In Fig. 7, we show the spectra of the system with $\alpha = 1/2, \kappa = 2$ with different lattice sizes. When $L$ is even, the topological zero modes will show up in the nontrivial regime with $\lambda > 0$. There are always two zero-energy modes in this case, which are localized at the two ends of the 1D lattice, as shown in Fig. 7(a). However, if the lattice size becomes odd, then zero mode always presents in both the trivial and nontrivial regimes. Besides, there are only one single zero mode instead two as in the case with even $L$, see Fig. 7(b). The zero mode is localized at the left end of the lattice for $\lambda < -2$ and $\lambda > 0$, but becomes localized at the right end for $-2 < \lambda < 0$. Such even-odd effect has also been reported in the off-diagonal Aubry-André-Harper (AAH) model [35].

The situation becomes much complicated for the system with larger $\kappa$. For the commensurate lattice with $\alpha = p/q$, where $p$ and $q$ are co-prime integers, we find that when $L$ is a multiple of $q \times \kappa$, all the topological edge modes come in pairs in the nontrivial regime. Fig. 8(a) presents the energy spectra for the system with $\alpha = 1/2, \kappa = 3$ and $L = 300,$
FIG. 7. (Color online) Even-odd effect in the off-diagonal mosaic lattices with $\alpha = 1/2$ and $\kappa = 2$. (a) shows the spectrum under open boundary conditions when $L = 300$ while (b) is the spectrum for the system with $L = 301$. The color indicates the inverse participation ratio (IPR) of the eigenstates. The insets show the distributions of the edge modes at the specific $\lambda$ values as indicated by the arrows.

where two edge modes are always observed at every specific $\lambda$ value, which are localized at the two ends of the 1D lattice. However, if $L$ is not a multiple of $q \times \kappa$, the edge mode can also be observed in the trivial regime and only one single mode localized at one end of the lattice is observed, as can be seen in Fig. 8(b)-(f). Same phenomena can also be observed in system with other values of $\alpha$ and $\kappa$. So in the off-diagonal mosaic lattice, richer phenomena exist due to the presence of mosaic modulations.

C. LOCALIZED STATES IN THE INCOMMENSURATE OFF-DIAGONAL MOSAIC LATTICE

Here we plot the distributions of the eigenstates for the incommensurate off-diagonal mosaic lattices with $\kappa = 2$ and $\lambda = 3.5$, see Fig. 9. For the lattice with $L = 377$, there are 377 eigenstates. We show the distribution of the normalized hopping amplitude and 6 different eigenstates. For the states near the band edge, the distribution weight are almost the same on two neighboring sites, as shown in (a) and (b) for the $n = 1$ and 10 eigenstate, respectively. These sites are connected by the modulated hopping terms which are local minimum or maximum in the lattice. As we move away from the band edge, the distribution weight on the two sites will become different, as can be seen in (c)-(f). Though the states become more extended, the main peak of the state still centers around two lattice sites which are connected by the modulated hopping terms.
FIG. 8. (Color online) Energy spectra and edge modes for the off-diagonal mosaic lattices with \( \alpha = 1/2 \) and \( \kappa = 3 \). (a) The edge modes in the nontrivial regimes come in pairs when \( L \) is a multiple of \( q \times \kappa \). (b)-(f) While if \( L \) is not a multiple of \( q \times \kappa \), edge mode will also appear in the trivial regime, and only one single edge mode which is localized at one end of the lattice is observed, as shown in (b)-(f).
FIG. 9. (Color online) The distribution of eigenstates (red dots) and hopping amplitude (gray squares) in the real space for the incommensurate off-diagonal mosaic lattice with $\alpha = (\sqrt{5} - 1)/2$ and $\kappa = 2$. $n$ indicates the $n$th eigenstate of the system which are sorted by eigenenergies in ascending order. Here we have set $\lambda = 3.5$ and $L = 377$.
