Computer-aided engineering techniques are indispensable in modern engineering developments. In particular, partial differential equations are commonly used to simulate the dynamics of physical phenomena, but very large systems are often intractable within a reasonable computation time, even when using supercomputers. To overcome the inherent limit of classical computing, we present a variational quantum algorithm for solving the Poisson equation that can be implemented in noisy intermediate-scale quantum devices. The proposed method defines the total potential energy of the Poisson equation as a Hamiltonian, which is decomposed into a linear combination of Pauli operators and simple observables. The expectation value of the Hamiltonian is then minimized with respect to a parameterized quantum state. Because the number of decomposed terms is independent of the size of the problem, this method requires relatively few quantum measurements. Numerical experiments demonstrate the faster computing speed of this method compared with classical computing methods and a previous variational quantum approach. We believe that our approach brings quantum computer-aided techniques closer to future applications in engineering developments.

I. INTRODUCTION

Partial differential equations (PDEs) are frequently used to describe the dynamics of physical phenomena such as heat conduction, fluid dynamics, and solid mechanics [1]. Solving these problems as quickly as possible is a key factor in accelerating engineering developments that combine computer simulations and real-world experiments. Although many advances have been made in terms of treating very large physical systems using classical computers [2, 3], obtaining solutions within a reasonable computational time is increasingly intractable.

Another possible and attractive approach that would significantly reduce the computational costs of solving PDEs is the application of quantum computing. Quantum computing has attracted considerable attention over recent decades as a potential means of providing faster and more powerful computation than classical computing.

Quantum algorithms for solving linear systems have been developed [4, 5], and these provide an exponential speedup over classical algorithms when the coefficient matrix of the linear system is sparse. Cao et al. [6] developed an algorithm for solving the Poisson equation, which is one of the most important PDEs in various areas of engineering, such as electrostatics [7] and computational fluid dynamics [8, 9]. Although it is widely believed that the abovementioned quantum algorithms will demonstrate quantum supremacy once fault-tolerant quantum computers with sufficient qubits and error correction techniques are ready, it is expected to be a long time until such a quantum computer can be realized. Thus, recent interest in quantum computing has focused on the development of quantum algorithms that perform some meaningful computations with a small number of qubits and a shallow circuit. In other words, it is important to construct a quantum algorithm that can be implemented on so-called noisy intermediate-scale quantum (NISQ) devices.

Variational quantum algorithms (VQAs) are possible candidates for use on NISQ devices, exhibiting several advantages over classical algorithms. In VQAs, a certain cost function is written as the expectation value of a Hamiltonian, and is evaluated on a quantum computer using a trial quantum state prepared by a parameterized quantum circuit. This cost function evaluation is iteratively performed while updating the classical parameters so that the cost function can be minimized, which yields the ground state of the Hamiltonian. Thus, VQAs are effectively hybrid quantum–classical algorithms. A well-known example of a VQA is a variational quantum eigensolver (VQE) [10]. The VQE successfully calculates the eigenvalue of a certain system Hamiltonian, and has been widely studied in terms of the quantum circuits suitable for hardware architectures [11, 12] and the construction of efficient optimizers [13–15]. Another popular VQA is the quantum approximate optimization algorithm (QAOA) [16], which can be used to solve combinatorial optimization problems. The QAOA was originally based on the concept of adiabatic quantum computing [17, 18]; it has since been extended to more general families of operators, and is thus widely known as the quan-
VQAs for solving linear systems have also been proposed. Bravo-Prieto et al. [20] proposed a VQA for a linear system in which the system matrix is written as a linear combination of unitary operators. This algorithm prepares a quantum state whose amplitude is proportional to the solution of a linear system output by the Harrow–Hassidim–Lloyd algorithm [4]. Liu et al. [21] presented a scheme for efficiently solving the Poisson equation by explicitly decomposing a system matrix derived from the finite difference discretization of the Poisson equation. However, these methods only provide normalized solutions and cannot evaluate the norm of the solutions. Additionally, the latter research requires $O(\log N)$ expectation calculations at every iteration in the optimization procedure, where $N$ is the size of the problem.

