Spatio-temporal Spread of Fermi-edge Singularity as Time Delayed Interaction and Impact on Time-dependent RKKY Type Coupling

(Dated: June 18, 2021)

Fermi-edge singularity and Anderson’s orthogonality catastrophe are paradigmatic examples of non-equilibrium many-body physics in conductors, appearing after a quench is created by the sudden change of a localised potential. We investigate if the signal carried by the quench can be used to transmit a long ranged interaction, reminiscent of the RKKY interaction, but with the inclusion of the full many-body propagation over space and time. We calculate the response of a conductor to two quenches induced by localised states at different times and locations. We show that building up and maintaining coherence between the localised states is possible only with finely tuned interaction between the localised states and the conductor. This puts bounds to the use of time controlled RKKY type interactions and may limit the speed at which some quantum gates could operate.

The Fermi-edge Singularity (FES) Problem [1–4] and Anderson’s Orthogonality Catastrophe (OC) [5] are the concepts behind one of the first and most important examples of how a quench can drive a strongly correlated quantum response of a fermionic conductor. For the OC the quench is caused by abruptly switching a localised scattering potential producing a proliferation of zero energy particle-hole excitations. For the FES this is accompanied by the injection of an extra fermion into the conduction band, or its extraction. In both cases a screening cloud builds up near the potential that in the long time limit settles to a new ground state that is, up to the extra fermion for the FES, orthogonal to the initial ground state. The relaxation of the initial and final ground state overlap follows a characteristic power-law in time that depends only on the potential’s scattering phase shift. Such a time dependence resembles the universal power-law responses of strongly correlated systems and makes FES/OC a model system for quantum critical behaviour in the time domain. The Kondo effect in particular can be viewed as a superposition of OC cascades triggered by the Kondo spin flips [6]. Its universal many-body behaviour has made FES an important testing ground for a multitude of many-body techniques over more than 50 years [1–19]. Experimental and theoretical evidence started with absorption and emission spectra in metals and semiconductors [20–28], and extended then to nanostructured systems [29–49] and atomic gases [50–55].

It is, however, notable that with few exceptions [56, 57] the focus has been on global response functions, and that there is a major lack of investigation of the spatial build-up and spread of the FES. In this paper we show that considering the spatio-temporal spread offers a new perspective on FES physics, and we provide a systematic access. The FES quench can indeed be viewed as a coherent signal propagating through a fermionic bath. Picking up the signal at some distance causes a coupling with the source of the quench. We formalise this aspect and formulate the FES signal as a time delayed, long ranged effective interaction with a strong memory effect due to the slow power-law decay of response functions. The memory effect invalidates the use of an effective Hamiltonian so that we provide two appropriate formulations. One is fundamental in the form of a time dependent action on the Keldysh contour that incorporates the concept of time delayed interaction. The other one is formulated in the language of open system dynamics and concretely focuses on the time evolution of the density matrix. We illustrate the approaches through the example sketched in Fig. 1 where we investigate FES in combination with a quantum gate operation between two localised qubit type states. To transmit the signal we choose to inject a fermion into the conductor and extract it at a different location as this represents the simplest case of such a transmission that captures the relevant physics. The time delay in the signal is due to the finite Fermi velocity $v_F$ and does not require the FES itself. The latter, however, causes a significant renormalisation of the transmission amplitude and, in particular, a decoherence even after extraction unless special fine tuned conditions are met. This is in contrast the usual modelling of effective interactions carried through a different medium such as the RKKY interaction. These are permanently present and thus time and FES are of no significance. But if they are intended to be switched on and off as required for a quantum gate operation [58] our work shows that time delay, entanglement with the conductor and the FES are essential processes to be taken into account.

![FIG. 1. Sketch illustrating the time non-local interaction mediated by a fermionic conductor, triggered by the tunnelling transitions $W_j(t_j)$ at positions $x_j$ and times $t_j$ for $j = 1, 2$. The same transitions switch on the FES scattering potentials $V_j$ renormalising the excitation peak travelling at velocity $v$.](image-url)
Time non-local interactions. – The minimal model shown in Fig. 1 consists of a Fermi gas with two localised states. For simplicity we consider spinless or spin polarised fermions, and we start with a noninteracting Hamiltonian $H_c = \sum_k c_k^a c_k$, where $c_k$ is the dispersion and $c_k$ are the fermion operators, but an extension to interactions will be considered later. The localised states are single orbitals located at positions $x_j$ with operators $d_j$, energies $E_j$, and Hamiltonians $H_j = E_j d_j^\dagger d_j$, for $j = 1, 2$. Transitions are induced by tunnelling terms $H_W = \sum_j W_j(t)d_j^\dagger \psi(x_j) + h.c.$, where $\psi(x)$ is the field operator corresponding to $c_k$, and $W_j(t)$ are time dependent amplitudes, applied over a range $\delta x_W \ll \pi/k_F$ (with $k_F$ the Fermi momentum) such that tunnelling can be expressed as point-like at $x_j$. The FES physics arises from the interaction $H_I = V_1 \psi^\dagger(x_1) \psi(x_1) d_1^\dagger d_1 + V_2 \psi^\dagger(x_2) \psi(x_2) d_2^\dagger d_2$. Here we assume that initially level $d_1$ is occupied and $d_2$ empty such that tunnelling out of $d_1$ and into $d_2$ switches on the scattering potentials $V_j$. Tunnelling events are induced by sharp pump peaks $W_j(t) = W_j(\delta(t-t_j) - \delta(t-t_{j+1})$ that trigger the FES and make the concept of a time delayed interaction between times $t_1$ and $t_2$ well defined. Such an operation comes also close to controlling an interaction between the $d_j$ levels as required for a quantum gate operation. We thus treat $H_W$ separately from the evolution under $H = H_c + H_I + H_0 + H_V$.

The role of the travelling excitation as an effective interaction between the $d_j$ levels is akin to the RKKY interaction. Yet the latter is modelled as a static interaction, whereas we keep the full time dynamics and the finite propagation velocity. Although such an interaction does not require FES, we will show that the additional scattering on $V_j$ leads to a substantially renormalised response.

To illustrate how FES appears in this interaction we consider the effective action between the $d_j$ levels obtained in the standard way [59] from integrating out the conductor’s degrees of freedom in a path integral formulation. For the presently considered noninteracting fermions the action is quadratic in the $\psi(x)$ fields and the path integral is readily evaluated. This leads, in addition to the bare propagation under the $H_j$, to the effective action $S_{eff} = S_L + S_C$ (with setting $\hbar = 1$ throughout)

$$S_L = \sum_{j,j'} \int_\mathcal{K} dt dt' W_j(t) d_j^\dagger(t) G(x_j, t; x_{j'}, t') W_j(t') d_j(t'),$$

and $S_C = -i \text{Tr} \ln(G_0 G^{-1})$. Here $G$ is the full fermion propagator in the presence of a path of the $d_j$ fields and $G_0$ the propagator for $d_j \equiv 0$. In the FES language of Ref. [4] $S_L$ is the analog to the open line propagators and $S_C$ is the closed loop sum expressing the OC, which both are here resolved further in space and include the two scattering centres $j = 1, 2$. Since the system is dynamic the full time dependence is retained, and the time integrations run over the Keldysh contour $\mathcal{K} : -\infty \rightarrow +\infty \rightarrow -\infty$. The trace in $S_C$ involves integration over contour time and space.

