(Dated: June 16, 2021)

A quantum resonator in a thermal-equilibrium state with a high temperature has a large average exciton number and has a significant occupation over the high Fock-states. The resonator could be cooled down through constant measurements on the ground state of a coupled two-level system (qubit). We find, however, that the measurement-induced cooling might become inefficient in the high-temperature regime. Beyond the conventional strategy, we propose a measurement-induced-cooling protocol via acting a strong interaction outside the space of the resonator-qubit system. In particular, the excited state of the two-level system is coupled to an outside state through a driving field. The strong interaction between these two states can greatly enlarge the cooling range in regard to the non-vanishing populated Fock-states of the resonator. Without any pre-cooling procedure, acting outside allows a significant reduction on the populations over the high Fock-states and then the ground-state cooling after a sequence of measurements. The fast transition induced by a strong acting-outside constrains the ancillary system at its ground state and then simulates a quantum Zeno effect, that consistently provides a possible realization for measurements required for cooling. Our protocol is applied to cool down a high-temperature magnetic resonator. It is then generalized to a hybrid cooling protocol by interpolating the methods with and without acting on the outside, which can accelerate the cooling process and promote the overlap between the final state of the resonator and its ground state.

I. INTRODUCTION

Open quantum systems are prone to be thermalized due to the inevitable coupling with a finite-temperature environment [1–4]. Pioneering experiments over the last decade have begun exploring quantum behaviour of micro-size harmonic resonator systems, adapting various cooling techniques to cool specific modes far below the environmental temperature [5–7]. Thus the ground-state cooling and the more general pure-state preparation [8, 9] for a quantum system has long been a challenge and an indispensable task for the majority of quantum technologies. Cooling is a crucial onset for the initialization of a quantum system, the adiabatic quantum computing [10–14], and the ultrahigh-precision measurements [15, 16], to name a few.

Measurement-induced cooling [17–22] constitutes a class of significant subroutines among quantum measurement-based control technologies, including the one-way computation [23, 24], the preparation of spatially localized states [25], and the entanglement generation [26]. In a broader sense, these applications emerge from the heated investigations [27–30] surround the quantum Zeno effect (QZE) [31, 32]. Conventionally, it states that measurements, such as the von Neumann projection and the generalized spectral decomposition [33], will affect in an essential way the dynamics of the measured system and result in a hindrance of the decoherence process. Because cooling a system to a ground state is essentially connected with an arbitrary pure state via a unitary operation, it is a straightforward consequence once the target system remains at its initial state by QZE.

A typical and successful practice of measurement-based cooling has been performed on a continuous-variable target system, e.g., a mechanical oscillator, via constant measurements acted on an ancillary discrete-variable system, e.g., a two-level system or qubit [34–37]. It was firstly theoretically proposed in Ref. [34] and experimentally realized in Ref. [38]. Various strategies, such as qubit-assisted ground-state cooling of the linear [35] and non-linear mechanical resonators [36] and one-shot measurement cooling [20], are proposed afterwards to achieve nice outputs. Under certain situations, however, measurement-based cooling might become inefficient when the initial temperature becomes sufficiently high. The occupation over high Fock-states might not be reduced or even the system will instead be heated up.

In this work, we present a protocol allowing the ground-state cooling of a harmonic resonator coupled to the transition of two levels in a three-level system. Cooling is performed via strong driving the excited state of the preceding transition and an outside level, that is decoupled from the target resonator. The continuous driving is effectively a measurement that projects the resonator-qubit system onto the ground state as the conventional protocol. And our protocol has a considerable advantage over the previous one in regard to reducing the populations over much higher Fock-states. We practice our cooling protocol in the magnet system as quantized to be bosonic magnons. The magnon system is a significant interface that can be coupled with microwaves [39–43], electric currents [42, 44, 45], mechanical motion [43, 46–48], and light [49–51]. The varying magnetization induced by the magnon excitons inside the magnet, e.g., a yttrium iron garnet (YIG) sphere, leads to the defor-

* Email address: jingjun@zju.edu.cn
mation of its geometry structure, which forms the vibrational modes (phonons) of the sphere [46, 52]. High temperature gives rise to (1) a large number of excitons and consequently a strong magnon-phonon interaction making the mechanical degree of freedom non-negligible; (2) a large linewidth [41] reducing the coherent operation time. At the temperature in the order of one hundred Kelvin, the average exciton number of the magnon system could reach hundreds. We find that after a series of fixed-time unitary evolutions periodically interrupted by projective measurements on the ground state of the ancillary three-level-system, the magnon mode could be cooled near to its ground state.

