INTERPRETATION OF PLUG-AND-PLAY (PNP) ALGORITHMS FROM A DIFFERENT ANGLE

ABINASH NAYAK

ABSTRACT. It’s well-known that inverse problems are ill-posed and to solve them meaningfully one has to employ regularization methods. Traditionally, the most popular regularization approaches are Variational-type approaches, i.e., penalized/constrained functional minimization. In recent years, the classical regularization approaches have been replaced by the so called plug-and-play (PNP) algorithms, which copies the proximal gradient minimization processes, such as ADMM or FISTA, but with any general denoiser. However, unlike the traditional proximal gradient methods, the theoretical analysis and convergence results have been insufficient for these PnP-algorithms. Hence, the results from these algorithms, though empirically outstanding, are not well-defined, in the sense of, being a minimizer of a Variational problem. In this paper, we address this question of “well-definedness”, but from a different angle. We explain these algorithms from the viewpoint of a semi-iterative regularization method. In addition, we expand the family of regularized solutions, corresponding to the classical semi-iterative methods, to further generalize the explainability of these algorithms, as well as, enhance the recovery process. We conclude with several numerical results which validate the developed theories and reflect the improvements over the traditional PnP-algorithms, such as ADMM-PnP and FISTA-PnP.

1. Introduction

1.1. Inverse Problems and Regularization: Mathematically, an inverse problem is often expressed as the problem of estimating a (source) \( \hat{x} \) which satisfies, for a given (effect) \( b \), the following matrix (or operator) equation

\[
A \hat{x} = b,
\]

where the matrix \( A \in \mathbb{R}^{n \times m} \) and the vectors \( \hat{x} \in \mathbb{R}^{n}, b \in \mathbb{R}^{m} \) are the discrete approximations of an infinite dimensional model describing the underlying physical phenomenon. The inverse problem (1.1) is usually ill-posed, in the sense of violating any one of the Hadamard’s conditions for well-posedness: (i) Existence of a solution (for \( b \) not in the range of \( A \)), (ii) uniqueness of the solution (for non-trivial null-space of \( A \)) and, (iii) continuous dependence on the data (for ill-conditioned \( A \)). Conditions (i) and (ii) can be circumvented by relaxing the definition of a solution for (1.1), for example, finding the least square solution or the minimal norm solution (i.e., the pseudo-inverse solution \( x^\dagger \)). The most (practically) significant condition is condition-(iii), since failing of this leads to an absurd (unstable) solution. That is, for an injective \( A \) and an exact \( b \) (noiseless), the solution of (1.1) can
be approximated by the (LS) least-square solution \( (x^\dagger) \), i.e., \( x^\dagger \) is the minimizer of the following least-square functional

\[
F(x) = ||Ax - b||_2^2. \tag{1.2}
\]

However, practical data are typically contaminated by noise, i.e., we have \( b_\delta \) instead of \( b \) such that \( ||b - b_\delta|| \leq \delta \), and hence, the simple least-square solution (corresponding to \( b_\delta \) in (1.2)) fails to approximate the true solution, i.e., \( ||x^\dagger - x^\ddagger|| \gg \delta \) implying \( ||x^\dagger - \hat{x}|| \gg \delta \), due to the ill-posedness of the inverse problem (1.1). To counter such instabilities or ill-posedness of inverse problems, regularization methods have to be employed, which are broadly divided into two types.

1.2. Variational (or penalized) regularization.

Such approaches, also known as Tikhonov-type regularization, are probably the most well known regularization techniques for solving linear as well as nonlinear inverse problems (see [1, 2, 3, 4, 5]), where (instead of minimizing the simple least-square functional (1.2)) one minimizes a penalized (or constrained) functional:

\[
F(x; D, \lambda, R) = D(Ax, b_\delta) + \lambda R(x), \tag{1.3}
\]

where \( D \) is called the data-fidelity term (imposing data-consistency), \( R \) is the regularization term (imposing certain structures, based on some prior knowledge of the solution \( \hat{x} \)) and, \( \lambda \geq 0 \) is the regularization parameter that balances the trade-off between them, depending on the noise level \( \delta \), i.e., \( \lambda = \lambda(\delta) \). The formulation (1.3) also has a Bayesian interpretation, where the minimization of \( F(x; D, \lambda, R) \) corresponds to the maximum-a-posteriori (MAP) estimate of \( \hat{x} \) given \( b_\delta \), where the likelihood of \( b_\delta \) is proportional to \( \exp(-D(x)) \) and the prior distribution on \( \hat{x} \) is proportional to \( \exp(-R(x)) \). Classically, \( D(Ax, b_\delta) = ||Ax - b_\delta||_p^p \) and \( R(x) = ||Lx - \bar{x}||_q^q \), where \( L \) is a regularization matrix with the null spaces of \( A \) and \( L \) intersecting trivially, and \( p, q \) determine the involved norms. For large scale problems the minimization of (1.3) is done iteratively, i.e., starting from an initial guess \( x_0^\delta \) and step-sizes \( \tau_k > 0 \), the minimizer of (1.3) is approximated via the sequence

\[
x_{k+1}^\delta = x_k^\delta - \tau_k \nabla_x F(x_k^\delta; D, \lambda, R), \tag{1.4}
\]

Hence, one has to address the following two technicalities,

1. Compute the gradient \( \nabla_x F(x_k^\delta; D, \lambda, R) \) at each \( k \). It’s easier when both \( D(x) \) and \( R(x) \) are differentiable, as then, \( \nabla_x F(x_k^\delta; D, \lambda, R) = \nabla_x D(x_k^\delta) + \lambda \nabla_x R(x_k^\delta) \). However, when they are non-differentiable, then it’s not that straightforward. Then one has to make use of convex optimization techniques, such as proximal gradient methods, to circumvent the differentiability issue, which is discussed later.

2. Convergence of the sequence of iterates \( \{x_k^\delta\} \) as \( k \to \infty \). For strictly convex \( D \) and \( R \), we have \( x_k^\delta \xrightarrow{k \to \infty} x^\ddagger \), where \( x^\ddagger \) is the global minimizer of (1.3). Again, if they are non-convex (which is the case for most modern \( R \)) then one has to analyze the behaviour of the sequence when \( k \to \infty \), for example, convergence to a local minimizer or a saddle-point etc.

1.3. Related Works.

The above two queries have been studied extensively for classical regularizers, such as TV or sparsifying wavelet transformation, and corresponding results can be found in the literature, for example in [6, 7, 8, 9, 10] and references therein.
Typically, for non-smooth (proper, closed, and convex) $\mathcal{R}$, the differentiability issue is circumvented by using a proximal operator (see [11, 12, 13])

$$\text{Prox}_{\lambda \mathcal{R}}(v) = \arg \min_x \lambda \mathcal{R}(x) + \frac{1}{2}||x - v||^2_2.$$ (1.5)

Basically, for smooth $\mathcal{D}(x)$ and non-smooth $\mathcal{R}(x)$, the minimization problem corresponding to (1.3) can be solved via two first-order iterative methods:

1. Forward-backward splitting (FBS), also known as Iterative shrinkage/soft thresholding algorithm (ISTA) and has a faster variant Fast ISTA (FISTA), where each minimization step is divided into two sub-steps, given by

$$z_{k+1}^\delta = x_k^\delta - \tau_k \nabla \mathcal{D}(x_k^\delta) \quad \text{← data-consistency step} \quad (1.6)$$

$$x_{k+1}^\delta = \text{Prox}_{\lambda \tau_k \mathcal{R}}(z_{k+1}^\delta) \quad \text{← data-denoising step} \quad (1.7)$$

where $\tau_k \geq 0$ is the step-size at the $k^{th}$ iteration.

2. Alternating direction method of multipliers (ADMM), where three sequences are alternatively updated as follows,

$$x_{k+1}^\delta = \text{Prox}_{\frac{1}{\rho} \mathcal{D}}(z_k^\delta - u_k^\delta) \quad \text{← data-consistency step} \quad (1.8)$$

$$z_{k+1}^\delta = \text{Prox}_{\lambda \rho \mathcal{R}}(x_{k+1}^\delta + u_k^\delta) \quad \text{← data-denoising step} \quad (1.9)$$

$$u_{k+1}^\delta = u_k^\delta + x_{k+1}^\delta - z_{k+1}^\delta, \quad \text{← noise update step} \quad (1.10)$$

where $\rho > 0$ is the Lagrangian parameter, which only effects the speed of convergence and not the solution (minimizer) of (1.3).

From the above two expressions, one can observe that each method comprises of two fundamental steps: (1) data-consistency, and (2) data-denoising. This motivated, authors in [14], to replace the $\text{Prox}_{\sigma \mathcal{R}}$ operator in the denoising step of ADMM by an off-the-shelf denoiser $H_\sigma$, with denoising strength corresponding to noise level $\sigma$, and termed it as the PnP-algorithm (plug-and-play method). However, once the proximal operator is replaced by any general denoiser, then the Variational problem (1.3) breaks down and, some natural question arise: Does this new sequence of iterates $\{x_k^\delta\}$, formed based on a denoiser, converge? If so, then converge to what? What’s the meaning of the solution? Is it a minimizer of a MAP estimate? For example, in the traditional case, the FBS/ADMM iterates converge to the minimizer of the problem (1.3).

Though empirical results show the convergence of these PnP-algorithms, there is no proof of it for any general denoisers. However, under certain assumptions/restrictions (such as boundedness/ nonexpansiveness etc.) on the denoiser, there has been some convergence proof, see [15, 16, 17, 18, 19] and references therein. There are also some other variants of such PnP-methods, such as Regularization by Denoising (RED)[20], Regularization by Artifact-Removal (RARE) [21], etc.

**Contribution of this paper.**

- In this paper, we try to answer the above question, the convergence of the iterates and meaning of the solution of a PnP-method, from a different angle. We show a connection between these PnP-algorithms and semi-iterative regularization methods. We then present a bound for the difference of a “PnP-solution” and a “regularized LS-solution”, where the definitions of these terms are explained below.
• PnP-algorithms, like Variational regularization, are very sensitive to the regularization/denoising parameter. Here, we present a method to significantly reduce the sensitivity of these algorithms to the denoiser's strength of denoising. This is crucial, since this can transform a bad denoiser (denoisers with too strong or too weak denoising) to a good one (an appropriate level of denoising), without actually altering the involved denoiser.