The $W_j(t)$ control the paths $d_j(t)$ in $S_{eff}$ and thus control the response to this interaction. Notably if the $d_j(t)$ are identical on the two Keldysh branches $\mathcal{K}_\pm : +\infty \rightarrow \pm \infty$, as is the case for classical realisations of $d_j(t)$, then $S_C = 0$ and the OC drops out. This is akin to the linked cluster theorem as the forward and backward time integrations are identical. Any quantum effect involves different $d_j(t)$ on $\mathcal{K}_\pm$ and maintains the OC. In this limit we recover too the cases of the overlap integrals of the FES spectra and of Loschmidt echos where $V_j$ are nonzero only on one Keldysh branch. The proper interaction is carried through the Green’s function $G(x_j, t; x_{j'}, t')$ and thus the time delayed interaction is carried only through the open line contribution. While more general interactions $W_j$ such as a density-density interaction instead of tunnelling would close these line contributions to loops too, they remain always decoupled from the OC. We can expect that $G$ exhibits a similar power-law renormalisation as the standard FES amplitudes but shifted in time by the finite propagation velocity. For instance, in a Lorentz invariant system with propagation velocity $v$ a behaviour $t^\gamma$ for some exponent $\gamma$ would be shifted to $(t - x/v)^\gamma$. Hence the time delayed interaction peaks at $t = x/v$ and its decay off-peak is accelerated by the FES.

Time evolution of density matrix. – To provide a concrete realisation of these observations we connect $S_{eff}$ with the example of computing the time dependence of the reduced density matrix $\rho_{d}$ of the two $d_j$ states. By focusing on $W_j(\delta(t-t_j))$ all times $t, t'$ in the path integral are pinned to $t_j$ on the Keldysh branches $\mathcal{K}_\pm$. The number of possible paths $d_j(t)$ is then small and the path integral is evaluated directly. It is advantageous to delay tracing out the $\psi(x)$ and write $\rho_{d}(t) = Tr_c \{ U(t) \rho(0) U^\dagger(t) \}$, where $\rho(0)$ is the full initial density matrix, $U(t)$ the evolution operator and $Tr_c$ the trace over the conductor’s degrees of freedom. The placement of $U$ and $U^\dagger$ corresponds to the evolution on the two Keldysh branches. For the pulsed transitions $U(t) = e^{-itH_0} e^{-iW_j} e^{-itW_1}$ at $t > t_2 > t_1$ [59–61], where $W_j = e^{-itH_1} [W_j d_j^\dagger \psi(x_j) + h.c.] e^{itH_1}$.

It is easy to show [59] that $e^{-iW_j} = 1 - i\alpha_j \hat{W}_j - \beta_j \hat{W}_j^2$, which is an exact result with amplitudes $\alpha_j = \sin(w_j)/w_j$, $\beta_j = [1 - \cos(w_j)]/w_j^2$ for $w_j \sim W_j/\sqrt{\delta x_W}$, and limits further the number of created paths.

The two short pulses are chosen by analogy with the switching on and off of an exchange interaction between two qubits as the basis of a quantum gate generating entanglement between two qubits [58]. For the transmitted signal we obtain a similar gate operation between the $d_j$ levels but also decoherence due to the continuum of the fermionic fluctuations, both being strongly affected by the FES. To illustrate we assume that initially $\rho_{d}(0) = |1, 0\rangle \langle 0, 1|$, where $|n_1, n_2\rangle$ is the occupation number basis for $n_1 = 0, 1$ the eigenvalues of $d_j^\dagger d_j$. Applying a pulse on $d_1$ at time $t_1$ followed by a pulse on $d_2$
at time \( t_2 \) the density matrix at \( t > t_2 > t_1 \) takes the form

\[
\rho_d(t) = \begin{pmatrix}
D_0 & 0 & 0 & 0 \\
0 & A & C^* & 0 \\
0 & C & B & 0 \\
0 & 0 & 0 & D_1
\end{pmatrix},
\]

(2)

spanned in the basis \{\( (0,0), (1,0), (0,1), (1,1) \)\}. The zeros arise from terms without particle conservation along the full Keldysh contour.

Initially \( A = 1 \) and all other amplitudes are zero. To put the result in context we compare it with the effect of a conventional exchange interaction \( H_J = J(d_1^d d_2 + d_2^d d_1) \). Since \( H_J^2 = J^2 H_J \) the evolution operator becomes \( U(t) = e^{-iH_J t} = 1 - i \sin(Jt)H_J - [1 - \cos(Jt)]H^2_J/J \), similarly to the form of \( U(t) \). The resulting density matrix takes the same form as Eq. (2) with \( A = \cos(Jt), B = \sin(Jt), C = i \sin(2Jt)/2 \), and \( D_0 = D_1 = 0 \). Since no further degrees of freedom exist the density matrix remains a pure state but entangles the qubits.

The present case for \( \rho_d \) has several crucial differences. The first is that the coupling to the fermionic continuum causes decoherence, which is the result of correlations within the trace of \( \rho_d(t) \) that connect operators in \( U(t) \) with operators in \( U^d(t) \). These correspond to contractions between the two Keldysh branches and make it impossible to write down a unitary evolution of the reduced density matrix in the form \( U_d(t) \rho_d(0) U^d_d(t) \). Hence entanglement with the continuum is generated that is lost for entangling the two qubits. This is the usual issue of a quantum system coupled to an environment (and not explicitly considered in the RKKY description), and overcoming the resulting decoherence is the key challenge for quantum control. It is, however, not our present focus.

Instead we highlight the additional features brought in by the time retardation of the interaction and the FES. These are illustrated through the coefficient \( C \), expressing the only route here to build up entanglement between the two \( d_j \) states. The other coefficients involve only classical paths \( d_j(t) \) and display only a weak FES dependence [59]. For \( C \) we have [59]

\[
C = -\alpha_1 \alpha_2 (1,0) \text{Tr}_c \{ e^{-iHt} (\mathbb{1} - \beta_2 \hat{W}_2^2) (\mathbb{1} - \beta_1 \hat{W}_1^2) \} \rho(t) \hat{W}_1 \hat{W}_2 e^{iHt} |0,1\rangle.
\]

(3)

This expression is exact but the contributions in terms of \( \beta_1,2 \) provide only qualitatively similar corrections to the leading term so that in the discussion we shall focus on the leading expression only, whereas in the figures we plot the full expression. Since \( C \) results from the coupling between the Keldysh branches it is created by the same effects causing the decoherence through the environment and has a comparable amplitude. This is, however, only a consequence of the chosen simple model and not a fundamental concern, so that we focus entirely on the qubit entangling capacity of \( C \) instead.