The rest of this work is arranged as following. In Sec. II, we introduce the model for a resonator coupled with a three-level system in the presence of a laser field resonantly driving the excited and the outside states. In contrast to the conventional qubit-assisted protocol [35], the cooling protocol realized in our model is established through the driving-induced projection on the ground-state of the ancillary system, which generalizes a much wider cooling range with respect to the populated Fock-states. The detailed derivation of the cooling coefficient is provided in appendix A. In Sec. III, we apply our cooling protocol to the magnon system. Cooling performances in the low-temperature and the high-temperature scenarios are evaluated and compared with each other. The distinction of the conventional and the current protocols also exhibits in the population histogram of the Fock-states after a fixed number of measurements. In Sec. IV, we propose a hybrid cooling protocol combining the conversional method and the acting-outside one. It could considerably promote the cooling performance in both speed and fidelity. The acting-outside cooling protocol is further analysed in the aspect of quantum Zeno effect on the measurement subspace under various strengths. We summarize the whole work in Sec. V.

II. COOLING MODEL AND COEFFICIENT

Our cooling protocol [see Figs. 1(b) and 1(c)] is an alternative realization of cooling a target resonator through the effective projection on the ground state of the ancillary system, which is assisted by the resonant driving the transition between the excited state of the conventional qubit-system and the outside state. In particular, we consider a model consisted of a resonator [e.g., the magnon mode in Fig. 1(a)] and an effective three-level system (a solid defect or emitter):

\[ H = H_0 + H_I \]
\[ = \omega_m b^\dagger b + \omega_e |e\rangle \langle e| + \omega_f |f\rangle \langle f| + g_m (b + b^\dagger) (\sigma_{eg}^+ + \sigma_{eg}^-) + 2g_f \cos vt (\sigma_{fe}^+ + \sigma_{fe}^-), \]

(1)

where \( b \) (\( b^\dagger \)) is the annihilation (creation) operator of the resonator with frequency \( \omega_m \), \( |e\rangle \) and \( |f\rangle \) are the excited and the outside levels in the three-level system with frequency \( \omega_e \) and \( \omega_f \), respectively. The energy of the ground state \( |g\rangle \) is assumed \( \omega_g = 0 \). To perform our cooling protocol, the resonator is supposed to be coupled to the transition of \( |e\rangle \leftrightarrow |g\rangle \) with a coupling strength \( g_m \) and far off-resonant from the transition of \( |e\rangle \leftrightarrow |f\rangle \). Note the outside level \( |f\rangle \) is essentially decoupled from the resonator and both \( |g\rangle \) and \( |e\rangle \), which is not necessarily the highest level in the three-level system. An external driving field is resonantly coupled to the transition between the excited state and the outside level with strength \( g_f \), i.e., \( v = \omega_f - \omega_e \). By notation, the atomic transition operators indicate \( \sigma_{ij}^+ = |i\rangle \langle j| \) and \( \sigma_{ij}^- = \langle j| \langle i| \).

When \( g_f = 0 \), the total Hamiltonian in Eq. (1) is reduced to the well-known Jaynes-Cummings (JC) model \( H = \omega_e |e\rangle \langle e| + \omega_m b^\dagger b + g_m (\sigma_{eg}^+ b + \sigma_{eg}^- b^\dagger) \), that is used in the conventional measurement-induced cooling scheme. It is worth noting that in our context, \( |g\rangle \) and \( |e\rangle \) constitute an “inner” subspace mimicking the qubit system used in the conventional protocol, and then any operation involving \( |f\rangle \) could be called as acting “outside”.

In the rotating frame with respect to \( H_0 = \omega_m b^\dagger b + \omega_e |e\rangle \langle e| + \omega_f |f\rangle \langle f| \) and under the rotating wave approximation (RWA), the overall Hamiltonian reads,

\[ H_I' = e^{-iH_0 t} H e^{iH_0 t} - H_0 \]
\[ \approx g_m (\sigma_{eg}^+ b + \sigma_{eg}^- b^\dagger) + g_f (\sigma_{fe}^+ + \sigma_{fe}^-), \]

(2)
where we have applied the resonant condition \( \omega_m = \omega_r \).

Regarding the effective Hamiltonian \( H'_f \) in Eq. (2) connecting the target system and the ancillary system as a black-box, our protocol still follows the general circuit model of the measurement-based cooling. As shown in Fig. 1(c), it is a concatenation of the free unitary evolutions under the effective Hamiltonian \( H'_f \) and the repetition of the projective measurements on the ground-state of the ancillary system \( M_g \equiv |g\rangle\langle g| \). Initially, the resonator [represented by the upper line in Fig. 1(c)] is prepared at the thermal-equilibrium state and the three-level system is at the ground state, then the overall density matrix reads,

\[
\rho(0) = |g\rangle\langle g| \otimes \rho_m^{\text{th}},
\]