• We also address the question of when to stop/terminate the iterations to recover “an appropriate solution”. Again, the meaning of an appropriate solution is described below, which depends on some selection criteria.

• In addition, we compare the FBS-PnP algorithm with the ADMM-PnP algorithm and point out some of the pros and cons of these algorithms. Note that, although in the traditional setting (1.3) both these algorithms produce a similar result, the minimizer of (1.3), but for their PnP versions they may differ depending on the scenarios, as the convergence is not known.

• Finally, we end with presenting several numerical results in support of the theories developed in this paper, which also validates the efficiency and effectiveness of the modified algorithms suggested here. We perform computational experiments on X-ray computed tomography problems, and compare the results obtained using our approach with the traditional ADMM-PnP and FBS-PnP algorithms, using BM3D as the denoiser.

2. Structure imposing descent directions

In the previous section we explained Variational or Tikhonov-type regularization method and their variants. The second most popular regularization technique is known as Semi-iterative regularization method.

2.1. Semi-iterative regularization.

Landweber, in [22], showed that minimizing the simple LS functional (1.2) via the gradient direction, with a constant step-size, leads to the recovery of the solution of (1.1) in a semi-convergent manner, i.e., starting from an initial guess $x_0^\delta$, the sequence of iterates

$$x_k^\delta = x_{k-1}^\delta + d_{k-1}^\delta,$$

(2.1)

where $d_{k-1}^\delta := -\tau \nabla_x D(x_{k-1}^\delta) = -\tau A^*(Ax_{k-1}^\delta - b_\delta)$ (when $D(x) = ||Ax - b_\delta||_2^2$) for $0 \leq \tau < \frac{1}{2||A||_2^2}$, initially converges towards the true LS-solution $x^\dagger$ but then diverges away from $x^\dagger$, i.e., the recovery-errors follow a semi-convergent nature. That is, the iteration index $k$ plays the role of a regularization parameter, where for smaller values of $k$ the recovered solution $x_k^\delta$ is over-regularized (over-smoothed) and for larger values of $k$, $x_k^\delta$ is under-regularized (over-fitted). Therefore, for “an appropriate” index $k(\delta)$ one would obtain a regularized estimate $x_{k(\delta)}^\delta$ to the solution of (1.1), where an appropriate index depends on the choices of the selection criteria, this is discussed in details later. However, as one can notice, through this approach one cannot make use of any prior knowledge of the solution $\hat{x}$, i.e., no structures can be imposed on the recovery process. Also, note that, instead of a constant step-size ($\tau$) in (2.1), one can have varying step-sizes $\tau_k \geq 0$ for each iterations, but for simplicity we let $\tau_k = \tau$, unless otherwise stated; for more details and generalizations of this method (like Krylov-Subspace or Conjugate-gradient semi-iterative methods) see [23, 22, 24, 1].
2.2. Regularized solution vs. Regularized solution family.

Before we jump into our new formulation to explain PnP-algorithms, and to have a better understanding of it, we make a quick inspection on the pros and cons of the aforementioned regularization methods. The similarity between both the methods is that, first, one generates a “family of regularized-solutions” (depending on a parameter) and then, an “appropriate regularized solution (\(x^\delta\))” is selected, based on some a-priori or a-posteriori selection rules or criteria, which only estimates the true solution \(\hat{x}\) depending on the noise-level \(\delta\). In the dissimilarity, the constraint-regularization offers a much larger set of regularized solutions which depends not only on the choices of \(\lambda\) but also on \(\mathcal{R}\) (the constraint/regularizer), i.e., the set (family) of regularized solutions in Tikhonov-type methods is

\[
T_1 := \{ x^\delta(\mathcal{D}, \lambda, \mathcal{R}) : x^\delta(\mathcal{D}, \lambda, \mathcal{R}) \text{ is a minimizer of (1.3) with } \lambda = \lambda(\delta) \geq 0 \},
\]

where as, the classical (simple) semi-iterative regularization can only provide a set of regularized solutions depending on the iteration index \(k\), i.e.,

\[
I_1 := \{ x^\delta(\mathcal{D}, k) : x^\delta_k = x^\delta_{k-1} - \tau_{k-1} \nabla_\delta \mathcal{D}(x^\delta_{k-1}), \ 1 \leq k \leq k(\delta) \leq \infty \}. \tag{2.3}
\]

However, on the plus side, a regularized solution in the family (2.3) can be obtained much faster (though without any structures in it) than a regularized solution in (2.2), as in \(T_1\) one has to minimize completely the associated functional in (1.3).

Remark 2.1. Note that, the formulations (1.3) and (2.1) only yield corresponding families of regularized solutions \(T_1\) and \(I_1\), respectively, and not a solution of (1.1). One estimate the true solution \(\hat{x}\) through these families of solutions depending on some “parameter choice or selection criteria”. That is, based on a specific criterion, say \(\mathcal{S}_0\), one chooses a regularized solution from either the family (2.2), \(x^\delta_0(\mathcal{D}, \lambda(\delta), \mathcal{R}) \in T_1\), such that \(\delta \to 0\) implies \(\lambda(\delta; \mathcal{S}_0) \to 0\) and \(x^\delta_0(\mathcal{D}, \lambda(\delta), \mathcal{R}) \to \hat{x}\), or from the family (2.3), \(x^\delta_0(\mathcal{D}, k(\delta)) \in I_1\), such that \(\delta \to 0\) implies \(k(\delta; \mathcal{S}_0) \to \infty\) and \(x^\delta_0(\mathcal{D}, k(\delta)) \to \hat{x}\). Of course, when the selection criterion changes, the regularized solution changes too and hence, the families (2.2) and (2.3) of regularized solutions get extended by the parameter choice criterion, i.e.,

\[
T_2 := \{ x^\delta(\mathcal{D}, \lambda, \mathcal{R}; \mathcal{S}) : x^\delta(\mathcal{D}, \lambda, \mathcal{R}) \text{ is a minimizer of (1.3) with } \lambda = \lambda(\delta) \geq 0, \text{ and } \mathcal{S} \text{ is any selection criterion} \}, \tag{2.4}
\]

\[
I_2 := \{ x^\delta(\mathcal{D}, k; \mathcal{S}) : x^\delta_k = x^\delta_{k-1} - \tau_{k-1} \nabla_\delta \mathcal{D}(x^\delta_{k-1}), \ 1 \leq k \leq k(\delta) \leq \infty, \text{ and } \mathcal{S} \text{ is any selection criterion} \}. \tag{2.5}
\]

Note that, for practical problems, it’s near impossible to obtain the optimal parameters for the respective families, since the true solution \(\hat{x}\) is unknown. Although the problem of choosing an appropriate selection criterion is non-trivial, especially for large scale problems with unknown error, there has been a lot of studies in the literature in this regard, for example Cross-Validation (CV), Generalized Cross-Validation (GCV), Discrepancy principle (DP), L-curve, monotone error rule etc., see [25, 26, 27, 28, 29, 30, 31, 32].

Remark 2.2. One may be tempted to fuse the above two families naively, for example, one can incorporate the iteration index \(k\) as an additional regularization parameter in (2.4) and can define a regularized solution, \(x^\delta(\mathcal{D}, \lambda, \mathcal{R}, k; \mathcal{S})\), as the \(k\)-th iterate \(x^\delta_k(\mathcal{D}, \lambda, \mathcal{R})\) when minimizing (1.3), as defined in (1.4), which satisfies
the selection criterion $S$, for fixed $(D, \lambda, R, S)$. However, note that, under this definition, now the regularized solution $x^\delta_k(D, \lambda, R)$ is not a solution (minimizer) corresponding to a Variational problem (1.3) anymore. Moreover, this does not work for PnP-algorithms, for any general denoiser, as not all PnP-algorithms can be formulated as a Variational problem. Nevertheless, the advantage of such definition is that one doesn’t have to worry about the convergence of the iterates $x^\delta_k(D, \lambda, R)$, since, if it does not belong to the family $I_\delta$, then we are not looking for the solution of (1.3) anymore. In addition, this also speeds up the recovery process, as one does not have to iterate indefinitely for convergence. This make sense, to a certain extent, since we are interested in the solution of (1.1) and the formulation (1.3) only aids us to approximate the true solution $\hat{x}$, and a solution of (1.3) is only an estimate of (1.1) depending on $\lambda$. Hence, even when the iterates (1.4) converge (for fixed $(D, \lambda, R)$) to $x^\delta_\lambda$, a minimizer of (1.3), $x^\delta_\lambda$ is not the solution of (1.1), rather, one typically generates a list of $\{x^\delta_\lambda\}_\lambda$ and an appropriate estimate of $\hat{x}$ is then selected based on the selection criterion $S$. This naive idea lays the ground for our formulation to interpret the PnP-algorithms, but has to be polished properly for meaningful definitions, which is done in later sections.