This paper describes a method for solving the Poisson equation by formulating the system Hamiltonian based on the concept of the minimum potential energy. This approach allows us to evaluate the norm of the solutions. The system matrix of the discretized Poisson equation is split into a linear combination of the tensor product of Pauli operators and simple observables. The number of decomposed terms is independent of the system size, i.e., $O(N^3)$, which significantly reduces the required number of expectation calculations on quantum computers.

The remainder of this paper is organized as follows. In Sec. II, the optimization problem for solving the Poisson equation is formulated based on the concept of VQAs. Section III describes the numerical implementation based on the formulation, and then Sec. IV provides several results from numerical experiments. Finally, the conclusions to this study are presented in Sec. V.

II. FORMULATION

A. Derivation of optimization problem

Consider the Poisson equation defined in an open bounded domain $\Omega \subset \mathbb{R}^d$, where $d$ is the number of spatial dimensions. Let $u(x)$ denote the state field at the spatial coordinate $x \in \mathbb{R}^d$. Considering a function $f(x) : \Omega \rightarrow \mathbb{R}$, the Poisson equation is then defined as

$$\nabla^2 u(x) = f(x) \quad \text{in} \quad \Omega. \quad (1)$$

As general boundary conditions, the Dirichlet and Neumann boundary conditions are, respectively, defined as

$$-n \cdot \nabla u(x) = 0 \quad \text{on} \quad \Gamma_N,$$

$$u(x) = 0 \quad \text{on} \quad \Gamma_D, \quad (2)$$

where $n$ is the normal vector pointing outward from the boundary of the domain $\Omega$, and $\Gamma_N \cup \Gamma_D = \partial \Omega$, which means that any point on $\partial \Omega$ is included in either $\Gamma_N$ or $\Gamma_D$. In the following, the spatial coordinate $x$ is omitted for readability.

Here, let us consider the total potential energy, defined as

$$E := \frac{1}{2} \int_{\Omega} \nabla v \cdot \nabla v d\Omega - \int_{\Omega} v f d\Omega, \quad (4)$$

for $v \in \mathcal{V}$ with

$$\mathcal{V} := \{ v \in H^1(\Omega) \mid v = 0 \text{ on } \Gamma_D \} \quad (5)$$

where $H^1(\Omega)$ is a Sobolev space. The stationary condition of the total potential energy with respect to a function $v$ yields

$$0 = dE(v; \delta v)$$

$$= \int_{\Omega} \nabla \delta v \cdot \nabla v d\Omega - \int_{\Omega} \delta v f d\Omega$$

$$= \int_{\Gamma_N} \delta v n \cdot \nabla v d\Gamma - \int_{\Omega} \delta v \nabla^2 v d\Omega - \int_{\Omega} \delta v f d\Omega$$

$$= \int_{\Gamma_N} \delta v n \cdot \nabla v d\Gamma - \int_{\Omega} \delta v (\nabla^2 v + f) d\Omega \quad (6)$$

where $dE(v; \delta v)$ represents the Gâteaux derivative of $E$ with respect to $v$ in the direction $\delta v \in \mathcal{V}$. In Eq. (6), Gauss’s theorem was applied from the second line to the third, and the integration on $\Gamma_D$ vanished because the trace of $\delta v = 0$ on the boundary with the Dirichlet boundary condition imposed. Because $\delta v$ is arbitrary, the above stationary condition recovers the Poisson equation from the second term of the right-most side of Eq. (6), which is known as the principle of minimum potential energy. This means that minimizing the total potential energy with respect to the function $v$ yields the state field $u$, governed by the Poisson equation. Therefore, the ground state of the Hamiltonian whose expectation value corresponds to the total potential energy gives the solution of the Poisson equation.

Now, to derive the Hamiltonian, Eq. (4) is discretized using some method such as the finite difference or finite element method. The discretized version of the total potential energy, $E_h$, is given as