After the whole system evolves for a desired period \( \tau \), the projective measurement \( M_g \) is performed on the discrete system to check whether it is still in the ground state. If so, the state takes the form

\[
\rho(\tau) = \frac{M_g U(\tau) \rho(0) U(\tau)^\dagger M_g}{\text{Tr}[M_g U(\tau) \rho(0) U(\tau)^\dagger M_g]},
\]

where \( U(\tau) = \exp(-i H'_f \tau) \) and the denominator is the probability of the three-level system being its ground state by a single measurement. The ground-state cooling demands constant repetition of the preceding procedure. The whole process is in essence stochastic and probabilistic due to the uncertainty of measurement results. After \( N \) measurements, the total time taken by the cooling protocol is \( t = N \tau \) under the assumption that the detections/measurements are instantaneously accomplished. The success probability of detecting the three-level system at its ground-state \( |g\rangle \) at time \( t \) reads,

\[
P_\text{s}(N) = \text{Tr} \left[ V_g(\tau) N \rho_m^{\text{th}} V_g(\tau)^N \right],
\]

where the nonunitary evolution operator \( V_g(\tau) \equiv \text{Tr}[M_g U(\tau)] \) acts merely in the resonator space. For the resonator prepared at a thermal-equilibrium state \( \rho_m^{\text{th}} = \sum_{n} p_n |n\rangle\langle n| \) with \( p_n = \frac{n^n}{(1 + n)_{n+1}} \) and \( n_{th} = \text{Tr}[b^\dagger b \rho_m^{\text{th}}] \), the probability to find the resonator in its ground state is upper-bounded by \( p_0 = 1/(1 + n_{th}) \).

The evolution operator \( V_g(\tau) \) is diagonal in the Fock-state basis \( \{|n\rangle\} \):

\[
V_g(\tau) = \sum_{n \geq 0} \alpha_n(\tau) |n\rangle\langle n|,
\]

where \( \alpha_n(\tau) \) can be defined as the cooling coefficients (see more details in appendix A)

\[
\alpha_n(\tau) = \frac{\Omega_n^2 + n g_m^2 (\cos \Omega_n \tau - 1)}{\Omega_n^2}, \quad \Omega_n \equiv \sqrt{g_f^2 + n g_m^2}.
\]

In the absence of the driving field, i.e., \( g_f = 0 \), the cooling coefficient will reduce to that for the conventional cooling protocol \([35]\)

\[
\beta_n(\tau) = \cos \left( g_m \sqrt{n} \tau \right)
\]

under \( \omega_m = \omega_r \). Note \( \alpha_0(\tau) = \beta_0(\tau) = 1 \) and \( |\alpha_n(\tau)|, \quad |\beta_n(\tau)| \leq 1 \). Either \( |\alpha_n(\tau)| \) or \( |\beta_n(\tau)| \) serve as a factor multiplied with the populations over Fock states, which are independent on the initial temperature or the initial population distribution. For the current protocol, \( |\alpha_n(\tau)|^2 = 1 \) occurs with special \( n \)'s satisfying \( \Omega_n \tau = 2k \pi \), where \( k \) is an arbitrary integer. While for the conventional protocol, the coefficient \( |\beta_n(\tau)|^2 \) becomes unit in magnitude when \( g_m \sqrt{n} \tau = k \pi \). It is therefore important to understand that both protocols have an applicable range with a finite width, that could be roughly regarded as the (quasi)-period of those special \( n \)'s.

**FIG. 2.** (Color online) Cooling coefficients as functions of the Fock-state index \( n \) after a single measurement and ten measurements on the ground state of the ancillary systems. The blue-solid line and the black-solid line with circle markers indicate \( |\alpha_n(\tau)|^2 \) in our protocol using an ancillary three-level system. The red-solid line and the yellow-dashed line indicate \( |\beta_n(\tau)|^2 \) in the conventional protocol using an ancillary two-level system. The coupling between the resonator and the ancillary system is \( g_m/\omega_m = 0.0004 \). The driving strength is much stronger than the coupling \( g_f/g_m = 50 \). The measurement period is \( \omega_m \tau = 700 \).