![FIG. 2. Plot of coefficient \( |C(t = t_2)| \) at \( K = 1 \) for the indicated phase shifts \( \delta_1 \) for repulsive \( V_j < 0 \) at \( \Delta x = x_2 - x_1 = 1000a \) (using \( a = v_F = 1 \) to set space and time units). The finite time-of-flight causes the sharp peak at \( t_2 - t_1 = \Delta x/v \), and the FES its substantial suppression. The insets show the further suppression of the peak amplitude with interactions \( K \) (right), and with \( \delta_1 \) for a selection of \( K \) (left). Used parameters are \( W_j = 0.8\sqrt{a}, n_p = 0.4/a, n_h = 0.6/a, \delta xW = a \).](image)
relevant in 1D it matters for weakly interacting systems mostly at time scales that can be tuned to be longer than the times considered here, and its inclusion would unnecessarily obscure the results.

To leading order in the power laws \( C \) is expressed as

\[
C \equiv -\alpha_1 \alpha_2 W_1 W_2 e^{-i\Delta E_1 (t_1 - t)} e^{-i\Delta E_2 (t_2 - t)} \times (e^{-ik_F(x_1 - x_2)} C_L + e^{+ik_F(x_1 - x_2)} C_R)/2\pi a,
\]

where the coefficients \( C_\nu \) with \( \nu = \pm \) arise from the injection of a right or left moving fermion with momenta near the Fermi momentum \( \nu k_F \). If we introduce \( g_{s,t} = (a - ix + ivt)/a \) as the power-law basis with short distance cutoff \( a \) we have

\[
C_\nu = g_{0,t_1-t} - g_{0,t_2-t} - g_{x_1-x_2,0} + g_{x_1-x_2,10} \times \left( \frac{(1+K_\nu)^2}{2\pi K_\nu} + \frac{(g_{s,1} - g_{s,2})(1+K_\nu)}{2\pi K_\nu} \right) g_{x_1-x_2,10} \times \frac{1}{\pi K_\nu} - \frac{1}{\pi K_\nu} \times \frac{1}{\pi K_\nu} - \frac{1}{\pi K_\nu} \times \frac{1}{\pi K_\nu} - \frac{1}{\pi K_\nu}.
\]

At \( t = t_2 \) all dependence on \( \delta_2 \) vanishes. For \( x_2 - x_1 = 0 \) this expression reduces further to the standard FES response whereas at nonzero \( x_2 - x_1 \), as seen in Fig. 2, the last two factors produce a pronounced peak at \( t_2 - t_1 = |x_2 - x_1|/v \) as consequence of the finite propagation velocity. Hence, in contrast to the instantaneous \( H_J \) a fine tuning must be made to maximise the correlation between the two levels. Note that since the Hamiltonian is nonrelativistic tails of the correlators build up immediately and \( C \) is nonzero already at all \( t_2 - t_1 < |x_2 - x_1|/v \). Figure 2 also shows the substantial impact of FES. Varying \( \delta_1 \) from 0 to \( \pm \pi/2 \) suppresses the peak amplitude by more than an order of magnitude, but in the tails we observe that the interference between the OC and the contribution from the added fermion can lead to both larger or smaller amplitudes. The figure shows as well that interactions have a similar reducing effect but display also a partial compensation of the FES effect by shifting the maximum of \( C \). Similar behaviour can be found in the dynamics of a Kondo spin coupled to interacting chains [65] and is thus not specific for the considered system.

Further distinction from a standard quantum gate arises entirely from the OC induced relaxation. This is the lasting effect of the correlation with the conductor and takes the role of an interaction that cannot just be switched off unless further fine tuning is achieved. Indeed \( C \sim -2(\delta_1 + \delta_2)^2/\pi^2 K \) at long times \( t \gg t_2 \), suppressing with \( C \to 0 \) thus the transfer of information between the \( d_j \) unless the \( V_j \) are such that \( \delta_1 = -\delta_2 \). The behaviour as function of \( t > t_2 \) is shown for a selection of phase shifts and \( K = 1 \) in Fig. 3 in which the condition \( \delta_1 = -\delta_2 = 0 \) leaves \( C \) unchanged from its magnitude at \( t = t_2 \), as is indeed expected for a RKKY type coupling in a noninteracting system. For \( \delta_1 = -\delta_2 \neq 0 \) the amplitude saturates as noted at a constant value at large \( t \). But the signal shows now a transient behaviour with a satellite peak at \( t - t_2 = |x_2 - x_1|/v \) caused by one of the last two factors in Eq. (5) and relies on \( \delta_1 \neq 0 \). This effect arises due to the many-body interference of the OC at \( x_1 \) with the excitations created by the fermion absorption at \( x_2,t_2 \), manifesting as another Fermi-edge-style singularity. For \( \delta_1 + \delta_2 \neq 0 \) we see a similar transient behaviour but then the further (albeit rather slow) decay with increasing \( t \). Interactions with \( K \neq 1 \) are shown in the inset of Fig. 3. Here interactions can reduce and even enhance the amplitudes but do not change the qualitative features.

**Conclusions.** We provided a new viewpoint on FES as a time delayed effective interaction propagating at finite velocity. To pick up the spatio-temporal spread we considered a characterisation through excitation and readout pulses at different locations. By associating the pulses with transitions of localised levels we illustrated the effect on the evolution of the reduced density matrix \( \rho_\delta \), with primary focus on the interaction’s capacity to induce quantum correlations or entanglement, quantified through the build up of off-diagonal matrix components. Although the FES enhances correlations in the conductor, it also suppresses the travelling pulse and reduces the transmitted signal. The OC is especially detrimental, persisting even after the readout and causing a power-law decay that unavoidably removes any correlations or entanglement built up through the effective interaction, unless the scattering potentials are fine tuned to \( \delta_1 = -\delta_2 \). Such physics thus requires careful evaluation if pieces of conductors are used for transmitting interactions between quantum gates [66], and any operation should avoid FES physics. Since the latter is triggered by sharp transitions, such gates should be operated with smoother excitations such as minimal excitation pulses [67, 68].

I. PATH INTEGRAL FOR INTERACTION

The derivation of the effective action for the time retarded interaction starts from the full action of the combined system of localised $d_j$ states and the continuum $\psi(x)$. If these $d_j$ and $\psi(x)$ represent now Grassmann fields the action reads $S = S_c + \sum_{j=1,2} S_j + S_V + S_W$, with

$$ S_c = \int_K dt \int dx \psi(x,t) (i\partial_t - H_c) \psi(x,t), \quad (S1) $$

$$ S_j = \int_K dt d_j(t)(i\partial_t - E_j)d_j(t), \quad (S2) $$

$$ S_V = -\int_K dt V_1 \psi(x_1,t)\psi(x_1,t)[1 - d_1(t)d_1(t)] $$

$$ -\int_K dt V_2 \psi(x_2,t)\psi(x_2,t)d_2(t)d_2(t), \quad (S3) $$

$$ S_W = \sum_{j=1,2} \int_K dt W_j(t)\psi(x_j,t)d_j(t) + c.c., \quad (S4) $$

in which the time integrals run over the Keldysh contour $K: -\infty \to +\infty \to -\infty$. We consider only noninteracting fermions here in which $H_c$ is local and thus $S_c$ requires only a single spatial integral.