2.3. **Structured iterations.**

Here, instead of expanding the family $I_\delta$ to incorporate the PnP-algorithms, we expand the family $I_\delta$ to address the above problems. First, note that when minimizing (1.2), $d^\delta_k$ in (2.1) needs to be a descent direction only and doesn’t have to be the negative gradient (which is the steepest descent direction). Hence, any direction with the following property can be considered as a descent direction, for simplicity we choose $D(x) = ||Ax - b_\delta||_2^2$,

$$
\left( d^\delta_k, -\nabla D(x^\delta_k) \right)_2 = \left( d^\delta_k, -A^*(Ax^\delta_k - b_\delta) \right)_2 > 0,
$$

(2.6)

where $(.,.)_2$ is the associated $\ell_2$-product. It’s also easy to verify that if

$$
||e^\delta_k - \tau \nabla xD(x^\delta_k)||_2^2 \leq \epsilon_k(\delta),
$$

(2.7)

for some $\epsilon_k(\delta) \geq 0$, then, starting from initial points $z^\delta_0$ and $x^\delta_0$,

$$
||z^\delta_k - x^\delta_k||_2^2 \leq ||z^\delta_0 - x^\delta_0||_2^2 + \sum_{i=0}^{k-1} ||e^\delta_i - \tau \nabla xD(x^\delta_i)||_2^2 \leq ||z^\delta_0 - x^\delta_0||_2^2 + \sum_{i=0}^{k-1} \epsilon_i(\delta)
$$

(2.8)

where $z^\delta_i = z^\delta_{i-1} + e^\delta_i$ and $x^\delta_i = x^\delta_{i-1} - \tau \nabla xD(x^\delta_{i-1})$. Hence, if for some $\epsilon(\delta) \geq 0$, $||z^\delta_0 - x^\delta_0||_2^2 \leq \epsilon(\delta)$ and $\epsilon_i(\delta) \leq \epsilon(\delta)$, for $0 \leq i \leq k-1$, then we have

$$
||z^\delta_k - x^\delta_k||_2^2 \leq C(k) \epsilon(\delta),
$$

(2.9)

where the (increasing) constant $C(k)$ depends only on the iteration index $k$. In other words, if any direction $d^\delta_k$ satisfies conditions (2.6) and (2.7), we call it the descent and proximity properties, respectively, then the iterates $z^\delta_k$, formed based on it, also remains close to the LS iterates $x^\delta_k$, upto some constant depending on the iteration index $k$. And, since in a semi-iterative regularization $k(\delta)$ is bounded away from infinity, the new iterates $x^\delta_k$ are bounded at most $C(k(\delta))\epsilon(\delta)$ away from the LS iterates $x^\delta_k$. Also, note that, for the residues or discrepancy terms
that is, if the residues of the LS iterates are small ($||Ax_k^δ - b_δ||_2^2 \approx δ$), then so are the residues of $z_k^δ$ with an error term $C(k)ε(δ)||A||_2^2$, where $A$ is usually bounded. This is helpful when the selection criterion, such as discrepancy principle, depends on the residue norms, i.e., terminate the iterations when the residue norms of the iterates $x_k^δ$ is around certain limit ($||Ax_k^δ - b_δ||_2^2 \approx δ$), and (2.10) implies that for those iterations the residue norms corresponding to the new iterates $z_k^δ$ is also around that limit, with an error term, implying that the iterates $z_k^δ$ have also fitted the data to that extent. Hence, one can see that when minimizing (1.2), replacing the vanilla descent directions $−∇x D(x_k^δ)$ with an “appropriate” descent direction $d_k^δ$ one can impose certain structures in the recovery process through the iterates $z_k^δ$, and thus, can recover a regularized structured solution $z_k^δ(δ)$. With this formulation, the family of regularized solution $I_2$, as defined in (2.5), is expanded to

$$I_3 := \left\{ x^δ(D, k, d_k^δ; S) : x_k^δ = x_k^{δ-1} + d_k^{δ-1}, \ 1 \leq k \leq k(δ) \leq ∞, \ \text{s.t. } \left( d_k^{δ-1}, −τ_{k-1} ∇x D(x_k^{δ-1}) \right)_2 > 0 \ \text{and } S \text{ is any selection criterion} \right\}.$$  

Figure 1 elaborates the families of solutions, $I_3$ and $I_2$, visually. Note that, although $I_3 \supset I_2$, $I_3$ is neither a super-set nor subset nor equals to $I_2$. However, for a fixed $S_0$, any $x^δ(D, λ(δ), R) ∈ I_2$ can be “approximated” by a $x^δ(D, k(δ), d_k^δ) ∈ I_3$, where the extent of approximation depends on the choice of $λ(δ)$, since, one can observe that when minimizing (1.3) using the FBS approach (1.6), the resulting direction at the k-1 step is given by

$$d_k^{δ-1} = \text{Prox}_{λR}(x_k^{δ}) − x_k^{δ-1}$$  

$$= \left( \text{Prox}_{λR}(x_k^{δ}) − x_k^{δ}\right) + (-τ ∇x D(x_k^{δ-1})),$$

and hence, if

$$||\text{Prox}_{λR}(x_k^{δ}) − x_k^{δ}||_2 < ||−τ ∇x D(x_k^{δ-1})||_2,$$

we have

$$\left( d_k^{δ-1}, −τ ∇x D(x_k^{δ-1}) \right)_2 > τ||∇x D(x_k^{δ-1})|| \left( τ ||∇x D(x_k^{δ-1})|| − ||\text{Prox}_{λR}(x_k^{δ}) − x_k^{δ}|| \right) > 0,$$

i.e., $d_k^{δ-1}$ is a descent direction if (2.13) holds. But, note that, as the residues $D(x_k^δ)$ get smaller so does the gradient $−τ ∇x D(x_k^δ)$ for a fixed $τ$, for example, for the $ℓ_2$-discrepancy term, $D(x) = ||Ax − b_δ||_2^2$, we have $−τ ∇x (D(x_k^{δ-1})) = −τ A^*(Ax_k^{δ-1} − b_δ)$, which gets smaller as the residues $Ax_k^{δ-1} − b_δ$ get smaller and hence, (2.13) won’t hold for such iterates, and also for larger $λ$ values. Therefore, for a given $λ(δ)$, the largest iterate $k(δ)$ for which (2.13) holds, yields a regularized solution $x^δ(D, k(δ), d_k^δ)$ which can be close to $x^δ(D, λ(δ), R)$.

**Remark 2.3.** Note that, if a direction $d_k^δ$ satisfies (2.6) for all $k$, then the corresponding recovery-errors for the iterates $z_k^δ$ will also follow a semi-convergent nature. However, the parameter choice value $k(δ)$, for a fixed selection criterion $S_0$, will be different for the respective iterates. Also, equation (2.9) does not suggest that $||z_k^δ(δ) − x|| \leq ||x_k^δ(δ) − x||$, where $x$ is the true solution, but, if we believe that
A. Nayak Interpreting PnP-algorithms

(a) Semi-iterative regularization for different descent directions \( d^\delta_k \).

(b) Tikhonov-type regularization for different regularizers \( R \).

Figure 1. Semi-iterative vs. Tikhonov-type regularization.

\( d^\delta_k \) is a “better” direction than \(-\tau \nabla x D(x^\delta_k)\), then we would expect that the iterates \( z^\delta_k \) approximate the true solution better than \( x^\delta_k \). In any case, in the absence of the true solution, a “better solution” for a fixed \( S_0 \) is the one that satisfies \( S_0 \) better.

Moreover, for \( z^\delta_k(x) \) to be a regularized solution, \( z^\delta_k(x) \to \hat{x} \) when \( \delta \to 0 \), and this is true from (2.9) provided \( C(k)\epsilon(\delta) \to 0 \). That is, for a fixed selection criterion \( S_0 \), and hence \( k(\delta) \), \( \epsilon(\delta) = o(1/k^2(\delta)) \). In other words, as the noise level decreases the descent direction should get closer to the negative gradient direction, i.e., when \( \delta \to 0 \), \( d^\delta_k \to -\tau x D(x^\delta_k) \Rightarrow z^\delta_k \to x^\delta_k \), and \( k_i(\delta) \to \infty \) for \( i = 1, 2 \), resulting in \( x^\delta_{k_i}(\delta) \to \hat{x} \) and \( z^\delta_{k_i}(\delta) \to \hat{x} \).

The natural question that one can ask now is, when can a regularized structured solution be obtained without encountering the semi-convergence in the recovery errors? The answer is ‘none’ for those structure imposing directions \( d^\delta_k \) that satisfies (2.6) for all \( k \), as then one minimizes the LS functional (1.2) for noisy \( b_3 \), leading to the semi-convergence of the recovery errors. However, one can relax the condition (2.6) appropriately to circumvent the semi-convergence as well as recover a structured regularized solution, but then, it won’t fall in the family \( I_3 \). Hence, one has to define an extension of the family \( I_3 \) to encompass such structured regularized solutions, details in the later sections.

3. PnP-algorithms as structured iterations

The core of any PnP-algorithm is the data-consistency step followed by the data-denoising step, where the denoising operator doesn’t need to be a proximal operator anymore. We first analyze the FBS-PnP algorithm and then the ADMM-PnP algorithm.

3.1. Forward-backward splitting (FBS) - PnP.
In this algorithm, for a fixed denoiser $H_\sigma$ (of denoising strength corresponding to noise level $\sigma$) and starting from an initial choice $x^\delta_0$, at any iteration step $k \geq 1$, we have

$$x^\delta_{k-1} \mapsto x^\delta_k = x^\delta_{k-1} - \tau_k \nabla_x D(x^\delta_{k-1}) \quad \text{← data-consistency step (3.1)}$$

$$x^\delta_k \mapsto z^\delta_k = H_{\sigma_k}(x^\delta_k) \quad \text{← data-denoising step (3.2)}$$

where $H_{\sigma_k}$ is the updated $k$th denoiser, with the denoising strength corresponding to $\sigma_k = \tau_k \sigma$, which yields a new sequence of denoised iterates $\{z^\delta_k\}$. Hence, an approach similar to (2.12), provides a structure imposing direction $d^\delta_{k-1}$, which can be defined as

$$d^\delta_{k-1} := z^\delta_k - x^\delta_{k-1} = \underbrace{-\tau \nabla_x D(x^\delta_{k-1})}_{\text{data-consistency}} + \underbrace{(H_{\sigma_k}(x^\delta_k) - x^\delta_k)}_{\text{data-denoising}},$$

and the direction $d^\delta_{k-1}$, as defined in (3.3), will also be a descent direction provided it satisfies (2.6). Therefore, when $H_{\sigma_k}$ satisfies

$$||H_{\sigma_k}(x^\delta_k) - x^\delta_k|| < ||\tau \nabla_x D(x^\delta_{k-1})||,$$

then one can easily show that $d^\delta_{k-1}$ satisfies (2.6), since

$$\left(d^\delta_{k-1}, -\tau \nabla_x D(x^\delta_{k-1})\right)_2 \geq \tau ||\nabla_x D(x^\delta_{k-1})|| (||\nabla_x D(x^\delta_{k-1})|| - ||H_{\sigma_k}(x^\delta_k) - x^\delta_k||) > 0.$$
\( \tau > 0 \), we have \( x_1^\delta = y_1^\delta \) and
\[
\| z_1^\delta - y_1^\delta \| = \| H_{\sigma_1}(x_1^\delta) - x_1^\delta \|,
\]
\[
\| z_2^\delta - y_2^\delta \| \leq \| H_{\sigma_2}(x_2^\delta) - x_2^\delta \| + (1 + \tau \| A^* A \|) \| H_{\sigma_1}(x_1^\delta) - x_1^\delta \|
\]
\[
\| z_3^\delta - y_3^\delta \| \leq \| H_{\sigma_3}(x_3^\delta) - x_3^\delta \| + (1 + \tau \| A^* A \|) \| z_2^\delta - x_2^\delta \|
\]
\[\vdots\]
\[
\| z_k^\delta - y_k^\delta \| \leq \sum_{i=0}^{k-1} (1 + \tau \| A^* A \|)^i \| H_{\sigma_{k-i}}(x_{k-i}^\delta) - x_{k-i}^\delta \|. \tag{3.5}\]