$$E_h := \frac{1}{2} v^\top A v - v^\top f, \quad (7)$$

where $v$ and $f$ denote vectors whose components are the values of $v$ and $f$, respectively, at the nodes discretizing the domain $\Omega$. $A$ is a positive-definite symmetric matrix obtained from the discretization of the first term in Eq. (4) into the quadratic form. Let $|v\rangle$ and $|f\rangle$ be the state vectors encoding $v$ and $f$, respectively. Without loss of generality, the squared norm of $f$ can be assumed to be 1 from the linearity of the Poisson equation, which means that $|f\rangle$ can be regarded as a quantum state. However, it should be noted that $|v\rangle$ is not necessarily a quantum state, because the squared norm of the solution vector is not necessarily 1. Thus, we introduce a parameter $r \in \mathbb{R}$ and a parameterized quantum state $|\psi(\theta)\rangle$, where $\theta$ is a parameter set, and
For $N$ (FEM), in which the mesh size of all finite elements is 1. Observables. This is one of the contributions of the solution by Eq. (12), i.e., the expectation values of the $[20, 21]$, the proposed method calculates the norm of the $\theta$ and the optimization problem is to minimize Eq. (11) using first-order elements, depending on the boundary conditions, as follows: With periodic boundary conditions,

$$A_{\text{periodic}} := \begin{bmatrix} 2 & -1 & 0 & \ldots & 0 & -1 \\ -1 & 2 & -1 & 0 & \ldots & 0 \\ 0 & -1 & 2 & -1 & \ldots & 0 \\ \vdots & \vdots & \ddots & \ddots & \ddots & \vdots \\ 0 & \ldots & 0 & -1 & 2 & -1 \\ -1 & 0 & \ldots & 0 & -1 & 2 \end{bmatrix} \in \mathbb{R}^{N \times N}. $$ (13)

With Dirichlet boundary conditions,

$$A_{\text{Dirichlet}} := \begin{bmatrix} 2 & -1 & 0 & \ldots & 0 \\ -1 & 2 & -1 & 0 & \ldots & 0 \\ 0 & -1 & 2 & -1 & \ldots & 0 \\ \vdots & \vdots & \ddots & \ddots & \ddots & \vdots \\ 0 & \ldots & 0 & -1 & 2 & -1 \\ 0 & \ldots & 0 & -1 & 2 & -1 \end{bmatrix} \in \mathbb{R}^{N \times N}. $$ (14)

With Neumann boundary conditions,

$$A_{\text{Neumann}} := \begin{bmatrix} 1 & -1 & 0 & \ldots & 0 \\ -1 & 2 & -1 & 0 & \ldots & 0 \\ 0 & -1 & 2 & -1 & \ldots & 0 \\ \vdots & \vdots & \ddots & \ddots & \ddots & \vdots \\ 0 & \ldots & 0 & -1 & 2 & -1 \\ 0 & \ldots & 0 & -1 & 2 & -1 \end{bmatrix} \in \mathbb{R}^{N \times N}. $$ (15)

The matrix $A_{\text{Dirichlet}}$ is the same as that derived in previous research [21] using the finite difference method (FDM). In one dimension, the matrices derived from the FEM using first-order elements coincide with those from the central difference scheme in the FDM.

While previous research [21] has shown that the matrix $A_{\text{Dirichlet}}$ can be decomposed into $O(n)$ terms consisting of Pauli and simple operators, the present study provides the decomposition of the above matrices $A_{\text{periodic}}, A_{\text{Dirichlet}},$ and $A_{\text{Neumann}}$ into $O(n^3)$ terms consisting of Pauli operators and simple observables. The matrix $A_{\text{periodic}}$ can be split into two matrices as follows:

$$A_{\text{periodic}} = A_{\text{even}} + A_{\text{odd}}, $$ (16)

Letting $r_{\text{opt}}$ and $\theta_{\text{opt}}$ denote the solution of this optimization problem, the state vector that encodes the solution of the Poisson equation is $|u\rangle = r_{\text{opt}} \psi(\theta_{\text{opt}})$. Here, these two minimizations with respect to $r$ and $\theta$ can be performed sequentially, i.e., minimizing $E_h$ with respect to $r$, followed by $\theta$ as

$$\min_{r, \theta} E_h(r, \theta) = \min_{\theta} E_h(r_{\text{opt}}(\theta), \theta), $$ (10)

where $r_{\text{opt}}(\theta)$ is the optimal value of $r$ for a fixed value of $\theta$. As the cost function $E_h$ is parabolic with respect to $r$, its minimum is analytically derived as follows:

$$E_h(r_{\text{opt}}(\theta), \theta) = -\frac{1}{4} \frac{\langle f, \psi(\theta) | X \otimes I^\otimes n | f, \psi(\theta) \rangle^2}{\langle f, \psi(\theta) | I_1 \otimes A | f, \psi(\theta) \rangle} $$

$$ = -\frac{1}{2} \frac{\langle f, \psi(\theta) | X \otimes I^\otimes n | f, \psi(\theta) \rangle^2}{\langle \psi(\theta) | A | \psi(\theta) \rangle}, $$ (11)

with

$$r_{\text{opt}}(\theta) := \frac{\langle f, \psi(\theta) | X \otimes I^\otimes n | f, \psi(\theta) \rangle}{\langle \psi(\theta) | A | \psi(\theta) \rangle}. $$ (12)

Consequently, $r$ can be deleted from the cost function, and the optimization problem is to minimize Eq. (11) with respect to $\theta$. Thus, unlike previous approaches [20] [21], the proposed method calculates the norm of the solution by Eq. (12), i.e., the expectation values of the observables. This is one of the contributions of the proposed method.

### B. Evaluation of cost function

In this paper, we focus on the one-dimensional Poisson equation, discretized by the finite element method (FEM), in which the mesh size of all finite elements is 1. For $N$ nodes in one dimension, the matrix $A$ is described using first-order elements, depending on the boundary conditions, as follows: With periodic boundary conditions,

$$A_{\text{periodic}} := \begin{bmatrix} 2 & -1 & 0 & \ldots & 0 \\ -1 & 2 & -1 & 0 & \ldots & 0 \\ 0 & -1 & 2 & -1 & \ldots & 0 \\ \vdots & \vdots & \ddots & \ddots & \ddots & \vdots \\ 0 & \ldots & 0 & -1 & 2 & -1 \\ -1 & 0 & \ldots & 0 & -1 & 2 \end{bmatrix} \in \mathbb{R}^{N \times N}. $$ (13)

With Dirichlet boundary conditions,

$$A_{\text{Dirichlet}} := \begin{bmatrix} 2 & -1 & 0 & \ldots & 0 \\ -1 & 2 & -1 & 0 & \ldots & 0 \\ 0 & -1 & 2 & -1 & \ldots & 0 \\ \vdots & \vdots & \ddots & \ddots & \ddots & \vdots \\ 0 & \ldots & 0 & -1 & 2 & -1 \\ 0 & \ldots & 0 & -1 & 2 & -1 \end{bmatrix} \in \mathbb{R}^{N \times N}. $$ (14)

With Neumann boundary conditions,

$$A_{\text{Neumann}} := \begin{bmatrix} 1 & -1 & 0 & \ldots & 0 \\ -1 & 2 & -1 & 0 & \ldots & 0 \\ 0 & -1 & 2 & -1 & \ldots & 0 \\ \vdots & \vdots & \ddots & \ddots & \ddots & \vdots \\ 0 & \ldots & 0 & -1 & 2 & -1 \\ 0 & \ldots & 0 & -1 & 2 & -1 \end{bmatrix} \in \mathbb{R}^{N \times N}. $$ (15)

The matrix $A_{\text{Dirichlet}}$ is the same as that derived in previous research [21] using the finite difference method (FDM). In one dimension, the matrices derived from the FEM using first-order elements coincide with those from the central difference scheme in the FDM.
where

\[
A_{\text{even}} := \begin{bmatrix}
1 & -1 & 0 & 0 & \ldots & 0 \\
-1 & 1 & 0 & 0 & \ldots & 0 \\
0 & 0 & 1 & -1 & \ldots & 0 \\
0 & 0 & -1 & 1 & \ldots & 0 \\
\vdots & \ddots & \ddots & \ddots & \ddots & \ddots \\
0 & \ldots & 0 & 0 & 1 & -1 \\
0 & \ldots & 0 & 0 & -1 & 1
\end{bmatrix},
\]  

(17)

and

\[
A_{\text{odd}} := \begin{bmatrix}
1 & 0 & 0 & \ldots & 0 & -1 \\
0 & 1 & -1 & 0 & \ldots & 0 \\
0 & -1 & 1 & 0 & \ldots & 0 \\
\vdots & \ddots & \ddots & \ddots & \ddots & \ddots \\
0 & \ldots & 0 & 1 & -1 & 0 \\
-1 & 0 & \ldots & 0 & 0 & 1
\end{bmatrix}.
\]  