The range is independent on the number of measurements \( N \), since it boundary is determined by the cooling coefficient with a unit magnitude, besides that for the ground state \( |n = 0 \rangle \). According to Eq. (7) and \( \Omega_n = 2j \pi/\tau \), \( j \in \mathbb{N} \), the states \( |n_j\rangle \) satisfying \( n_j = [(2j \pi/\tau)^2 - g_f^2]/g_m^2 \) will survive under the measurement-induced cooling. These \( j \)'s for \( n_j > 0 \) constitute a set \( A = \{j \mid j \in \mathbb{N}, \tau \geq g_f/2n\pi \} \). The rest Fock-states will be depopulated by measurements. In parallel, under the conventional cooling protocol, the protected Fock-states \( |n_k = k^2 \pi^2/(2g_m^2 \tau^2)\rangle \) constitute another set \( B = \{k \mid k \in \mathbb{N} \} \). The quasi-periods for both protocols are then

\[
\Delta_\alpha = \frac{4(2j + 1)\pi^2}{g_m^2 \tau^2}, \quad \Delta_\beta = \frac{(2k + 1)\pi^2}{g_m^2 \tau^2},
\]

respectively. Comparing \( \Delta_\alpha \) and \( \Delta_\beta \) and taking account of the initial values \( j \geq g_f/2n\pi \) and \( k \geq 1 \), the acting outside with a strong coupling \( g_f \) yields a much larger
cooling range with respect to the non-vanishing occupied Fock-states of the resonator.

In Fig. 2, we plot $|\alpha_n|^2$ and $|\beta_n|^2$ for each Fock-state after a single measurement $N = 1$ and ten measurements $N = 10$. For the ground state $|n = 0\rangle$, both coefficients are unit in magnitude, that is the foundation for all protocols of measurement-induced cooling. We focus on the first quasi-period, i.e., the first interval bounded by the ground state and the second $n$ at which $|\alpha_n|^2 = 1$ or $|\beta_n|^2 = 1$. With the parameters from the magnon-mode system [53], the second Fock-state that is unavailable to be cooled under the conventional protocol is about $n \approx 125$ implied by $|\beta_n|^2 = 1$. It is greatly widened to $n \approx 2000$ implied by $|\alpha_n|^2 = 1$. In addition, $|\alpha_n|^2 < 10^{-3}$ applies to $500 < n < 1350$ when $N = 10$, which means that the population in this range has been significantly cancelled by merely 10 measurements. So that the acting-outside protocol could be used to cool down the resonator with a much higher temperature.

General expressions for the resonator initialled as a thermal-equilibrium state after $N$ periods of equal-time evolution spaced by $N$ measurements could be written as $p_m(N\tau) = |V_g(\tau)|^2 p_m N \alpha |V_g(\tau)|^2 / P_g(N)$, where the normalization coefficient $P_g(N)$ is given by Eq. (5). Under the large-$N$ limit, the cooling operator becomes more and more sparse

$$V_g(\tau)^N = \sum_{n \geq 0} \alpha_n \langle n | \sum_{j \in A} \langle j | \langle 0 | 0 \rangle | 0 \rangle + \sum_{j \in A} | j \rangle | j \rangle .$$

Then after $N$ measurements, the density matrix of the resonator initialized as the thermal-equilibrium state becomes

$$\rho_m(N\tau) = \sum_{n \geq 0} |\alpha_n|^2 p_n |n\rangle \langle n| \rightarrow_{N \rightarrow \infty} (\sum_{j \in A} | j \rangle | j \rangle / P_L),$$

where the populations $p_{n \geq 0}$ describe the initial distribution of the resonator in Fock-states and the success probability $P_g(N)$ is

$$P_g(N) = \sum_{n \geq 0} |\alpha_n|^2 N \rightarrow_{N \rightarrow \infty} p_0 + \sum_{j \in A} p_{nj} \equiv P_L.$$

Under measurements, the average exciton number of the resonator becomes

$$\bar{n}(N) \equiv \text{Tr} \left[ b^\dagger b p_m(N\tau) \right] = \sum_{n \geq 0} \bar{n} |\alpha_n|^2 p_n / \sum_{n \geq 0} |\alpha_n|^2 p_n = \sum_{j \in A} \bar{n}_j p_{nj} / p_0 + \sum_{j \in A} p_{nj}.$$  

It indicates that the final $\bar{n}(N)$ is directly determined by the non-vanishing population of the resonator system in the set of the cooling-free Fock-states. For the conventional cooling protocol, $j \in A$ in Eq. (13) should be replaced by $j \in B$. Therefore, $\bar{n}(N \rightarrow \infty) \approx 0$ can be achieved by both cooling protocols for a sufficiently low temperature. Consider Eq. (9) and Fig. 2, however, the average exciton number of the resonator cannot approach zero no matter how many measurements are performed in the presence of non-negligible populations $p_{nj}$ over special Fock-states. In the next section, it is shown that our acting-outside protocol can realize the ground-state cooling in the high-temperature regime, by significantly enlarging the cooling range covering more higher Fock-states. The resonator system is chosen as a magnon mode.