That is, for the \( k(\delta) \) iteration the denoised iterate \( z_{k(\delta)}^\delta \) will be bounded away from the LS iterate \( y_{k(\delta)}^\delta \), at most by the factor given in (3.5), which also depends on the denoising strength of the denoiser \( H_{\sigma_k} \) at each iteration \( k \). Of course, this does not guarantee that \( \| z_{k(\delta)}^\delta - \hat{x} \| \leq \| y_{k(\delta)}^\delta - \hat{x} \| \), as it can happen that the iterates may be over-smoothed (for stronger denoiser \( H_{\sigma_k} \)) and might have crossed the optimal solution. The point being, if we trust in our denoiser to be "appropriate" and directing the iterates \( x_k^\delta \) towards the true solution \( \hat{x} \) through \( z_k^\delta \), i.e., towards a "better" direction, then we would hope the shift in (3.5) to be in the proper direction, and hence, leading to \( \| z_k^\delta - \hat{x} \| \leq \| y_k^\delta - \hat{x} \| \). In §3.1.1 and §3.1.2 we provide some suggestions when dealing with a bad denoiser \( H_{\sigma_k} \), i.e., when the original denoiser \( H_{\sigma_k} \) is too strong or too weak, then how can it be improved to perform the appropriate level of denoising to recover better estimates of the true solution, without actually altering the original denoiser.

In this section we showed that if the denoiser \( H_{\sigma_k} \) satisfies the descent condition (3.4), at each iteration \( k \), then the FBS-PnP algorithm will fall in the family \( \mathcal{I}_3 \). The weakness, which also the strength, of the condition (3.4) is that, the recovery errors corresponding to the iterates \( z_k^\delta \) will also follow a semi-convergent path, and hence, the iterations have to be terminated at an appropriate early instance \( k(\delta) \), as explained in remark 2.3. To overcome this inconvenience, as stated in remark 2.3, the family \( \mathcal{I}_3 \) needs to be further extended, which is done later.

3.1.1. Reinforcing weaker denoisers.

In practice, one usually starts with a denoiser of certain strength, say \( \sigma \), and at every iteration \( k \), the denoising of \( x_k^\delta \) is done via \( H_{\sigma_k} \), where \( \sigma_k = \sigma \tau_k \), where \( \tau_k \) is the associated step-size for that iteration. As discussed in §3.1 the FBS-PnP algorithm is guaranteed to fall in the regularized family \( \mathcal{I}_3 \) provided the denoiser \( H_{\sigma_k} \) satisfy (3.4). Now, for a weaker denoiser (i.e., \( \| H_{\sigma_k}(x_1^\delta) - x_1^\delta \| \) is small), though the structure imposing direction \( d_1^\delta \), as defined in (3.3), will satisfy (3.4), the iterates \( x_k^\delta \) won’t be sufficiently denoised, i.e., the denoised iterates \( z_k^\delta \) will still contain certain amount of noise. Of course, during the next minimization process, one can opt for an “appropriate” stronger denoiser \( H_{\sigma_k} \), if possible, to provide stronger denoising of the iterates \( x_k^\delta \). There is also a second approach to augment the denoising strength of \( d_k^\delta \), without altering the denoiser, for example, when one has only one denoiser to work with. Observe that, the satisfaction of the condition (3.4), by a denoiser \( H_{\sigma_k} \), is also dependent on the step-size \( \tau \). That is, even for
a weaker denoiser $H_{\sigma_k}$, if the value of $\tau$ is small enough, then $H_{\sigma_k}$ will fail to satisfy the condition (3.4), i.e., the denoising strength of the weaker denoiser will increase implicitly. Hence, by decreasing the step-size $\tau$ smaller than the previous choice, such that $||H_{\sigma_k}(x^\delta_k) - x^\delta_k||$ is slightly smaller than $||-\tau D(x^\delta_k) - x^\delta_k||$, will not only lead to a descent direction but also, the amount of denoising will be increased for the original denoiser $H_\sigma$, see Example 5.1. However, this does increase the computational time, as with smaller values of $\tau$ the descent rate also decreases.

3.1.2. Attenuating stronger denoisers.

In contrast to a weak denoiser, a stronger denoisers $H_\sigma$ may not lead to the satisfaction of the condition (3.4), since, the extent of denoising $||H_{\sigma_k} - x^\delta_k||$ may exceed the improvements coming from the data-consistency step $||x^\delta_k - x^\delta_{k-1}||$. Again, the obvious way to overcome this issue is by opting for a weaker denoiser $H_\sigma$, the next time, such that the condition (3.4) is satisfied. However, this can lead to several attempts of numerous minimization process to find an appropriate denoiser, which can substantially increase the computational time. Note that, unlike the previous tweak, here one cannot increase the step-size randomly to compensate the strong denoising in (3.4), as then the descent process will break down, for larger step-sizes.

A cleverer approach of handling this issue is through relaxing the denoising strength of the strong denoiser $H_\sigma$ by incorporating an additional parameter, i.e., for any $\alpha \in (0,1)$, define

$$z^\delta_k = z^\delta_k(\alpha) := x^\delta_k + \alpha (H_{\sigma_k}(x^\delta_k) - x^\delta_k)$$

$$(3.6)$$

Hence, if $||H_{\sigma_k}(x^\delta_k) - x^\delta_k|| > ||x^\delta_k - x^\delta_{k-1}|| = ||-\tau D(x^\delta_k)||$, then for any

$$\alpha < \frac{||x^\delta_k - x^\delta_{k-1}||}{||z^\delta_k - x^\delta_{k-1}||} = \frac{||-\tau D(x^\delta_k)||}{||H_{\sigma_k}(x^\delta_k) - x^\delta_{k-1}||} < 1,$$  \hspace{1cm} (3.7)

we will have the resulting direction

$$d^\delta_k = z^\delta_k - x^\delta_{k-1}$$

$$(3.8)$$

$$(x^\delta_k - x^\delta_{k-1}) + \alpha (H_{\sigma_k}(x^\delta_k) - x^\delta_{k-1})$$

satisfy the condition (2.6). Usually, one can choose $\alpha = \gamma \frac{||-\tau D(x^\delta_k)||}{||H_{\sigma_k}(x^\delta_k) - x^\delta_{k-1}||} < 1$, where the proximity parameter $\gamma > 0$ controls the closeness of $d^\delta_k$ to $-\tau D(x^\delta_k)$ through the parameter $\alpha(\gamma)$. That is, if $\alpha$ is small then $d^\delta_k$ is close to $-\tau D(x^\delta_k)$, leading to weak denoising and if $\alpha$ is close to 1, then it leads to strong denoising. This can be seen in Table 2 for Example 5.2.

An alternative way of estimating a proper $\alpha$ value is through minimizing $z^\delta_k(\alpha)$ based on the selection criterion, i.e.,

$$\alpha_0 := \arg \min_{\alpha \in (0,1)} S(z^\delta_k(\alpha))$$

$$\hspace{1cm} \text{such that, } z^\delta_k(\alpha) = x^\delta_k + \alpha (H_{\sigma_k}(x^\delta_k) - x^\delta_{k-1}).$$

Note that, the minimization problem (3.9) may not be a strictly convex, i.e., there might not be a global minimizer $\alpha_0$. Nevertheless, this is simply a sub-problem intended to find an appropriate $\alpha$ value between 0 and 1, depending on the selection criterion $S$, and hence, even if the best $\alpha_0$ is not obtained (which is not a requirement), any $\alpha \in (0,1)$ will reduce the denoising strength and empirical experiments
(see Example 5.2) show that it works fine. Also, the alpha value from (3.9) doesn’t guarantee that \( d^\delta_k(\alpha_0) := z^\delta_k(\alpha_0) - x^\delta_{k-1} \) will satisfy (2.6), but, it does attenuates the strong denoising of \( H_{\sigma_k} \) and provides an iterate \( z^\delta_k \) which satisfies the selection criterion the best. One can also mix the above two \( \alpha \) criteria, i.e., opt one criterion for certain steps and then switch to the other, and can repeat this process, see Example 5.2 for details.

**Remark 3.1.** Note that, inspired from (3.9), one can also choose the denoising strength of the denoiser \( H_{\sigma_k} \), at every iteration, depending on the selection criterion, i.e., by defining the denoised iterates as a function of the denoising strength \( \sigma \)

\[
z^\delta_k(\sigma_k) := H_{\sigma_k}(x^\delta_k),
\]

one can choose the denoising strength \( \sigma_k \), within a certain range, which best satisfies the selection criterion, i.e.,

\[
\sigma_k := \arg \min_{\sigma \in [\sigma_0, \sigma_1]} S(z^\delta_k(\sigma))
\]

such that, \( z^\delta_k(\sigma) = H_{\sigma}(x^\delta_k) \).

However, remember that, the denoising step is the computationally expensive step during the iterative process, and hence, performing a minimization over the denoising strength can notably increase the computational time. In addition, similar to (3.9), the minimization in (3.11) need not be even convex.

### 3.2. Fast Forward-backward splitting (Fast FBS) - PnP

The plain FBS-PnP methods tend to show very slow convergence rate, even during the semi-iterative process, i.e., \( k(\delta) \) is very large. To speed up the descent rate faster algorithms are usually employed, such as the fast proximal gradient methods (FPGM) or FISTA, see [11]. The iterates in this algorithm have an intermediate momentum step to accelerate the descent process, which is given by, starting from initial \( z^\delta_0 = x^\delta_0 \) and \( t_0 = 1 \), for \( k \geq 1 \),

\[
x^\delta_{k-1} \mapsto x^\delta_k = x^\delta_{k-1} - t_k \nabla_x D(x^\delta_{k-1}) \quad \leftarrow \text{data-consistency step} \quad (3.12)
\]

\[
x^\delta_k \mapsto z^\delta_k = H_{\sigma_k}(x^\delta_k), \quad \leftarrow \text{data-denoising step} \quad (3.13)
\]

\[
x^\delta_k \mapsto x^\delta_k = z^\delta_k + \alpha_k(z^\delta_k - x^\delta_{k-1}) \quad \leftarrow \text{momentum-step} \quad (3.14)
\]

where \( \alpha_k = \frac{t_{k-1} - 1}{t_k} \) with \( t_k = \frac{(1+\sqrt{1+4t_0^2}) - 1}{2} \).