To obtain an effective action for the $d_j$ levels we integrate out the $\psi(x)$ fields as

$$ e^{iS_{eff}[d_j,d_j']} \int D[\psi^\dagger,\psi] e^{i(S_c+S_V+S_W)}, \quad (S5) $$

such that the total effective action is $\sum_j S_j + S_{eff}$. In the absence of interactions, as considered for the evaluation of the path integral, the $\psi(x)$ integrals are Gaussians and the $\psi$ integration is straightforward,

$$ \int D[\psi^\dagger,\psi] e^{i\langle \psi|G^{-1}\psi \rangle + \langle b|\psi \rangle + \langle \psi|b \rangle} = \det(iG^{-1}) e^{i\langle b|Gb \rangle}, \quad (S6) $$

where the inner product $(\cdot | \cdot)$ consists of the $x$ and $t$ integrations. We write the Green’s function in the kernel as $G^{-1} = G_{t1}^{-1} - V$, with $G_{t1}^{-1}(x,t;x',t') = \delta(t-t')\delta(x-x')[i\partial_t - H_c]$ and $V(x,t;x',t') = \delta(t-t')\{V_1\delta(x-x_1)\delta(x'-x_1)[1-d_1(t)d_1(t)] + V_2\delta(x-x_2)\delta(x'-x_2)d_1(t)d_2(t)\}$, and the inhomogeneous terms as $b(x,t) = \sum_j W_j(t)\delta(x-x_j)d_j(t)$.

The determinant factor can be written in the form

$$ \det(iG^{-1}) = \det(iG_{t1}^{-1}) \exp(Tr \ln(G_{t1}G^{-1})) \quad (S7) $$

Here $\det(iG_{t1}^{-1})$ is an unimportant constant that can be dropped. On the other hand $e^{iSC} = \exp(Tr \ln(G_cG^{-1}))$ is important. If we write it as $S_C = -iTr \ln(1+iG_cV)$ we see from expanding the logarithm that it describes the full set of simple closed loop diagrams connecting vertices $V$. This term therefore incorporates the closed loop contribution responsible for the OC [S1]. The full effective action then becomes $S_{eff} = S_L + S_C$ with

$$ S_L = \sum_{j,j'} \int dt dt' W_j(t)d_j(t)G(x_j,t;x_{j'},t')W_j(t')d_{j'}(t'), \quad (S8) $$

in which $G$ is the full Green’s function on the Keldysh contour including the scattering on the time dependent potential $V$ created by the realisations of the $d_j(t)$ fields. In contrast to the closed loops in $S_C$ the propagator is pinned to the times $t, t'$ at which the pulses $W_j$ are active and thus $S_L$ generalises the open line diagrams of the FES [S1].

II. EVOLUTION OPERATOR FOR DELTA FUNCTION PULSES

We consider a time dependent Hamiltonian of the form

$$ H_{full}(t) = H + W\delta(t-t_1), \quad (S9) $$

with $H = H_c + \sum_j H_j + H_V$ time independent and $W$ applied only through a pulse at time $t_1$ that is sharp enough
to be treated as a delta function pulse. Such a time dependence allows for a simple solution for the evolution operator \( U(t) \) which, however, requires some care. Indeed integrating the equation of motion \( i \hbar \partial_t U(t) = H_{\text{full}}(t) U(t) \) over times \( t_1 - \delta t < t < t_1 + \delta t \) for some \( \delta t > 0 \) produces \( U(t_1 + \delta t) - U(t_1 - \delta t) = -i \hbar W U(t) \). The fact that the right hand side is nonzero shows on the left hand side that \( U(t) \) is discontinuous at \( t_1 \). This in turn makes the right hand side ambiguous. The correct treatment of this situation is an old problem and, for instance, in Refs. [S2, S3] a thorough discussion is provided.

It turns out that the naive solution produces the correct answer. If we solve the equation of motion in the usual way by going to the interaction picture with \( H \) perturbation and perform a formal integration we obtain the standard form of the time ordered exponential

\[
U(t) = e^{-i \hbar H t} \exp \left( -i \int_0^t dt' W(t') \delta(t' - t_1) \right),
\]  

(S10)

where \( T \) is the time ordering operator and \( \tilde{W}(t) = e^{-i \hbar W} e^{i \hbar H t} \). The implicit but far from obvious assumption in Eq. (S10) is that \( T \) commutes with the integration. Accepting it though allows us immediately evaluate the integral in the exponential. Noting then that \( T \) has no effect for equal time expressions we obtain

\[
U(t) = e^{-i \hbar H t} e^{-i \tilde{W}(t)} = e^{-i \hbar H (t-t_1)} e^{-i W} e^{-i \hbar H t_1},
\]

(S11)

for \( t > t_1 \) and \( U(t) = e^{-i \hbar H t} \) for \( t < t_1 \). Although a rigorous treatment requires a more refined approach [S2, S3], Eq. (S11) is indeed the correct result. The last part of the equation provides the appropriate physical picture: the system evolves under \( H \) before and after \( t_1 \), and the effect of the pulse is entirely contained in the unitary and nonperturbative operator \( e^{-i \hbar W} \).

From the latter expression it is straightforward to obtain the evolution operator for sequences of pulses. Considering two pulses, \( H_{\text{full}} = H + W_1 \delta(t-t_1) + W_2 \delta(t-t_2) \), we have

\[
U(t) = e^{-i \hbar H (t-t_2)} e^{-i W_2} e^{-i \hbar H (t_2-t_1)} e^{-i W_1} e^{-i \hbar H t_1}
= e^{-i \hbar H t} e^{-i W_2(t_2)} e^{-i W_1(t_1)},
\]

(S12)

where we have assumed \( t > t_2 > t_1 \). Further pulses chain up in the same way.

III. EVALUATION OF THE PULSE OPERATORS

The operators \( e^{-i \tilde{W}_j} \) in the evolution operator resulting from pulses at times \( t_j \) can be given a closed form in which we only need to be careful with infinities. The point-tunnelling expressions

\[
\tilde{W}_j = e^{i \hbar H t_j} (W_j d_j \psi(x_j) + \text{h.c.}) e^{-i \hbar H t_j},
\]

(S13)

cause at higher powers in the expansion of \( e^{-i \tilde{W}_j} \) products of \( \psi(x_j) \) and \( \psi^\dagger(x_j) \) that through the anticommutation rule \( \{ \psi(x), \psi^\dagger(x') \} = \delta(x-x') \) cause divergences. It thus must be noted that Eq. (S13) itself is a convenient limit of the more general interaction

\[
\tilde{W}_j = e^{i \hbar H t_j} \int dx (W_j d_j \psi(x) + \text{h.c.}) e^{-i \hbar H t_j},
\]

(S14)

where \( W_j(x) \) is a spatially dependent potential that is sharply peaked at \( x = x_j \) and integrates to the amplitude \( W_j \) in Eq. (S13). The order \( W_j^2 \) itself would be unproblematic even with Eq. (S13). Using Eq. (S14) we find that

\[
\tilde{W}_j^2 = e^{i \hbar H t_j} \int dx dx' W_j(x) W_j(x')
\]

\[
\times \left( d_j^\dagger d_j \psi(x) \psi^\dagger(x') + d_j d_j^\dagger \psi(x') \psi(x) \right) e^{-i \hbar H t_j}
\]

\[
\approx W_j^2 e^{i \hbar H t_j} \left( d_j^\dagger d_j \psi(x_j) \psi^\dagger(x_j) + d_j d_j^\dagger \psi(x_j) \psi(x_j) \right)
\times e^{-i \hbar H t_j},
\]