### III. MEASUREMENT COOLING OF MAGNONs

The general protocol indicated by the cooling operator $V_g$ in Eq. (6) and its coefficient $\alpha_n$ in Eq. (7) is now applied to the magnon system. Normally, it is set up by a sphere made of a ferrimagnetic insulator yttrium iron garnet (YIG), which has a giant magnetic quality factor ($\sim 10^5$) and supports the ferromagnetic magnons with a long coherence time ($\sim \mu$s) [54–56]. The paradigmatic model described by Eq. (1) is then physically relevant to a magnetic emitter (the three-level system) coupled to the Kittel mode (the resonator system) via the induced magnetic fields by putting a diamond nitrogen-vacancy center nearby a YIG sphere [53]. The Kittel mode, in which all the spins precess in phase and with the same amplitude, could be efficiently excited by an external magnetic field and becomes separable from the other modes in spectrum due to its dipolar character, as shown in Fig. 1(a). If the excited state of the three-level system is resonant with the Kittel mode ($\sim 10$ GHz), then the coupling strength could get into a strong-coupling regime ($g_m \approx 10$ MHz, much larger than the decay rate $\Gamma \approx 0.2$ MHz) [53]. A laser field, of which the Rabi frequency is much stronger than the coupling strength between the magnetic resonator and the three-level system, is assumed to be resonant with the transition $|e\rangle \leftrightarrow |f\rangle$ and far off-resonant from that of $|g\rangle \rightarrow |e\rangle$, as shown in Fig. 1(b). Note again that in Fig. 1(b), the ancillary state $|f\rangle$ is required to be far off-resonant from the resonator and the transition $|e\rangle \leftrightarrow |g\rangle$.

The average exciton numbers $\bar{n}(N)$ of the magnon resonator started from a thermal-equilibrium state under the conventional and the acting-outside protocols are shown in Fig. 3 with various temperatures. When $T = 0.1$ K, the conventional protocol based on the ancillary two-level system demonstrates a significant advantage over our protocol based on the ancillary three-level system. That could be expected from the cooling-coefficient distribution in Fig. 2, where the conventional cooling protocol is featured with a much sharper slope in a limited interval of Fock-states, indicating a much larger cooling rate in the lower excited subspace. And there is few populations over the higher Fock-states with such a low temperature. Then the two-level system method fa-
FIG. 3. (Color online) The average magnon number as a function of measurement numbers. The black solid lines marked with triangles and the red solid line marked with circles indicate the results of the conventional and the acting-outside cooling protocols, respectively. (a) \( T = 0.1 \text{ K} \), (b) \( T = 1.0 \text{ K} \), (c) \( T = 2.2 \text{ K} \). The frequency of the Kittel mode is set as \( \omega_m = 15.6 \text{ GHz} \), which is resonant with the level \( |e\rangle \). The coupling strength between the resonator and the three-level system is \( g_m = 2\pi \times 1 \text{ MHz} \). The measurement interval is \( \omega_m \tau = 700 \).

To show the merits of our acting-outside protocol over the conventional cooling protocol at an even high temperature, their cooling performance can also be compared in terms of the fidelity for the ground state of the resonator.

The pattern shown in Fig. 3(a) is completely inverted in Fig. 4(a), where the to-be-cooled resonator is prepared at a higher temperature \( T = 10 \text{ K} \) while keeping the rest parameters invariant. Now the average population of the resonator starts from \( \bar{n} \approx 83 \). As indicated by the cooling range in Fig. 2, the three-level-system method overwhelms the two-level-system method in the presence of non-negligible populations over higher Fock-states. In Fig. 4(a), the conventional cooling strategy assisted by a two-level system is found to heat up rather than cool down the resonator, whose the average population is firstly enhanced to about 113 during the first 20 measurements and then gradually reduced to its initial value after 300 measurements. In sharp contrast, our cooling protocol assisted by a driven three-level system could reduce the average population of the resonator to \( \bar{n} \approx 4 \) after 60 measurements. Combining Fig. 4(a) and Fig. 4(b), the magnon resonator can be continuously cooled down by the acting-outside protocol to \( \bar{n} \approx 0.5 \) after 300 measurements with a fidelity over 0.6. Both protocols are source-exhaustive with respect to the success probability of measurements. In Fig. 4(c), both \( P_g(N) \) decrease to less than 0.1 after 40 measurements.

The remarkable distinction between the conventional
cooling method and the acting-outside method can also
exhibit in the population distribution in the Fock space.
As shown in Fig. 5(a), when a resonator with frequency
in the order of 10 GHz, such as our magnon system in
the Kittel mode, is prepared at $T = 10$ K, it has a con
siderable population even at $|n = 200\rangle$. After $N = 50$
measurements, one can see in Fig. 5(b) that nearly 47%
population aggregate at the ground state $|n = 0\rangle$ and
the residue are centered around a high Fock state $|n = 125\rangle$.
Apparently the conventional two-level-system cooling be
comes inefficient in the reduction of the population over
such high Fock-states due to its narrow cooling range (see
Fig. 2). In contrast, the three-level-system cooling al
ows a much wider population reduction over the excited
states. As shown in Fig. 5(c), nearly 53% population has
aggregated at the ground state by 50 measurements.
And the residue are populated at low Fock states near
the ground state, demonstrating a clear decreasing dis
tribution with increasing $n$. Over the state $|n = 20\rangle$, the
population becomes lower than 0.01. Regarding Figs. 3,
4, and 5, we claim with certainly that our acting-outside
protocol overwhelms the conventional protocol in a suffi
ciently high-temperature regime.