Now, one can also perform similar analysis as done for the vanilla FBS-PnP method, we skip the details.

### 4. Expansion of the regularization family

Before we proceed to attach a meaning to the ADMM-PnP algorithms we would like to address the question raised in the last part of remark 2.3, i.e., can the family of regularized solutions \( I_3 \) be generalized to soften the condition (2.6), which leads to the semi-convergence of the recovery errors? To answer this question, let’s first interpret the family \( I_3 \) from a different perspective. First, note that the formulation of \( I_3 \) in (2.11) is also equivalent to

\[
I'_3 := \{ x^\delta(\mathcal{D}, k, d^\delta_k; S) : x^\delta_k = x^\delta_{k-1} + d^\delta_{k-1}, \text{ subject to } D(x^\delta_k) \geq \epsilon(\delta) \geq 0, \text{ such that } d^\delta_k \text{ satisfies (2.6) and } S \text{ is any selection criterion.} \},
\]
where the lower bound $\epsilon(\delta)$ for the discrepancy term $D$ now serves the purpose of $k(\delta)$ and determines the extent of regularization, for example, if $\epsilon(\delta) \approx \eta \delta$, for $\eta > 1$, leads to Morozov’s discrepancy principle (DP) [5, 33, 25]. Equivalently, the formulation in $T'_3$ suggests to minimize the data-discrepancy functional $D$, via a (descent) direction $d_k^\delta$ satisfying (2.6), but constraint to $D(x_k^\delta) \geq \epsilon(\delta) \Leftrightarrow D(x_k^\delta) = \epsilon(\delta)$, i.e., not to minimize $D$ completely, which avoids overfitting the noisy data $b_k$.

Therefore, the key is to not overfit the noisy data, which motivates us to generalize the constraint $D(x_k^\delta) \geq \epsilon(\delta)$, for larger iterations ($k > k(\delta)$), to

$$0 \leq \epsilon_1(\delta) \leq D(x_k^\delta) \leq \epsilon_2(\delta),$$

such that $\epsilon_2(\delta) \xrightarrow{\delta \rightarrow 0} 0$ (for asymptotic convergence), where the lower bound $\epsilon_1(\delta)$ avoids overfitting and the upper bound $\epsilon_2(\delta)$ avoids underfitting of the data. Now, if we enforce the directions $d_k^\delta$ to satisfy (2.6) for $x_k^\delta$ satisfying $D(x_k^\delta) > \epsilon_2(\delta)$, we minimize the discrepancy-term $D$, where as, removing the constraint (2.6) on those directions $d_k^\delta$ for which $D(x_k^\delta) \leq \epsilon_2(\delta)$ but constraining them implicitly through $x_k^\delta$ such that $\epsilon_1(\delta) \leq D(x_k^\delta + d_k^\delta) \leq \epsilon_2(\delta)$, one is able to relax the descent criterion while (still) avoiding the overfitting to the noisy data. Hence, the new conditions for directions $d_k^\delta$ are

$$\left(\frac{d_k^\delta}{\nabla_x D(x_k^\delta)}\right)_2 > 0, \quad \text{for } D(x_k^\delta) > \epsilon_2(\delta) \quad \text{or} \quad k \leq k(\delta)$$

$$D(x_k^\delta + d_k^\delta) \geq \epsilon_1(\delta), \quad \text{for} \quad D(x_k^\delta) \leq \epsilon_2(\delta) \quad \text{or} \quad k > k(\delta).$$

Note that, with this modification, the recovery errors for the iterates $x_k^\delta$ does necessarily follow semi-convergence, nor a convergence, trail anymore, it may end up oscillating/ fluctuating around the optimal solution, see Figures 4g and 4h. Again, the answer to “does it improve the recovery process?” depends on the choice of the recovery directions $d_k^\delta$ and the selection criteria $S$. The formal extension of the family $I'_4$ can be expressed as

$$I_4 := \{x^\delta(D, k, d_k^\delta; S) : x_k^\delta = x_{k-1}^\delta + d_{k-1}^\delta, \text{ s.t. } d_{k-1}^\delta \text{ satisfies } (4.3),$$

$$\text{and } S \text{ is any selection criterion.}\}.$$

Observe that, by increasing the number of constraints from one in equation (4) to two in equation (4.4), we are able to expand the family of regularized solutions, i.e., for $\epsilon_1(\delta) < \epsilon_2(\delta)$, we have $I_4 \supset I'_3$ and when $\epsilon_1(\delta) = \epsilon_2(\delta)$, then $I_4 = I'_3$.

Moreover, the family $I_4 \supset T_2$ (the family of Tikhonov-regularization), since, for any $\lambda(\delta) > 0$ the discrepancy of the regularized solution is always positive, i.e., $D(x^\delta(D, \lambda(\delta), R)) > 0$, and the directions $d_k^\delta$ in $I_4$ need not satisfy (2.6) for all $k$.

Moreover, the advantage of defining a regularized solution as in $I_4$ over $T_2$ is that, one does not have to worry about the convergence of $\{x_k^\delta\}$ anymore, as we are not finding the minimizer of a Variational problem (1.3), rather, estimating the solution of the inverse problem (1.1) iteratively using a sequence of iterates $x_k^\delta$, defined by the directions $d_k^\delta$, where the best estimate is determined via a selection criterion.

Observe that, although the initial iterate $x_0^\delta$ is not explicitly mentioned in the families of the regularized solutions $I_1, I_2, I_3$ and $I_4$, it is inherently embedded in the recovery process, unlike in the families $T_1$ and $T_2$, where $x_0^\delta$ does not matter. To explicitly state the importance of the initial iterates in these (non-Variational
or (semi-) iterative families, $\mathcal{I}_4$ can be expanded to

$$\mathcal{I}_5 := \{ x^\delta(D, k, d_k^\delta, x_0^\delta, S) : x_k^\delta = x_{k-1}^\delta + d_{k-1}^\delta, \text{ starting from } x_0^\delta, \text{ s.t. } d_{k-1}^\delta \text{ satisfies (4.3) and } S \text{ is any selection criterion.} \} .$$

(4.5)

The significance of the initial iterate $x_0^\delta$ can be prominently seen in the ADMM-PnP algorithm, which is discussed later. However, if the descent directions depend continuously, as a function, on its iterates, i.e., $||d_k^\delta(x_k^\delta) - d_k^\delta(z_k^\delta)||$ is small for small $||x_k^\delta - z_k^\delta||$, then for a small change in the initial iterates, $||x_0^\delta - z_0^\delta|| \leq \epsilon$, the difference in the recovered regularized solutions will also be bounded by a factor similar to (2.9), i.e., $||z_k^\delta - x_k^\delta|| \leq C(k)\epsilon$, that is, stability in the recovery process with respect to any small perturbations in the initial choices.

4.1. Differential equation’s solutions as a regularization family.

As one might have guessed by now, all the above families of solutions can be categorized as a discrete approximation of some differential equations, in particular, the evolution equation given by

$$\frac{\partial}{\partial t} x^\delta(\cdot, t) = f(x^\delta(\cdot, t))$$
$$x^\delta(\cdot, t = 0) = x_0^\delta \in \mathbb{R}^n,$$

(4.6)

where the function $f(x^\delta(\cdot, t))$ determines the flow or the evolution of a family of approximated solutions $x^\delta(\cdot, t)$ to the inverse problem (1.1), and an appropriate estimate $x^\delta(\cdot, T(\delta)) \in \mathbb{R}^n$ for $\dot{x}$ is determined via a selection criterion. When $f(x^\delta(\cdot, t)) = -\tau(t)\nabla_t D(x^\delta(\cdot, t)) = -\tau(t)A^*(Ax^\delta(\cdot, t) - b_0)$, for $\tau(t) \geq 0$, we have the classical steepest-descent method in the continuous settings. And for $f(x^\delta(\cdot, t))$ satisfying $\left(f(x^\delta(\cdot, t)), -\nabla_t D(x^\delta(\cdot, t)) \right)^2 > 0$, it falls in the family $\mathcal{I}_3$ and for $f(x^\delta(\cdot, t))$ satisfying (4.3) we end in $\mathcal{I}_4$ family, in their respective continuous versions. Here, one can observe that a regularized solution is not only a function of $f(x^\delta(\cdot, t))$ (the flow direction), but also, on $x_0^\delta$ (the initial/starting state) and $T(\delta)$ (the stopping/terminal time), i.e., $x^\delta = x^\delta(\cdot; f, x_0^\delta, T(\delta))$. In contrast, the minimization of the Variational problem (1.3) is independent of the starting point and the descent direction, when minimized in an iterative manner, since a good starting point ($x_0^\delta$) and a faster descent direction ($f(x^\delta(\cdot, t))$) only improves the descent rate to reach the minimizer of the (1.3), but not the final solution. It only depends on the definition of the penalized/constrained functional ($\mathcal{R}$) and the penalty/regularization parameter ($\lambda$) in (1.3), i.e., $x^\delta(\cdot; \mathcal{R}, \lambda)$. Therefore, based on a fixed selection criterion $\mathcal{S}$, comparing a Variational regularized solution $x^\delta(\cdot; \mathcal{R}, \lambda)$ to a (semi-) iterative regularized solution $x^\delta(\cdot; f, T, x_0^\delta)$ we see that the analogous of $\mathcal{R}$ is $f$ and $\lambda$ is $T$. However, the (true) dependence of the initial point $x_0^\delta$ is still missing in the Variational solution (assuming one minimizes the convex functional completely and the iterates converge to the global minimizer) and has an importance in the (semi-) iterative method, as can be seen in ADMM-PnP for a general denoiser $H_\alpha$. Nevertheless, the recovery will be stable to a small perturbation in the initial condition for $f(x^\delta(\cdot, t))$ depending continuously on $x^\delta(\cdot, t)$, i.e., one can estimate a bound for the difference of the solution flow at any time $t$, which is given by

$$||x^\delta(\cdot, t) - z^\delta(\cdot, t)|| \leq c(t) \int_0^t ||f(x^\delta(\cdot, s)) - g(x^\delta(\cdot, s))|| ds + ||x_0^\delta - z_0^\delta||,$$

(4.7)
for some constant $c(t)$, where $x^\delta(.,t)$ is generated from the direction $f(.,t)$ and $z^\delta(.,t)$ from $g(.,t)$. And if $||f(.,t) - g(.,t)|| \leq c^\delta(t)$ and $||x_0^\delta - z_0^\delta|| \leq \epsilon$, then we have

$$||x^\delta(.,t) - z^\delta(.,t)|| \leq c(t) \int_0^t c^\delta(s)ds + ||x_0^\delta - z_0^\delta|| \leq C(t)\epsilon,$$

for some other constant $C(t)$, when $c^\delta(s) \leq \epsilon$ for all $s \leq t$.