(S15)

where the second line would also follow from Eq. (S13) and can be used for the practical evaluation of \( \tilde{W}_j^2 \). For \( \tilde{W}_j^3 \), however, we obtain

\[
\tilde{W}_j^3 = e^{i \hbar H t_j} \int dx dx' dx'' W_j(x) W_j(x') W_j(x'')
\]

\[
\times \left( d_j^\dagger d_j d_j^\dagger \psi(x) \psi^\dagger(x') \psi(x'') + d_j d_j^\dagger d_j \psi(x') \psi(x) \psi^\dagger(x'') \right)
\]

\times e^{-i \hbar H t_j}.
\]

(S16)

Through the anticommutation relations for the \( \psi(x) \) and \( d_j \) this expression can then be reduced to

\[
\tilde{W}_j^3 = e^{i \hbar H t_j} \int dx dx' W_j(x) W_j^2(x')
\times \left( d_j^\dagger \psi(x) + d_j \psi^\dagger(x) \right) e^{-i \hbar H t_j} = w_j^2 \tilde{W}_j,
\]

(S17)

with

\[
w_j^2 = \int dx W_j^2(x).
\]

(S18)

Without the \( x \) integrations this expression would have been left with the complication of diverging anticommutators that would have required an unnecessary cure, for instance, through point splitting. From the two results above it follows immediately that \( \tilde{W}_j^{2n+1} = w_j^2 \tilde{W}_j \) and \( \tilde{W}_j^{2n} = w_j^{2n-2} \tilde{W}_j^2 \) for integer \( n \). Consequently we have

\[
e^{-i W_j} = 1 - i \alpha_j \tilde{W}_j - \beta_j \tilde{W}_j^2,
\]

(S19)

with

\[
\alpha_j = \sin(w_j)/w_j,
\]

(S20)

\[
\beta_j = [1 - \cos(w_j)]/w_j^2.
\]

(S21)
This means that the exact form of $e^{-iW_j}$ looks like its second order expansion with renormalised amplitudes. Notably, if we let $w_j \to 0$ then $\alpha_j \to 1$ and $\beta_j \to 1/2$, matching the second order amplitudes. Unitarity of Eq. (S19) imposes furthermore that

$$\alpha_j^2 \hat{W}_j^2 = 2\beta_j \hat{W}_j^2 - \beta_j^2 \hat{W}_j^4.$$  \hfill (S22)

By the same methods that brought Eq. (S16) to Eq. (S17) we verify that indeed $\hat{W}_j^2 = w_j^2 \hat{W}_j^2$, and unitary follows from the trigonometric identity $2\beta_j - w_j^2 \beta_j^2 = \alpha_j^2$.

IV. STRUCTURE OF DENSITY MATRIX AND CORRELATORS

Let $|n_1, n_2\rangle$ denote the occupation state of the $d_1$ and $d_2$ levels. We assume that at time $t = 0$ the localised states are in the $|1, 0\rangle$ configuration and the fermionic conductor is in equilibrium. The initial density matrix is thus $\rho(0) = |1, 0\rangle \langle 1, 0| \otimes \rho_{\text{c}}$, with $\rho_{\text{c}}$ the conductor’s equilibrium density matrix. We apply the first $W_1$ pulse at time $t_1 > 0$ and the second $W_2$ pulse at time $t_2 > t_1$. At any time $t > t_2$ the reduced density matrix takes the form

$$\rho_d(t) = \begin{pmatrix} D_0 & 0 & 0 & 0 \\ 0 & A & C^* & 0 \\ 0 & C & B & 0 \\ 0 & 0 & 0 & D_1 \end{pmatrix},$$ \hfill (S23)

spanned in the basis $\{|0, 0\rangle, |1, 0\rangle, |0, 1\rangle, |1, 1\rangle\}$. The zeros arise from amplitudes that do not preserve the particle number in the fermionic conductor. (Note that here particle conservation must be considered along the full Keldysh contour; in real time the number of particles in the conductor is allowed to vary.) The nonzero amplitudes at times $t > t_2 > t_1$ are given by

$$A = \langle 1, 0 | \text{Tr}_c \{e^{-iHt} (\mathbb{1} - 2\hat{W}_2^2) (\mathbb{1} - 2\hat{W}_1^2) \} \rho(0) \times (\mathbb{1} - \beta_1 \hat{W}_1^2) (\mathbb{1} - \beta_2 \hat{W}_2^2) e^{iHt} \rangle |1, 0\rangle,$$ \hfill (S24)

$$B = \alpha_1^2 \alpha_2^2 \langle 0, 1 | \text{Tr}_c \{e^{-iHt} \hat{W}_1 \rho(0) \hat{W}_1 e^{iHt} \} |0, 1\rangle,$$ \hfill (S25)

$$C = -\alpha_1 \alpha_2 |1, 0\rangle \langle 1, 0 | \text{Tr}_c \{e^{-iHt} (\mathbb{1} - 2\hat{W}_2^2) (\mathbb{1} - 2\hat{W}_1^2) \} \rho(0) \times (\mathbb{1} - \beta_1 \hat{W}_1^2) e^{iHt} \rangle |0, 1\rangle,$$ \hfill (S26)

$$D_0 = \alpha_1^2 \langle 0, 0 | \text{Tr}_c \{e^{-iHt} (\mathbb{1} - 2\hat{W}_2^2) \hat{W}_1 \rho(0) \hat{W}_1 \} |0, 0\rangle,$$ \hfill (S27)

$$D_1 = \alpha_2^2 |1, 1\rangle \langle 1, 1 | \text{Tr}_c \{e^{-iHt} \hat{W}_2 (\mathbb{1} - \beta_2 \hat{W}_2^2) \} \rho(0) \times (\mathbb{1} - \beta_1 \hat{W}_1^2) e^{iHt} \rangle |1, 1\rangle.$$ \hfill (S28)

The evaluation of these amplitudes is done by keeping track of which tunnelling transitions are nonzero on the $d_j$ levels, which gives rise to corresponding $\psi(x_j)$ or $\psi^\dagger(x_j)$ operators. The latter are then rearranged, using the cyclicity of $\text{Tr}_c$ such that standard correlators $\langle \ldots \rangle = \text{Tr}_c \{\ldots \rho_c\}$ with $\rho_c$, at the far right, are obtained. Expressions such as $\hat{W}_2^2 (\psi^\dagger(x_j) \psi(x_j))^2$ are replaced by $\psi_{\beta_j}^\dagger \psi_{\beta_j} \psi_{\alpha_j} \psi_{\alpha_j}$ as shown in Sec. III. Further simplifications are obtained through identity (S22) and the trigonometric relation between $\alpha_j$ and $\beta_j$.