With respect to the measurement-induced cooling mecha
nism, the protocol based on the driven three-level
system is dramatically distinct from the conventional
protocol assisted by the two-level system in the JC model.
The strong interaction between the excited level $|e\rangle$ and
the outside level $|f\rangle$ extracts the residue population on $|e\rangle$
in a continuous way, which gradually forces the whole sys
tem into the zero-exciton subspace $|g\rangle|n = 0\rangle$. It is then
an indirect cooling strategy as for the thermal resonator,
whose manifest is in the higher-temperature regime than the conventional one. In Fig. 6 for the ini
tial temperatures varying from $T = 90$ K to $T = 120$
K, it is observed that our cooling method would have a
decent performance at a temperature in the order of
one hundred Kelvin. For example, it is found that for a
magnon mode prepared at $T = 100$ K, the average ex
citon number for such a resonator with a frequency in
the order of 10 GHz could be reduced from $\bar{n} \approx 500$
to $\bar{n} \approx 50$ by 50 measurements and subsequently down to
$\bar{n} \approx 10$ by 300 measurements. Applying the effective
temperature defined by $T = \hbar \omega_m/\left( k_B \ln(1 + 1/\bar{n}) \right)$, they
are found to be $T = 6.02$ K and $T = 1.25$ K, respectively.
So for a resonator prepared at even higher temperatures,
our strategy by acting-outside is a promising choice to
the ground-state cooling, though at a cost of continuous
measurements.

IV. HYBRID COOLING PROTOCOL AND
MEASUREMENT SUBSPACE PROTECTION

In the previous sections, the cooling speed of the our
three-level-system protocol is found to be slower than the
conventional two-level-system protocol within the same
cooling range in Fig. 2, and decreases rapidly with the
increasing number of measurements $N$ in Fig. 4. In this
section, we propose a hybrid cooling scheme by interpo
lating the methods with and without acting on the out
side, which is capable to accelerate the cooling process
by reducing the desired numbers of measurements $N$ for
the ground-state cooling.

The acting-outside strategy becomes inefficient when
the target resonator enters an effective low-temperature
regime (Note it is not a thermal-equilibrium state, yet
one can always “define” a temperature of a harmonic os
cillator system with $\bar{n}$ and the eigen-frequency), e.g., see
Fig. 4. Thus to cool down a resonator initially prepared
with a comparatively higher temperature, one could first
employ the acting-outside strategy, taking advantage of
its less-than-unit cooling coefficients over a wider range
of Fock-states; and then turn off the driving laser after a
while, continue to cool the resonator by the conventional
protocol, that is efficient in an effective low-temperature
regime. In Fig. 6, the hybrid protocol starts under the

![FIG. 5. (Color online) Population histogram for the resonator states over the Fock space. (a) the initial thermal state at $T = 10$ K. (b) and (c) the states cooled by the conventional and the acting-outside protocols by $N = 50$ measurements, respectively. $\omega_m = 15.6$ GHz, $g_m = 2\pi \times 1$ MHz, $g_f = 50g_m$, and $\omega_m\tau = 700$.](image)

![FIG. 6. (Color online) Average magnon numbers after $N$ measurements under various initial temperatures. The parameters are set as $\omega_m = 15.6$ GHz, $g_m = 2\pi \times 1$ MHz, $g_f = 50g_m$, and $\omega_m\tau = 220$.](image)
same condition as Fig. 4, i.e., $T = 10$ K. After the average magnon number $\bar{n}$ declines about one order in its initial magnitude to $\bar{n} = 10$ by $N = 30$ measurements, the outside driving is turned off, i.e., $g_f = 0$. We then find that the average magnon number [see Fig. 7(a)] declines with a remarkably faster rate afterwards. Meanwhile, the fidelity of the resonator in its ground state |0⟩ [see Fig. 7(b)] approaches unit in a sharper way than before. Although the success probability becomes worse [see Fig. 7(c)], the hybrid method exhibits a better cooling performance over both the conventional and the acting-outside methods. It is able to reduce the average magnon number from 83 to 0.09 by almost 4 orders in magnitude with a high fidelity $F \approx 0.92$ by only $N = 60$ measurements. Thus the acting-outside protocol can be used as a pre-cooling procedure for the conventional protocol.