Note that, if $f(x^\delta(.,t))$ satisfies (2.6) or (4.3) then it is also implicitly dependent on the discrepancy term $D(x)$ through the inner product with its gradient $-\nabla_x D(x^\delta_k)$, i.e., $f(x^\delta(.,t)) = f(x^\delta(.,t); D)$. Hence, to further generalize the class $\mathcal{I}_5$, one can even remove any dependence (implicit or explicit) on the discrepancy term $D$, i.e., no knowledge of the forward operator $A$ is used. For example, one can generate the flow of solutions $x^\delta(.,t)$ driven solely by a collection of informative dataset, i.e., using machine learning or deep learning algorithms, for example, the AUTOMAP network in [34]. The advantage of this formulation is that, any shortcomings or mismatch in the model $A$ can be compensated by replacing it with a data based model (say neural networks). However, this strength becomes weakness for (certain) noisy data and pushes the recovery process further into the realm of instabilities (now being generated by the data model), see [35], if no “proper regularization” is employed, where the proper regularization implies regularizing the recovery process rather than regularizing the neural network, this is a topic of discussion for another paper. Nevertheless, we end this section by defining the largest family of regularized solution to the inverse problem (1.1) as

$$\mathcal{I}_6 := \{ x^\delta(f, x_0^\delta, t; S) : x^\delta(f, x_0^\delta, t) \text{ is the solution of (4.6) corresponding to time } t, \text{ s.t. } f(x^\delta(.,t)) \xrightarrow{\delta \to 0} -\tau(t)\nabla_x D(x(.,t)) \text{ and } S \text{ is any selection criterion} \}.$$

(4.9)

4.2. Alternating direction method of multipliers (ADMM) - PnP.

Now we have developed all the theories needed to attach a meaning to the ADMM-PnP algorithms. Note that, a typical step in the ADMM-PnP algorithm is given by

$$x^\delta_{k+1} = \text{Prox}_{\frac{1}{\rho}D}((z^\delta_k - u_k^\delta) \quad \text{data-consistency step}$$

$$= \arg \min_x D(x) + \rho ||x - (z^\delta_k - u_k^\delta)||^2_2$$

$$z^\delta_{k+1} = H_{\sigma_k}(x^\delta_{k+1} + u_k^\delta) \quad \text{data-denoising step}$$

$$u^\delta_{k+1} = u_k^\delta + x^\delta_{k+1} - z^\delta_{k+1} \quad \text{noise update step}$$

(4.10) - (4.12)

where if $H_{\sigma_k}$, for $\sigma_k = \sigma/\rho$, corresponds to the proximal map of a proper, closed and convex regularizer $\mathcal{R}(x)$, then the Lagrangian parameter, $\rho > 0$, only affects the speed of the convergence and not the solution of (1.3), i.e., the iterates $x^\delta_k$ and $z^\delta_k$ will converge to the minimizer of the functional (1.3), irrespective of the value of $\rho$. However, this can not be guaranteed for any general denoiser $H_{\sigma_k}$, in fact, there might not even exists an associated proximal map corresponding to any general denoiser, and hence, a regularization function $\mathcal{R}(x)$ in (1.3). In this section we connect ADMM-PnP algorithms to the theories developed in the previous sections and also point out the significance of the Lagrangian parameter $\rho$ in this setting.
Note that, at any step \( k \), the minimizer \( (x^\delta_{k+1}) \) in the data-consistency step (4.10) has a closed form solution, for \( D(x) = \|Ax - b\|_2^2 \), given by
\[
x^\delta_k = (A^\ast A + \rho I)^{-1}(A^\ast b_\delta + \rho(z^\delta_{k-1} - u^\delta_{k-1})) \quad \leftrightarrow \quad \text{Tikhonov-}\ell_2 \text{ solution with } \lambda = \rho.
\]

Therefore, the resulting direction from \( x^\delta_k \) to \( x^\delta_{k+1} \), for \( k \geq 1 \), is given by
\[
d^\delta_k := x^\delta_{k+1} - x^\delta_k = (A^\ast A + \rho I)^{-1}\rho[\{z^\delta_k - u^\delta_k\} - \{z^\delta_{k-1} - u^\delta_{k-1}\}],
\]
and it’s a descent direction if it satisfy (2.6), i.e.,
\[
\left(d^\delta_k, -\nabla_x D(x_k)\right)_2 = \left((A^\ast A + \rho I)^{-1}\rho[\{z^\delta_k - u^\delta_k\} - \{z^\delta_{k-1} - u^\delta_{k-1}\}], -A^\ast(Ax^\delta_k - b_\delta)\right)_2 > 0
\]
which, though is trivial for \( k = 0 \) with \( x^\delta_0 = z^\delta_0 = u^\delta_0 \equiv 0 \), as
\[
\left(d^\delta_0, -\nabla_x D(x_0)\right)_2 = \left((A^\ast A + \rho I)^{-1}A^\ast b_\delta, A^\ast b_\delta\right)_2 > 0,
\]
is non-trivial for \( k \geq 1 \). However, this is where we can either use the regularization family \( \mathcal{I}_\delta \), as \( d^\delta_0 \) satisfies (2.6), or \( \mathcal{I}_0 \), where \( d^\delta_0 \) doesn’t need to satisfy any conditions, to attach a meaning to the iterative process of generating a regularized family of structured-solutions \( \{x^\delta_k\} \), where an appropriate solution \( (x^\delta_{k(\delta)}) \) is determined by some selection criteria.

As mentioned earlier, the ADDM-minimization corresponding to a traditional regularizer \( R(x) \) is independent of the Lagrangian parameter \( \rho \), as the iterates converge. But for any general denoiser \( H_\sigma \), there is no proof of convergence and hence, the choice of \( \rho \) will affect the recovered regularized solution. In addition, the initial choices \( (x^\delta_0, z^\delta_0, u^\delta_0) \) also influence the recovery process in this case, for reasons mentioned above or if we consider the iterative process to be in the family \( \mathcal{I}_\delta \) or \( \mathcal{I}_0 \) of regularized solutions. To show the nature of dependence on \( \rho \), we first transform the minimization in (4.10) to an equivalent constraint minimization, given by
\[
x^\delta_{k+1} := \begin{cases} \arg \min_x D(x) = \|Ax - b\|_2^2, \\ \text{subject to } \|x - (z^\delta_k - u^\delta_k)\|_2^2 \leq \epsilon(\rho), \end{cases}
\]
for some associated \( \epsilon(\rho) \sim 1/\rho \). That is, for larger values of \( \rho \), \( x^\delta_{k+1} \) is closer to \( z^\delta_k - u^\delta_k \), and for smaller values of \( \rho \), \( x^\delta_{k+1} \) will be farther away from \( z^\delta_k - u^\delta_k \), and closer to the noise corrupted solution \( (A^\ast A + \rho I)^{-1}(A^\ast b_\delta + \rho(z^\delta_k - u^\delta_k)) \). Hence, we divide the analysis into two parts:

4.2.1. When Lagrangian parameter is large. Assuming we start from \( x^\delta_0 = z^\delta_0 = u^\delta_0 \equiv 0 \), after the 1st step, we have a slightly improved \( x^1 \) towards the LS-solution (without being much corrupted by the noise), and hence, even for a weaker denoiser \( H_{\sigma_1} \), one can denoise it to get \( z^1 \). On the 2nd step, \( x^2 \) will again be improved only slightly towards the noisy LS-solution, because of the stronger constraint in (4.17), which can then be effectively denoised by the denoiser and so on. Therefore, starting from smooth initial choices, one can recover well denoised iterates \( \{z^i\} \), even for weaker denoisers. This process is very similar to FBS-PnP algorithm, though the iterates are not explicitly generated by descent directions, rather, through a constrained minimization at each step.
4.2.2. When Lagrangian parameter is small. In contrast to the above recovery process, here, even when the initial choices \((x_0, \delta_k, z_0, u_0)\) are smooth (say 0s), after the 1st iteration we will have \(x_1^\delta\) close to the noisy LS-solution, i.e., \(x_1^\delta\) too noisy, and hence, we need a much stronger denoiser to clean the corruptions, which in turn will move \(z_1^\delta\) far away from \(x_1^\delta\). Thus, this process (of high fluctuations between \(x_k^\delta\) and \(z_k^\delta\)) will be repeated at every step and we do not know if this will eventually converge to an appropriately denoised solution or not, see Example 5.3.

**Remark 4.1.** From the above two analysis, one can notice that when \(\rho\) is large the recovery process is very similar to the FBS-PnP method and one can clean the noise in the iterates \(x_k^\delta\) gradually towards the “improved” iterates \(z_k^\delta\), of course, the improvement depends on the denoiser \(H_{\sigma_k}\). But, here, the rate of descent can be very slow, similar to ISTA, and hence, it will be preferable to opt for the Fast FBS-PnP methods. Where as, if \(\rho\) is small then the rate of descent corresponding to the discrepancy term \(D(x)\) is fast, however, this doesn’t ensure that the rate of descent for a denoised solution to be fast too, since, the faster \(D\) decreases, the faster the noise increases in the iterates. Therefore, here it depends on the effectiveness of the denoisers to obtain a cleaner recovery.