In the expressions below we let $\psi_j = \psi(x_j)$ and use the notations $h_0 = H|v_1 = v_2 = 0, h_1 = H|v_1 \neq 0, v_2 = 0$, and $h_{12} = H|v_1 \neq 0, v_2 \neq 0$. We then obtain

$$A = 1 - A_1 - A_2 + A_3 + A_4,$$ \hfill (S29)

$$A_1 = \alpha_1^2 \alpha_2^2 \langle \psi^\dagger \psi \{e^{i\theta_0(t_1 + t_2)} \} \rangle,$$ \hfill (S30)

$$A_2 = \alpha_1^2 \alpha_2^2 \langle \psi^\dagger \psi \{e^{i\theta_0(t_2 - t_1)} \} \rangle,$$ \hfill (S31)

$$A_3 = 4\beta_1 \beta_2 \alpha_1 \alpha_2 \langle \psi \{e^{i\theta_0(t_2 - t_1)} \} \rangle,$$ \hfill (S32)

$$A_4 = \beta_1^2 \beta_2^2 \alpha_1 \alpha_2 \langle \psi \{e^{i\theta_0(t_1 - t_2)} \} \rangle.$$ \hfill (S33)

which are all expressions independent of the scattering potentials $V_j$. The further diagonal entries are

$$B = \alpha_1^2 \alpha_2^2 \langle \psi \{e^{i\theta_0(t_2 - t_1)} \} \rangle,$$ \hfill (S34)

$$D_0 = A_1 - B,$$ \hfill (S35)

$$D_1 = A_2 - A_3 - A_4.$$ \hfill (S36)

While $D_1$ remains independent of the $V_j$ there is an explicit $V_1$ dependence in $B$ and $D_0$. However, all time dependence so far is pinned to the pulse times $t_1$ and $t_2$. The dependence on $t$ (for $t > t_2 > t_1$) enters only through the off-diagonal component

$$C = -\alpha_1 \alpha_2 \langle \psi \{e^{i\theta_0(t_1 + t_2)} \} \psi \rangle,$$ \hfill (S37)

which is also the only term depending on $V_2$ as the latter potential is switched on only for times $t > t_2$.

The amplitudes $A_{1,2}$ can be evaluated immediately. Since $h_0$ does not perturb the ground state the correlator $\langle \psi \{e^{i\theta_0(t_1 + t_2)} \} \rangle$ equals the local hole density $n_h$. Likewise $\langle \psi \{e^{i\theta_0(t_2 - t_1)} \} \rangle$ gives the local particle density $n_p$. This leads to $A_1 = \alpha_1^2 \alpha_2^2 n_h$ and $A_2 = \alpha_1^2 \alpha_2^2 n_p$. The remaining amplitudes contain time propagating components and are evaluated through the bosonisation technique.

V. BOSONISATION

In the following we focus on one-dimensional (1D) systems such that the travelling signal remains directed and does not weaken its amplitude by expanding in a higher
dimensional space. This has the additional advantage that we can use the bosonisation technique [S4–S6] which a reliable method for the explicit evaluation of correlators. Bosonisation allows us furthermore to quantitatively include the renormalisation of system properties by interactions. We should emphasise, however, that we choose a 1D system and bosonisation for convenience to provide explicit analytical results but we do not wish to lose universality by the restriction to the particular pure 1D physics. Indeed in many cases the interactions in 1D can cause a collective strong coupling response that qualitatively changes the system’s properties. Such physics has been a central theme for 1D systems since many years but it is specific for this dimensionality. Notable is in particular that backscattering on the impurity causes an interaction-independent universal long time decay of the standard FES [S7]. Yet here we explicitly exclude such strong coupling physics. We thus shall use bosonisation in the same spirit as Schotte and Schotte [S8] who mapped the radial expansion of a pure s-wave scattering in higher dimensions onto a 1D description solved by bosonisation and thus could capture in such an elegant way the main many-body features of FES. For the present 1D description we shall keep nonetheless the fact that modes can travel to the right or the left and use a pure 1D description, but we either need to assume that backscattering on the impurity does not become relevant for the described physics (conditions are provided below), or that we deal with a quasi-1D system with sufficient degrees of freedom in the transverse directions such that the backscattering effect is reduced. Of course, purely 1D systems without backscattering can be realised experimentally as well such as through chiral quantum Hall edge states or helical edge states in topological insulators, and for such systems the description below can be applied with only straightforward adjustments.

The basic condition for bosonisation is that the fermionic band is sufficiently filled such that one can consider the portions near the Fermi points ±k_F as two independent bands of right movers R (near k_F) and left movers L (near −k_F). The original fermion field operator is then written as ψ(x) = e^{ik_r x}ψ_R(x) + e^{-ik_r x}ψ_L(x), where ψ_ν denotes the fermion operator on the ν = R, L movers branch. Furthermore the dispersion relation is linearised such that ε_{ν,ν} ≈ v_F(k − νk_F), with the signs ν = R = + and ν = L = − replacing the letters R, L where necessary. The resulting model is known as the Tomonaga-Luttinger model and is described by the Hamiltonian

$$H_{TL} = \sum_\nu \int dx \psi_\nu^\dagger (-i v_F \partial_x) \psi_\nu + H_{\text{int}},$$  \hspace{1cm} \text{(S38)}

in which we have chosen the chemical potential to be zero such that \( H_{\text{TL}} \) measures the excitations about the ground state. The Hamiltonian \( H_{\text{int}} \) contains the fermion-fermion interactions and can be expressed as

$$H_{\text{int}} = \sum_{\nu,\nu'} \int dx dx' V(x - x') \psi_\nu^\dagger(x) \psi_\nu(x') \psi_{\nu'}(x) \psi_{\nu'}(x'),$$  \hspace{1cm} \text{(S39)}

with \( V \) the interaction potential. In \( H_{\text{int}} \) we have omitted terms that couple the R and L movers beyond the written density-density interaction. Indeed such terms are irrelevant in the renormalisation group sense unless the fermion density is commensurate with the underlying lattice. We exclude such specific cases here, also in the spirit of the comments on the choice of a 1D model given above.

The mapping on bosonic degrees of freedom is then a standard procedure (see e.g. [S4–S6] for an in depth discussion), with the boson fields representing density fluctuations of the R and L movers. The Hamiltonian (S38) becomes quadratic in the boson fields, and for a sufficiently short ranged (screened) interaction \( V \) such that the interaction is most pronounced within a range \( < \pi/k_F \) all interactions can be treated as local. The Hamiltonian \( H_{TL} \) then becomes a quadratic form described by a \( 2 \times 2 \) matrix for the bosonic R and L fields with the off diagonal terms arising from the R and L density coupling in \( H_{\text{int}} \). Such a matrix can be immediately diagonalised and the resulting eigenmodes, \( \phi_{R,L} \), describe wave packets that still move only to the right or to the left, although when \( V \neq 0 \) both contain contributions from both original R and L moving density waves. The Hamiltonian is written accordingly as

$$H_{TL} = \tilde{H}_R + \tilde{H}_L \quad \text{with}$$

$$\tilde{H}_\nu = \int dx \frac{\nu}{4\pi K} (\partial_x \phi_\nu(x))^2,$$  \hspace{1cm} \text{(S40)}

for \( \nu = R, L \). Here \( K \) encodes the interaction strength of \( V \), normalised such that \( K = 1 \) corresponds to the non-interacting limit, \( 0 < K < 1 \) to repulsive interactions and \( K > 1 \) to attractive interactions, and \( v \) is a renormalised Fermi velocity, often equal to \( v = v_F/K \). The eigenmodes \( \phi_\nu \) obey the commutation relations