We now consider the effect of the external acting or driving in terms of the driving strength more than cooling. In addition to enlarge the cooling range, the acting-outside protocol can also induce the quantum Zeno effect on the ground-state of the ancillary three-level system against the leakage of the atomic population [57]. The Zeno effect is then consistent with the success probability of detecting the ancillary system in its ground state.

![Figure 7](image_url)  
**FIG. 7.** (Color online) Cooling results under a higher temperature $T = 10$ K, including (a) the average magnon number (b) the ground-state fidelity, and (c) the success probability as functions of the number of measurements $N$, under various protocols. The black lines marked with triangles and the red lines marked with circles are the results borrowed from Fig. 4. The blue lines marked with squares denote the hybrid cooling protocol, where the threshold point for the conversion between the conventional and the acting-outside protocols is chosen as $\bar{n} = 10$.

When the acting-outside strength $g_f$ overwhelms the coupling strength $g_m$ between the qubit-subsystem and the resonator, the transition $|e⟩ ↔ |f⟩$ raised by the external resonant-driving generates a time scale much shorter than that of the population leakage out of the measurement subspace, i.e., the state $|g⟩$ of the three-level system. This fast energy-exchange between the inner state $|e⟩$ and the outside state $|f⟩$ acts as a series of rapid repetition of the projection measurements, which could inhibit the population dynamics of the ground-state $|g⟩$ [57]. One can find in Fig. 8(b) that the success probability $P_g$ of detecting $|g⟩$ is asymptotically enhanced by increasing $g_f/g_m$. For the resonator part, the average magnon number $\bar{n}$ in Fig. 8(a) follows roughly the same pattern as $P_g$. It is interesting to see (1) for $g_f/g_m < 20$, the cooling protocol might actually heat up the target resonator, meaning cooling demands a sufficient strong acting outside; (2) the cooling efficiency does not follow a monotonic relation with $g_f/g_m$ under a fixed $N$. More importantly, the acting outside with a strong strength $g_f$ might provide an accessible realization for the projective operation $M_g$, which is the key elements in all measurement-induced cooling protocols.

![Figure 8](image_url)  
**FIG. 8.** (Color online) (a) The average magnon number $\bar{n}$ and (b) the success probability $P_g$ as functions of the normalized driving strength $g_f/g_m$. In (a) the black dashed line denotes the initial average exciton number under $T = 10$ K and in (b) the red dashed line denotes the unit probability. The number of measurements is fixed as $N = 50$. The other parameters are set as $\omega_m = 15.6$ GHz, $g_m = 2\pi \times 1$ MHz, $g_f = 50g_m$, and $\omega_m \tau = 700$.

**V. CONCLUSION**

In this work, we provide a whole picture about the discrete-system-assisted cooling protocols through the general expressions in Eqs. (11) and (13) for the final state of the target system after $N$ measurements. These
two equations also provide the large-$N$ limit, corresponding to the continuous measurement. It is important to note some undesired high Fock-states of the resonator are protected as well as the ground state. That is the main motivation of our protocol to avoid the inefficiency of the conventional cooling in the presence of a high-temperature environment. Acting outside of the conventional model, however, could exhibit remarkable properties by significantly widening the cooling range that covers those unwanted Fock-states.

In summary, we present a protocol realizing the ground-state cooling of a resonator system coupled to the transition in a 2D subspace of an ancillary three-level system. Then the continuous driving on the outside transition could efficiently cool down the target resonator prepared at a high temperature. As an application, the magnon resonator in the YIG sphere that is in the Kittel mode can be effectively cooled down when $T$ is in the order of 10 K and even 100 K by our acting-outside protocol. The discrepancy between the conventional cooling protocol and our protocol is made clear in our analysis.

In addition, a hybrid scheme is found to demonstrate an even better quantum cooling performance in both average and high-temperature environments. Acting outside of the conventional model, however, could exhibit remarkable properties.

### Appendix A: Cooling coefficients

This appendix is contributed to the derivation about the cooling coefficients in our measurement-induced-cooling model consisted of a target resonator and an ancillary three-level system, as provided in Eq. (1). In a general situation, there exists a nonvanishing detuning $\Delta \equiv \omega_e - \omega_b \neq 0$ between the resonator and the transition $|e\rangle \leftrightarrow |g\rangle$ in the ancillary system. In the rotating frame with respect to $\omega_m(b^\dagger b + |e\rangle\langle e|) + \omega_f(f^\dagger f)$, the total Hamiltonian in Eq. (1) becomes

$$\tilde{H}_1 = \Delta_e |e\rangle\langle e| + g_m (b^\dagger \sigma_{eg} + b \sigma_{eg}^\dagger) + g_f (f^\dagger \sigma_{fe} + \sigma_{fe}^\dagger),$$

under RWA and the assumption that the laser frequency is resonant with the detuning between the outside level $|f\rangle$ and the resonator, i.e., $\nu = \omega_f - \omega_b$.