**Remark 4.2.** In addition to the issues mentioned in the above remark, note that, in the ADMM minimization process, step (4.10) involves an additional minimization problem at each iteration \(k\). This further increases the computational time and complexity, for example, for large scale problem the matrix inversion \((A^T A + \rho I)^{-1}\) is impossible and one has to approximate the exact minimizer \(x_k^\delta\) via an iterative scheme (such as conjugate-gradient) for a certain number of fixed iterations, and hence, there is a further corruption to the meaning of ADMM-minimization. Therefore, unless one has some prior knowledge of an “appropriate” Lagrangian parameter \(\rho\), which can balance the speed of \(D\)-descent and the creeping up of the noise in the iterates, we (personally) prefer the fast FBS-PnP algorithms over ADMM-PnP methods, the differences in the performance can be seen in the numerical section.

**Remark 4.3.** Note that, as mentioned above, the first iterate of the ADMM process (starting from initial \(x_0^\delta = z_0^\delta = u_0^\delta \equiv 0\)) is an \(\ell_2\)-Tikhonov solution, i.e., \(x_1^\delta = \arg \min_x D(x) + \rho \|Lx\|^2_2\). Hence, one can generalize it by replacing the standard \(\ell_2\)-Tikhonov solution with any general \(\ell_2\)-Tikhonov solution, i.e.,

\[
\begin{align*}
x_1^\delta &= \arg \min_x D(x) + \rho \|Lx\|^2_2, \\
\end{align*}
\]

where \(L\) can be either any wavelet transformation or the gradient operator. This may serve as a better initial \(x_1^\delta\) for the ADMM-PnP process, than the standard \(\ell_2\)-solution, and hence, can lead to an improved regularized solution.

4.3. A mixture or collection of denoisers.

Typically, in the classical FBS-PnP or ADMM-PnP algorithms, a single denoiser \(H_{\sigma_k}\) is used in every iterations with varying level of denoising, i.e., \(H_{\sigma_k}\), where \(\sigma_k\) is either \(\tau_k \sigma\) or \(\varphi_k \sigma\). It makes sense if one tries to connect the PnP algorithms with a Variational problem, corresponding to a regularizer \(R\) in (1.3). However, if one categorizes the PnP algorithms as a sub-class of the iterative regularization families, then one can introduce different denoisers in different iteration steps, and thus, can obtain a much better recovery. In addition, one can even use a collection of denoisers (all or a subset of them) at any iterative step and can take a weighted
average of their outputs, where the weights can be determined through a selection criterion, which can be also different from the selection criterion of the solution (S). Hence, for a collection of denoisers \( \{H_{\sigma_i}\} \), one can either perform the naive recovery by using different denoisers during different minimization process and then choosing a recovered solution as the one which best satisfies the selection criterion among all the solutions, which themselves have satisfied the selection criterion the best during their respective minimization process. Alternatively, one can use different denoisers (or a collection of them) “appropriately” in different iteration of a minimization process and the recovered solution corresponds to that iterate which satisfies the selection criterion the best, where “appropriately” means to either subdue a very strong denoiser (as suggested in §3.1.2) or boost a weaker denoiser (as shown in §3.1.1), and also choosing appropriate weights for different denoisers, if a bunch of them are used together at one iteration. Again, this doesn’t ensure that the recovered solution through this process will be “better” than the one obtain naively using different denoisers for different minimization process, as the solution corresponding to the most appropriate denoiser \( H_{\sigma_i} \) can outperforms a mixture of good and bad denoisiers, but then, one does not know the best denoiser apriori. However, one can significant gain in the computational time when a combination of denoisers are used iteratively in one minimization process over using each one of them individually in separate minimization process.

5. Numerical Results

In this section we provide computational results validating the theories developed in this paper. Note that, the goal here is not to show the effectiveness of PnP-algorithms, which has been empirically shown in numerous papers, rather, we try to present some of the caveats of these algorithms, when do they fail, and how to improve them. Hence, in most of the examples we won’t focus on repeating the same experiment over and over with different parameter values (i.e., tuning the parameter values) to attain the best solution, i.e., with the optimal MSE (mean squared error) with respect to the (known) solution. Rather, for a fixed selection criterion \( S_0 \) and a fixed denoiser \( H_\sigma \), we present: (1) how can one attain the best solution based on \( S_0 \) and, (2) how to further improve the recovery for the same \( H_\sigma \) and \( S_0 \), say when the denoiser is too strong or too weak. We also compare Fast FBS-PnP with ADMM-PnP, i.e., the pros and cons of both these algorithms and, when do they fall in the family \( I_3 \) or in \( I_5 \).

All the experiments are computed in MATLAB where, unless otherwise stated, we consider the selection criterion (\( S_0 \)) as the cross-validation criterion, for some leave out set, and the denoiser \( H_\sigma \) as the BM3D denoiser (with the denoising parameter \( \sigma > 0 \) correspond to the standard deviation of the noise, and the MATLAB code for the BM3D denoiser is obtained from http://www.cs.tut.fi/foi/GCF-BM3D/, which is based on [36, 37], where we kept all the attributes of the code in their default settings, except the std. dev. which depends on \( \sigma \)). We set the discrepancy term \( D(x) = \|Ax - b\|_2^2 \), where the noise level \( \delta \) is such that the relative error in the data \( \left( \frac{|b - b_\delta|}{|b|} \right)^2 \) is around 1% (which is also, in this case, equivalent to a 40 dB SNR, signal to noise ratio), unless otherwise stated. Note that, the BM3D denoiser code provided at the above link works for (grayscale or color) images with intensities in the range \([0,1]\). Hence, for our problems when the image intensities fall outside this range, we transform the original denoiser with a simple rescaling.
trick, i.e., $\hat{H}_\sigma(x) = S^{-1}(H_\sigma(S(x)), x_-, x_+)$, where for any $x$ we have $x_- = \min(x)$, $x_+ = \max(x)$, $S(x) = \frac{x - x_-}{x_+ - x_-}$ and $S^{-1}(y, x_-, x_+) = y \cdot (x_+ - x_-) + x_-$. From now on, we denote $H_\sigma(x) = H_\sigma(S(x))$, unless otherwise stated. Also, in a typical FBS-PnP or ADMM-PnP algorithm the denoiser is denoted as $H_\sigma$, where $\hat{\sigma} = \frac{\tau \sigma}{\rho}$ (pro being the Lagrangian parameter), respectively. However, to analyze the behavior of the descent process, we instead use the original fixed denoiser $H_\sigma$ in the iterative process, i.e., $H_\sigma = H_\sigma$, unless otherwise stated.

In the following examples, the matrix equation (1.1) corresponds to the discretization of a radon transformation which is associated with the X-ray computed tomography (CT) reconstruction problems, where we generate the matrix $A \in \mathbb{R}^m \times n$, $x \in \mathbb{R}^n$ and $b \in \mathbb{R}^m$ from the MATLAB codes presented in [38]. We then add Gaussian noise to the noiseless $b$ to get $b_\delta$, with a relative error of 1%. The dimension $n$ corresponds to the size of a $N \times N$ image, i.e., $n = N^2$, and the dimension $m$ is related to the number of rays per projection angle and the number of projection angles, i.e., $m = M_1 \times M_2$, where $M_1$ implies the number of rays/angle and $M_2$ implies the number of angles.

**Example 5.1. [Semi-convergence + Weaker denoiser + Boosting]**

In the first example, we show the semi-convergence nature in the recovery errors shown by PnP-algorithms when an inappropriate denoiser (in this case a weak denoiser) is used during the minimization process and, how can one retrieve the “best” possible solution in this case. We also present how to boost the denoising strength of a weak denoiser $H_\sigma$, without altering the $\sigma$ value, to produce better results. We start with a standard $128 \times 128$ Shepp-Logan phantom (true image $x \in \mathbb{R}^{128} \times 128$ and $x \geq 0$), which is then re-scaled between [-1,1]. The purpose of rescaling is that, the constraint ($x \geq 0$) minimization corresponding to the standard Shepp-Logan phantom is relatively robust to noisy data, and since the point of this example is to show the instabilities occurring in PnP-algorithms, we re-scaled the original phantom. Moreover, real medical phantoms are not restricted to the non-negativity constraint. The matrix $A \in \mathbb{R}^{128 \times 128} \times 128$ is generated using $PRtomo()$ from [38], corresponding to a ‘fancurved’ CT problem with only 60 angles (i.e., every 6° over the full circle of 360°), and hence, the data $b := Ax \in \mathbb{R}^{128 \times 10860}$. We then contaminate the exact data $b$ with Gaussian noise $\epsilon_\delta$ to produce noisy data $b_\delta$, such that the relative error is around 1%. Now, we leave out 1% of the noisy data $b_\delta$ for the cross-validation error (the selection criterion $S_0$), and start the **Fast FBS-PnP** algorithm with the modified BM3D denoiser $H_\sigma$, for $\sigma = 5 \times 10^{-4}$ for all the iterations. We perform the minimization process for two values of $\lambda$, i.e., (1) $\lambda_1 = 10^{-4}$ and (2) $\lambda_2 = 10^{-5}$, and for 1000 iterations, to check the convergence or semi-convergence of the recovery errors. The results are shown in Table 1 and the figures in Figure 3. Note that, from Table 1 and Figure 3, we are able to recover a much better recovery, in regards to both the selection criterion ($S_0$) and the error measurement metrics, by reducing the step-size $\tau$. However, we do see that the descent rate has decreased, which is to be expected for the smaller $\lambda$ value. Also, note that the nature of the error metrics graphs, such as MSE (which is related to $D$), is similar to the nature of the cross-validation error graph (related to $S_0$), where, either both are semi-convergent (for $\tau = 10^{-4}$) or convergent (for $\tau = 10^{-5}$), i.e., the selection criterion $S_0$, as the cross-validation criterion, can be trusted to recover a regularized solution. Interestingly, unlike the MSE or PSNR graph, which
improves constantly for \( \tau = 10^{-5} \), the SSIM graph decreases first and then improves on further iterations, see Figure 3.