(18)

Because \(A_{\text{even}}\) can be written in simple form using Pauli operators as

\[
A_{\text{even}} = I^{\otimes n-1} \otimes (I - X),
\]  

(19)

and \(A_{\text{even}}\) and \(A_{\text{odd}}\) are interchanged by shifting the node number towards +1, \(A_{\text{odd}}\) can also be written using Pauli operators as

\[
A_{\text{odd}} = P^{-1} \left( I^{\otimes n-1} \otimes (I - X) \right) P,
\]  

(20)

where \(P\) is a shift operator defined as

\[
P := \sum_{i \in [0,2^n-1]} |(i+1) \mod 2^n\rangle \langle i|.
\]  

(21)

Considering the differences between matrices depending on the three types of boundary conditions in Eqs. \((17)\) – \((18)\), these matrices can now be described as follows using the tensor products of the Pauli operators, a shift operator, and a simple Hermitian \(I_0 = |0\rangle \langle 0|\):

\[
\begin{align*}
A_{\text{periodic}} &= I^{\otimes n-1} \otimes (I - X) \\
&\quad + P^{-1} \left( I^{\otimes n-1} \otimes (I - X) \right) P \\
A_{\text{Dirichlet}} &= A_{\text{periodic}} + P^{-1} \left( I^{\otimes n-1} \otimes X \right) P \\
A_{\text{Neumann}} &= A_{\text{periodic}} - P^{-1} \left( I^{\otimes n-1} \otimes (I - X) \right) P
\end{align*}
\]  

(22–24)

The expectation values of Hamiltonians including a shift operator can be evaluated as follows by applying the shift operator, which is unitary, to the quantum state:

\[
\langle \phi | P^{-1} \mathcal{H} P | \phi \rangle = \langle \phi' | \mathcal{H} | \phi' \rangle,
\]  

(25)

where \(|\phi\rangle\) is an arbitrary \(n\)-qubit state and \(|\phi'\rangle = P|\phi\rangle\). Now, the denominator of Eq. \((11)\) is described using a linear combination of the Pauli operators and simple Hermitians \(I_0, I_1\), and the numerator of Eq. \((11)\) is originally expressed by the Pauli operators. Because the expectation values of the identity operator are 1, i.e.,

\[
\langle \phi | I^{\otimes n} | \phi \rangle = 1
\]  

(26)

\[
\langle \phi | P^{-1} I^{\otimes n} P | \phi \rangle = \langle \phi' | I^{\otimes n} | \phi' \rangle = 1
\]  

(27)

the number of terms to be evaluated by a quantum computer is three for the periodic boundary condition, four for the Dirichlet boundary condition, and five for the Neumann boundary condition; of these, one term is for the numerator of Eq. \((11)\) and the others are for the linear combination in the denominator of Eq. \((11)\).

The above discussion can be easily extended to \(d\)-dimensional problems using the FDM and FEM. When using the FDM, the cost function is defined by the \(d\)-dimensional system matrix \(A_d\), that is,

\[
A_d := A \otimes I^{\otimes d} + I \otimes A \otimes I^{\otimes (d-1)} + \cdots + I^{\otimes d} \otimes A,
\]  

(28)

instead of \(A \otimes I^{\otimes n}\). When using the FEM, the decomposition of \(A_d\) into a linear combination of Pauli operators is derived by defining a graph corresponding to the finite elements, which is explained in Appendix A.

### III. IMPLEMENTATION

#### A. Overview of the algorithm

Here, we briefly describe the proposed algorithm.

Step 1 Initialize a set of parameters \(\theta\) in a classical computer.

Step 2 Evaluate the cost function \(E_b\) in Eq. \((11)\) using a quantum computer.

Step 3 If a certain terminal condition is satisfied, the optimization procedure halts; otherwise, proceed to Step 4.

Step 4 Update the set of parameters using some classical optimization scheme, then return to Step 2.

We use several kinds of terminal conditions in the numerical experiments. Thus, we will specify these conditions there.