![Diagram](image_url)

**FIG. 9.** (Color online) Cooling coefficients of (a) the acting-outside protocol $|\alpha_n\rangle^2$ or $|\tilde{\alpha}_n\rangle^2$ and (b) the conventional protocol $|\beta_n\rangle^2$ or $|\tilde{\beta}_n\rangle^2$ as functions of the Fock-state index $n$ after a single measurement. $g_m/\omega_m = 0.0004$, $g_f/g_m = 50$, and $\omega_n \tau = 700$.

Similar to the JC Hamiltonian, $\tilde{H}_1'$ conserves the overall excitons of the whole system. Then $\tilde{H}_1'$ is block-diagonal in the Hilbert space. It can be written as

$$\tilde{H}_1^{(n)} = \begin{pmatrix} 0 & g_m \sqrt{n} & 0 \\ g_m \sqrt{n} & \Delta_e & g_f \\ 0 & g_f & 0 \end{pmatrix},$$

in the $n$-exciton subspace spanned by $\{|g, n\rangle, |e, n - 1\rangle, |f, n - 1\rangle\}$. The free evolution operator during the measurement interval $\tau$ is straightforwardly written as $U(\tau) = \exp(-i\tilde{H}_1' \tau)$. And the nonunitary evolution operator under a single measurement on the ground state [see the argument around Eqs. (5) and (6)] is obtained by $V_g(\tau) = \text{Tr}[M_g U(\tau)] = \langle g | U(\tau) | g \rangle$, yielding the cooling coefficient

$$\tilde{\alpha}_n(\tau) = \langle n | V_g(\tau) | n \rangle.$$

$$= 2 g_f^2 \tilde{\Omega}_n + e^{-i \Delta_e \tilde{\Omega}_n} g_m^2 \left( i \Delta_e \sin \tilde{\Omega}_n \tau + 2 \tilde{\Omega}_n \cos \tilde{\Omega}_n \tau \right).$$

$$= \frac{2 g_f^2 \tilde{\Omega}_n}{2 \tilde{\Omega}_n^3 \tilde{\Omega}_n}.$$
Note under the condition $g_f = 0$, the whole model becomes the JC model used in the conventional cooling protocol with a nonvanishing detuning $[35]$. Up to a non-relevant phase factor originated from different rotating frames, one can check that $\tilde{\alpha}_n(\tau)$ reduces exactly to

$$\tilde{\beta}_n = e^{-i\tau \Delta_e/2} (\cos \Omega_c \tau + i \sin \Omega_c \tau \cos 2\theta_n),$$

(A5)

where

$$\Omega_c \equiv \sqrt{g_m^2 n + \Delta_e^2/4} \equiv \Omega_n|_{g_f = 0}, \quad \tan 2\theta = \frac{2g_m \sqrt{n}}{\Delta_e}. \quad \text{(A6)}$$

In the resonant case, i.e., $\Delta_e = \omega_m - \omega_c = 0$, the rotated Hamiltonian in Eq. (A2) becomes

$$H_1^{(n)} = \begin{pmatrix} 0 & g_m \sqrt{n} & 0 \\ g_m \sqrt{n} & 0 & g_f \\ 0 & g_f & 0 \end{pmatrix}. \quad \text{ (A7)}$$

Consequently, the cooling coefficient of our acting-outside protocol is obtained as

$$\alpha_n(\tau) = \frac{\Omega_n^2 + n g_m^2 (\cos \Omega_n \tau - 1)}{\Omega_n^2}. \quad \text{ (A8)}$$

That is Eq. (7) in the main text. In the same condition, the cooling efficient for the conventional protocol is

$$\beta_n(\tau) = \cos(g_m \sqrt{n} \tau). \quad \text{ (A9)}$$

In Fig. 9, we plot the cooling coefficients for both protocols under various detuning situations. One can observe in Fig. 9(b) that the quasi-periodic behavior of the coefficients $|\tilde{\beta}_n|$ for the conventional protocol is not sensitive to the detuning between the resonator and the excited state $|\phi\rangle$ of the ancillary system. In contrast, one can see in Fig. 9(a) that $|\tilde{\alpha}_n|$ of our protocol no longer behaves in a quasi-periodic pattern with a nonvanishing $\Delta_e$. A larger $\Delta_e$ yields a wider cooling range, since $|\tilde{\alpha}_n|$ decays asymptotically with $n$. Thus the detuning would improve the capacity of our protocol, that is lower-bounded by the resonant case with respect to the cooling range. Then we just need to discuss the resonant case in the main text.