Example 5.2. [Stronger denoiser + Attenuation + Family \( \mathcal{I}_3 \) or \( \mathcal{I}_5 \)]

In the second example we repeat the experiment performed in Example 5.1 but now, instead, using a stronger denoiser \( H_\sigma \), i.e., a larger value of \( \sigma \). Here we set \( \lambda = 10^{-4} \) and \( \sigma = 0.01 \), and perform the Fast FBS-PnP algorithm for 500 iterations. Then we repeat the process with attenuating the denoising strength of \( H_\sigma \) through the process described in §3.1.2, i.e., using (3.8), (3.9) and a combination of them.

Note that, while using the direction \( d^\delta_k \) as defined in (3.8), if the value of \( \gamma \) is close to 1, then the denoising is sufficient (lesser than the original strong denoiser \( H_\sigma \) but adequate enough), where as, if it is small (< 1), then the extent of denoising significantly decreases, as \( d^\delta_k \) gets too close to \(-\tau \nabla x D(x^\delta_k)\). This also leads to a sharper semi-convergence in the recovery errors, as can be seen in Table 2 and Figures 2. As for the combination of (3.8) and (3.9), we use (3.8) for those values of \( x^\delta_k \) for which \( D(x^\delta_k)/||b_k|| > \epsilon_1^\delta \) for some \( \epsilon_1^\delta \) (here, we chose \( \epsilon_1^\delta = 0.05 \)) i.e., when the relative error in the residue or discrepancy is above 5%, and use (3.9) for \( x^\delta_k \) satisfying \( D(x^\delta_k)/||b_k|| \leq \epsilon_1^\delta \). The reason behind this is, we would like the directions \( d^\delta_k \) to be a descent direction (satisfying (2.6)) for larger values of the residues and remove the constraint when the residues have reached a certain threshold, to avoid overfitting of the noisy data and leading to the semi-convergence of the recovery errors.

Table 2 shows the error measures for different recoveries and for different values of \( \gamma \), corresponding to \( d^\delta_k \) as defined in (3.8). Figure 4 shows the different recoveries, the PSNR values (peak signal-to-noise ratio) and the SSIM values (structural similarity index measure) for these recoveries. Note that, from Figure 4h, though it looks like the recovery corresponding to \( H_\sigma \) is good, but it’s actually over smoothed, as can be seen from Figures 3b and 4b, also from the PSNR and MSE curves, Figures 4g and 2b. The reason for such a high SSIM-value for an over-smoothed recovery, in this case, might be because of the simple structure or geometry of the original phantom, where even an over-smoothed recovery is structurally close to the true phantom. Now, as explained in §3.1, when \( d^\delta_k \)'s are generated from (3.8) then the recovered process falls in the regularization family \( \mathcal{I}_3 \), i.e., semi-convergence of the recovery errors, as can be seen from Figure 2b, for different values of \( \gamma \). Where as, for \( d^\delta_k \)'s originating from (3.9), or from (3.8)+(3.9), the recovery process falls in the regularization family \( \mathcal{I}_5 \), i.e., may not exhibit semi-convergence of the recovery errors, as can be seen from Figures 2a, 4g and 4h. Therefore, it suggests that, when the recovery process belongs to the family \( \mathcal{I}_3 \), i.e., all the \( d^\delta_k \)'s are descent directions, then the minimization process can be terminated at a much earlier instance and a recovered solution \( x^\delta_k(\delta) \) can correspond to the one satisfying the selection criterion the best, where as, if recovery process falls in family \( \mathcal{I}_5 \), then one can wait for longer period of iterations and can recover better solutions, as the fluctuating/oscillating iterates \( z^\delta_k \)'s can produce better approximations over time. In addition, note that, for the recovery process corresponding to \( \mathcal{I}_3 \), not only the recovery errors but also the selection-criterion (here, cross-validation) errors should follow a semi-convergent nature, as then, one can recover an appropriate regularized solution through early stopping, via monitoring the selection-criterion graph. In contrast, for the recovery process falling in \( \mathcal{I}_5 \), neither of them strictly follows a
semi-convergent nature, and hence, even the last iterate can serve as a regularized solution. These two phenomena can be seen in Table 2 and Figure 4.

**Example 5.3. [ADMM - small vs. large \( \rho \), with vs. without \( \sigma \) update]**

In this example we show the importance of the Lagrangian parameter \( \rho \), together with the update or no-update of the denoiser’s \( \sigma \) value during the iterative process, i.e., (1st) we perform the traditional ADMM-PnP algorithm, where \( H_\sigma \) is updated to \( H_\hat{\sigma} \), \( \hat{\sigma} = \frac{\sigma}{\rho} \) during the iterative process, and (2nd) we perform the minimization without updating the \( H_\sigma \) during the descent process. Again, note that, for the classical Tikhonov-type regularization, where the regularization function \( R(x) \) in (1.3) is proper, closed and convex, the (1st) method is guaranteed to converge to the minimizer of (1.3), although, the minimizer might not be the best estimate of the true solution \( \hat{x} \) during the minimization process, for a fixed \( \lambda \) value. Now, as described in §4.2, when \( \rho \) is small the first iterate \( x_1^0 \) is close the noisy LS-solution corresponding to the noisy data \( b_\delta \). Hence, the denoiser \( H_\sigma \) needs to be particularly good so that, after updating to \( H_\sigma \), it should be able to clean the large corruptions generated by the noisy data. Where as, for large \( \rho \), \( x_1^0 \) is close to \( x_0^0 \), and hence, will be smooth for smoother \( x_0^0 \). However, if \( H_\sigma \) is updated to \( H_\hat{\sigma} = \frac{\sigma}{\rho} \), then the denoising ability of \( H_\sigma \) is also reduced by a factor corresponding to \( \frac{1}{\rho} \), and thus, induce weak denoising. Therefore, for the fixed denoiser \( H_\sigma \), (2nd) method suggests to incorporate the denoiser \( H_\sigma \) without updating it. Moreover, since the convergence of ADMM-PnP algorithm for any general denoiser \( H_\sigma \) is not known, it does not hurt to implement it in either way; after-all, both these processes can be thrown in either \( I_5 \) or \( I_6 \) family and the better process is the one for which the recovered solution satisfies the selection criterion (S) the best.

In this example we repeat Example 5.1 but via the ADMM-PnP algorithm and using the strong BM3D denoiser \( H_\sigma \), for \( \sigma = 0.01 \). We perform two sets of ADMM-minimization process: 1st) small (\( \rho = 0.1 \)) and large (\( \rho = 500 \)) values of the Lagrangian parameter with updating the denoiser \( H_\sigma \) to \( H_\hat{\sigma} \), during the ADMM process; and, 2nd) small (\( \rho = 0.1 \)) and large (\( \rho = 500 \)) values of the Lagrangian parameter without updating the denoiser \( H_\sigma \) during the ADMM process. Note that, the minimizer of each \( x \)-update, i.e., \( x_k^0 \) as defined in (4.13), is only estimated by a certain number of conjugate-gradient (CG) steps and not through the matrix inversion. Here, we considered 100 CG-steps to approximate the \( x \)-minimizer to get the \( x_k^0 \) iterate. Hence, the 100 CG-steps, in combination with the 500 ADMM-steps, leads to a total of 50,000 iterations, although, there are only 500 denoising steps (which are actually computational expensive). Also, note that, the denoiser \( H_\sigma \) for \( \sigma = 0.01 \) acted as a strong denoiser in Example 5.2, where as, here it behaves like a weak denoiser, except when \( \rho \) is large and \( \sigma \) is not updated to \( \hat{\sigma} \). Table 3 and Figure 5 show the recoveries measures for different values of \( \rho \) and with or without the \( H_\sigma \) update. Hence, one can see that, recoveries corresponding to larger \( \rho \) values and without updating the denoiser \( H_\sigma \) provides the best result, as suggested above.

### 6. Conclusion and Future Research

In this paper we tried to explain the PnP-algorithms from a different angle. We defined certain families of regularized solutions and showed that the solution of a PnP-algorithm will fall in one of them. We started with an extension of the Landweber iterations to generate structured iterations, i.e., directions \( d_k^A \) satisfying...
This leads to the formulation of the regularization family $I_3$, which contains all the semi-iterative processes. This is further generalized to the family $I_5$, where the directions $d^s_k$ satisfy (2.6) for certain number of iterations and then the restriction is removed, i.e., once the iterates $x^s_k$ have approximated the data $b$ to a certain extent ($D(x^s_k) \leq \epsilon_1(\delta)$), we don’t want $d^s_k$ to be a descent directions anymore, as then, it will lead to semi-convergence in the recovery errors. The advantage of such a formulation, in addition to avoiding the semi-convergence, is that, one doesn’t have to worry about the convergence of the iterates $x^s_k$ anymore. Hence, it compensates the short-comings of both the classical regularization methods, i.e., the semi-iterative methods and Tikhonov-type methods. We showed that any iterate $x^s_k$ during the minimization process is an “approximate solution” of the inverse problem (1.1), and the goodness of the approximation is determined by a selection criterion $S_0$ for the solution. Therefore, one can terminate the iterative process at an early instance, if the error in the selection criterion $S_0$ starts getting worse, and hence, can reduce the computational time significantly. In fact, any $x \in \mathbb{R}^n$ can be considered as an approximate solution of (1.1), although it can be a lousy one and without a proper meaning attached to it. That is, a “regularized solution” $x^s$ is a one which approximates $\hat{x}$ better and better as noise vanishes, i.e., $\delta \rightarrow 0 \Rightarrow ||x^s - \hat{x}|| \rightarrow 0$, and is “well-defined” if there is a unique process of obtaining it, for example, via a properly defined sequence (finite or infinite) of iterates $x^s_k$ approaching to $x^s$. This lead to the formulation of our largest family of regularized solution $I_5$, as defined in (4.9), i.e., a solution state $x^s(.,t)$ corresponding to an initial value differential equation problem. In addition, we also showed how to improve the recoveries when dealing with an inappropriate denoiser $H_\sigma$, i.e., when the denoiser is too strong to oversmooth the recovered solution or when the denoiser is too weak to remove the noiser adequately. We also presented some of the pros and cons of using FBS-PnP algorithm over ADMM-PnP algorithm, and vice-versa.

In an upcoming paper, we extend this idea to the setting of training data, i.e., for a neural network denoiser or a denoising iterative scheme (unrolled NN). We believe that by incorporating this idea of regularization one can understand the instabilities arising in such methods, as shown in [35], and a way to handle them.