$$[\partial_x \tilde{\phi}_\nu(x'), \tilde{\phi}_\nu(x)] = 2i\pi K \nu \delta_{\nu,\nu'} \delta(x - x'),$$  \hspace{1cm} \text{(S41)}

such that \( \tilde{\phi}_\nu \) and \( \partial_x \tilde{\phi}_\nu \) are conjugate boson fields up to a normalisation. In terms of the eigenmodes the original fermion operators are expressed as

$$\psi_\nu(x) = \frac{\eta_\nu}{\sqrt{2\pi a}} e^{-\frac{i}{2}(\nu - K^{-1})} \tilde{\phi}_\nu(x) - \frac{i}{2}(\nu + K^{-1}) \tilde{\phi}_\nu(x),$$  \hspace{1cm} \text{(S42)}

with \( a \) a short distance cutoff, typically on the order of the lattice spacing. The \( \eta_\nu \) are Klein factors, operators that lower overall fermion number by one and guarantee the fermionic exchange statistics. But for the further analysis they produce only unit expectation values and will be dropped.

The scattering potentials \( V_j \) are in their fermionic form given by the Hamiltonian

$$H_V = V_1 \psi^\dagger(x_1) \psi(x_1) d_1^\dagger d_1 + V_2 \psi(x_2) \psi^\dagger(x_2) d_2^\dagger d_2.$$  \hspace{1cm} \text{(S43)}
With the splitting into $R$ and $L$ movers $H_V$ has a forward scattering contribution remaining either in the $R$ or in the $L$ band, and a backscattering contribution transferring between $R$ and $L$. We shall neglect the latter, although this may seem counter-intuitive as backscattering produces a relevant FES response with a universal time decay that is independent of $V_j$ [S7]. Yet as mentioned above our main aim is to provide a description of the travelling FES signal and use bosonisation as a convenient tool, but not to be limited to the particularities of the pure 1D response. In addition, even for the pure 1D case we should stress that the universal decay is a strong coupling response. It does not set in immediately but takes a characteristic time $\tau \sim (V_j^b)^{-1} (\xi/V_j^b)^{K/(1-K)}$ to build up before crossing over to the universal behaviour [S7]. Here $V_j^b = |V_j(2k_F)|$ is the backscattering Fourier amplitude of $V_j$. The time $\tau$ is of significance mostly for strongly interacting systems with $K < 0.7$ at which it can become very long. However, for typical scales as found in nanowires and not too strong interactions with $K > 0.7$ the value of $\tau$ becomes on the order of microseconds or much larger such that the strong coupling limit from backscattering is not reached in the time scales governing the described physics otherwise. The physics then remains perturbative in the backscattering amplitude and has a direct $V_j$ dependence similar to the effect of forward scattering [S7]. To capture the general effect of FES it is even in this pure 1D situation therefore sufficient to include only forward scattering.

In this case $H_V$ is expressed in terms of the boson fields as

$$H_V = \sum_\nu \left[ V_1 \psi_1^\dagger(x_1) \psi_1(x_1) d_1^\dagger d_1 + V_2 \psi_2^\dagger(x_2) \psi_2(x_2) d_2^\dagger d_2 \right]$$

$$= \left\{ \Delta E_1 - \frac{V_1}{2\pi K} \left[ \partial_x \tilde{\phi}_L(x_1) + \partial_x \tilde{\phi}_R(x_1) \right] \right\} d_1^\dagger d_1 + \left\{ \Delta E_2 - \frac{V_2}{2\pi K} \left[ \partial_x \tilde{\phi}_L(x_2) + \partial_x \tilde{\phi}_R(x_2) \right] \right\} d_2^\dagger d_2, \quad (S44)$$

which incorporate the fluctuating parts of the forward scattering. Here $\Delta E_j = N V_j^2/4\pi v K$, with $N$ the system’s particle number, are $d_j^\dagger$ dependent energy shifts providing a ground state energy renormalisation by the $V_j$ potentials. Since Eq. (S44) is linear in $\tilde{\phi}_v$ the total Hamiltonian $H_{TL} + H_V$ can be brought to the form of $H_{TL}$ by completing the square through a shift in the boson fields, $\partial_x \tilde{\phi}_v - \Delta$, such that the term proportional to $(\partial_x \tilde{\phi}_v) \Delta$ matches $H_V$. This can be performed on the operator level [S8] by defining the shift operators

$$\tilde{T}_1 = \exp \left( i \frac{\delta_1}{\pi K} [\tilde{\phi}_R(x_1) - \tilde{\phi}_L(x_1)] d_1^\dagger d_1 \right), \quad (S45)$$

$$\tilde{T}_2 = \exp \left( i \frac{\delta_2}{\pi K} [\tilde{\phi}_R(x_2) - \tilde{\phi}_L(x_2)] d_2^\dagger d_2 \right), \quad (S46)$$

where $\delta_j = 2KV_j/v$ is the scattering phase shift which for the linearised spectrum matches the Born approximation [S8]. Through the commutation relations (S41) we see that $H_{TL} + H_V = T_2^\dagger T_1^\dagger H_{TL} T_1 T_2 + \Delta E_1 d_1^\dagger d_1 + \Delta E_2 d_2^\dagger d_2$.

If we let $T_1 = \tilde{T}_1|d_1^\dagger d_1 = 1$ and $T_2 = \tilde{T}_2|d_2^\dagger d_2 = 1$ then it follows that $e^{-i\hbar t} = T_1^\dagger e^{-i\hbar t} T_1 e^{-i\Delta E_1 \delta_1}$ and $e^{-i\hbar t_2} = T_2^\dagger e^{-i\hbar t_2} T_2 e^{-i(\Delta E_1 + \Delta E_2) \delta_2}$, which allows us to write the correlators in $\rho_\delta$ entirely in terms of a time evolution under $h_0$. For instance, we have

$$C = -\alpha_1 \alpha_2 W_1 W_2 \langle e^{i\theta_1 \phi_1} \psi_1 T_1^\dagger e^{-i(h_0 + \Delta E_1)(t_1 - t_2)} T_1 \psi_2 \rangle^2 \times T_2^\dagger T_1^\dagger e^{-i(h_0 + \Delta E_1 + \Delta E_2)(t_2 - t_1)} T_1 T_2 e^{-i\hbar t_2}$$

$$\times \left( 1 - \beta_1 W_1^2 e^{i\theta_1 \phi_1} \psi_1 \psi_1^\dagger e^{-i\hbar t_1} \right) \times \left( 1 - \beta_2 W_2^2 e^{i\hbar t_2} \psi_2 \psi_2^\dagger e^{-i\hbar t_2} \right). \quad (S47)$$

Inserting the time dependence $O(t) = e^{i\hbar t} O e^{-i\hbar t}$ for any operator $O$ the latter expression can be rewritten as

$$C = -\alpha_1 \alpha_2 W_1 W_2 e^{-i\Delta E_1 (t_1 - t_2)} e^{-i\Delta E_2 (t_2 - t_1)} \times \left( \langle \psi_1 T_1^\dagger (t_1) T_1 (t_1) \psi_2^\dagger (t_2) T_2 (t_2) \rangle \right. \times \left( 1 - \beta_1 W_1^2 \psi_1 \psi_1^\dagger (t_1) \right) \times \left( 1 - \beta_2 W_2^2 \psi_2 \psi_2^\dagger (t_2) \right). \quad (S48)$$

Similarly we find

$$B = \alpha_1^2 \alpha_2^2 W_1^2 W_2^2 \left[ \langle \psi_1 (t_1) T_1^\dagger (t_1) T_1 (t_1) \psi_2^\dagger (t_2) T_2 (t_2) \rangle \right.$$

$$\times \left( 1 - \beta_1 W_1^2 \psi_1 \psi_1^\dagger (t_1) \right) \times \left( 1 - \beta_2 W_2^2 \psi_2 \psi_2^\dagger (t_2) \right), \quad (S49)$$

and corresponding expressions without $T_j$ operators for all other amplitudes in $\rho_\delta$. In all these expressions the fermion operators are replaced by Eq. (S42) and we note that [S4, S5]

$$\psi^\dagger (x) \psi (x) = n_p - \frac{1}{2\pi} \partial_x \tilde{\phi}_L (x) + \partial_x \tilde{\phi}_R (x) \right\} d_1^\dagger d_1 + \frac{1}{2\pi a} \left( e^{i[\tilde{\phi}_L (x) + \tilde{\phi}_R (x)]} + h.c. \right), \quad (S50)$$

and $\psi (x) \psi^\dagger (x) = (n_p + n_h) - \psi^\dagger (x) \psi (x)$, where the densities $n_p$ and $n_h$ regularise the divergences from the delta function of the anticommutator.

The final evaluation of all correlators is done by using the identity $\langle \prod_i \exp(\lambda_i \phi_i) \rangle = \exp(\sum_i \lambda_i \lambda_j G_{ij})$ valid for any theory with a quadratic bosonic Hamiltonian where $\phi_i = \phi_{v_i} (x_i, t_i)$ and [S6]

$$G_{ij} = \langle \tilde{\phi}_i \tilde{\phi}_j - \tilde{\phi}_i^2 - \tilde{\phi}_j^2 \rangle/2 = -K \delta_{v_i, v_j} \left[ a - i\nu_1 (x_i - x_j) + iv(t_i - t_j) \right]. \quad (S51)$$

In the latter equation we use the zero temperature $T = 0$ limit which is applicable as long as all considered time scales are shorter than the thermal time $\tau_T = 2\pi/k_BT$. For density-density correlators involving products of gradients we have

$$\langle \partial_x \tilde{\phi}_i \partial_x \tilde{\phi}_j \rangle = \frac{K \delta_{v_i, v_j}}{[a - i\nu_1 (x_i - x_j) + iv(t_i - t_j)]^2}. \quad (S52)$$
A subtlety arises from the term $\psi_1(t_1)\psi^\dagger_2(t_2)\psi_2(t_2)\psi^\dagger_1(t_1)$ in $\mathcal{B}$ which must remain real and the standard point splitting method of bosonisation is ambiguous. But there is no ambiguity in the noninteracting $K = 1, \delta_j = 0$ limit in which the evaluation of the fermionic amplitude is a basic application of Wick’s theorem. From continuity with this result we find that in this case the correlators of the form of Eq. (S52) must instead be given by $-K \delta_{ij}/\{a^2 + [v_3(x_i - x_j) - v(t_i - t_j)]^2\}$.

The final results for the amplitudes $A, B, C, D_{0,1}$ are then obtained straightforwardly but require a good bookkeeping as they consist of products of many factors of the form $\{a - iv_4(x_i - x_j) + iv(t_i - t_j)/a\}^{\gamma_{ij}}$ with the various exponents $\gamma_{ij}$ arising from the $\psi$ and $T$ operators. We shall write out explicitly only the leading part of the amplitude $C$, without the higher order contributions proportional to $\beta_{1,2}$, as the discussion in the main text focuses primarily on the latter. We have

$$C = -\alpha_1 \alpha_2 W_1 W_2 e^{-i\Delta E_1(t_1-t)} e^{-i\Delta E_2(t_2-t)} \times (e^{-ikp(x_1-x_2)}C_L + e^{+ikp(x_1-x_2)}C_R) / 2\pi a,$$  \hspace{1cm} (S53)

in which the amplitudes $C_{ij}$ are products of the power laws arising from the multiple contractions between the boson fields. With $g_{x,t} = (a - ix + ivt)/a$ we have

$$C_{ij} = \frac{\gamma_{ij}^{\delta_1} - \frac{2\delta_1^2}{\pi K}}{\frac{2\delta_1}{\pi K} - \frac{2\delta_2}{\pi K}} \frac{\delta_{ij}}{g_{\mathcal{B}_{x-t}} - \frac{2\delta_1}{\pi K}} \times \frac{g_{x_1-x_2,0}}{g_{x_2-x_1,0}} \frac{g_{x_1-x_2,t_1-t}}{g_{x_2-x_1,t_1-t}} \times \frac{\delta_{ij}}{g_{x_1-x_2,t_1-t}} - \frac{\delta_{ij}}{\frac{2\delta_1}{\pi K} - \frac{2\delta_2}{\pi K}} \times \frac{\delta_{ij}}{g_{x_1-x_2,t_1-t}} - \frac{\delta_{ij}}{\frac{2\delta_1}{\pi K} - \frac{2\delta_2}{\pi K}} = \frac{\delta_{ij}}{\frac{2\delta_1}{\pi K} - \frac{2\delta_2}{\pi K}} \times \frac{\delta_{ij}}{g_{x_1-x_2,t_1-t}} - \frac{\delta_{ij}}{\frac{2\delta_1}{\pi K} - \frac{2\delta_2}{\pi K}}$$  \hspace{1cm} (S54)

The first two $x_i$ independent factors arise only from the OC. The next two time independent factors compensate in amplitude but provide a phase to the coefficient. The further terms encode the full spatio-temporal spread of the FES signal, with peaks whenever in $g_{x,t}$ the condition $x - vt = 0$ is met. At $t = t_2$ this expression simplifies to

$$C_{ij} = \frac{\gamma_{ij}^{\delta_1} - \frac{2\delta_1^2}{\pi K}}{\frac{2\delta_1}{\pi K} - \frac{2\delta_2}{\pi K}} \frac{\delta_{ij}}{g_{\mathcal{B}_{x-t}} - \frac{2\delta_1}{\pi K}} \times \frac{g_{x_1-x_2,0}}{g_{x_2-x_1,0}} \frac{g_{x_1-x_2,t_1-t}}{g_{x_2-x_1,t_1-t}} \times \frac{\delta_{ij}}{g_{x_1-x_2,t_1-t}} - \frac{\delta_{ij}}{\frac{2\delta_1}{\pi K} - \frac{2\delta_2}{\pi K}} \times \frac{\delta_{ij}}{g_{x_1-x_2,t_1-t}} - \frac{\delta_{ij}}{\frac{2\delta_1}{\pi K} - \frac{2\delta_2}{\pi K}}$$  \hspace{1cm} (S55)

in which all dependence on $\delta_2$ drops out.