#### B. State preparation

In the proposed method, the quantum state \(|\psi(\theta)\rangle\) is prepared by applying a sequence of parameterized quantum gates \(U(\theta)\), the so-called ansatz, to the \(|0\rangle^{\otimes n}\) state. We use a hardware-efficient ansatz \((11)\) consisting of \(R_y\) gates and controlled \(Z\) gates \((20)\) to constrain the amplitude in the real space. This is valid in the solution of the Poisson equation with \(f(x) \in \mathbb{R}\). In the state preparation stage, the state vector \(|f\rangle\), which corresponds to the source term of the Poisson equation, must also be prepared. For the encoding of arbitrary state vectors, amplitude encoding techniques are required \((22)\) \((24)\). These encode classical data into the amplitudes of a quantum state. In the current study, for simplicity, we assume that there is a unitary \(U_b\) that efficiently prepares \(|f\rangle\) from \(|0\rangle^{\otimes n}\) (i.e., \(|f\rangle = U_b |0\rangle^{\otimes n}\)).
Using the following discussion, the parameter values $j_i$ are estimated as $\bar{q}_i$ (as the $i$-th sample of $\bar{q}$). Let $U$ be the Hamiltonian and $T = \sum_{i=1}^m T_i$, $T_i$ are $\Delta$-controlled Toffoli gates for $1 \leq i \leq m$, $\mu_i$ denotes the value of $U$. The shift operator $P$ is represented by a sequence of multi-controlled Toffoli gates with at most $n-1$ control lines, as shown in Fig. 1. With $k \geq 3$ denoting the number of control lines, a $k$-controlled Toffoli gate can be decomposed into $2k-4$ relative-phase Toffoli gates and a Toffoli gate using $k-2$ auxiliary qubits [25]. Because a shift operator has $k$-controlled Toffoli gates for $3 \leq k \leq n-1$, a CNOT gate, and an X gate, it can be expressed by $(n-2)(n-3)$ relative-phase Toffoli gates, $n-3$ Toffoli gates, a CNOT gate, and an X gate. Consequently, a quantum circuit for a shift operator requires $O(n^2)$ depth and $2n-3$ qubits, including auxiliary qubits.

---

**C. Quantum circuit for the shift operator**

The shift operator $P$ is represented by a sequence of multi-controlled Toffoli gates with at most $n-1$ control lines, as shown in Fig. 1. With $k \geq 3$ denoting the number of control lines, a $k$-controlled Toffoli gate can be decomposed into $2k-4$ relative-phase Toffoli gates and a Toffoli gate using $k-2$ auxiliary qubits [25]. Because a shift operator has $k$-controlled Toffoli gates for $3 \leq k \leq n-1$, a CNOT gate, and an X gate, it can be expressed by $(n-2)(n-3)$ relative-phase Toffoli gates, $n-3$ Toffoli gates, a CNOT gate, and an X gate. Consequently, a quantum circuit for a shift operator requires $O(n^2)$ depth and $2n-3$ qubits, including auxiliary qubits.

**D. Number of shots for expectation estimation**

To estimate the expectation value of a certain observable using a quantum computer, a quantum circuit with state preparation and measurement is run many times to sample an observable value and apply the Monte Carlo approach. Each run of a quantum circuit to obtain a sample is referred to as a “shot.” In this subsection, we estimate the number of shots required to estimate the expectations.

In the proposed method, the expectations to be estimated are $\langle f, \psi(\theta) | X \otimes I^{\otimes n} | f, \psi(\theta) \rangle$ and $\langle \psi(\theta) | A | \psi(\theta) \rangle$, where the latter consists of several terms depending on the boundary conditions, as mentioned in Sec. 11B. Let $q^{(j)}_i$ denote the $j$-th sample value for estimating the $i$-th expectation value. Here, $q^{(j)}_i$ denotes the value of the $j$-th sample of $\langle f, \psi(\theta) | X \otimes I^{\otimes n} | f, \psi(\theta) \rangle$, whereas $q^{(j)}_{j} \geq 2$ denotes the value of the $j$-th sample of $\langle \psi(\theta) | A | \psi(\theta) \rangle$. In the following discussion, the parameter values $\theta$ are assumed to be fixed and are omitted to simplify the notation. Using $S_i$ shots, the $i$-th expectation value $\bar{q}_i$ is estimated as follows:

$$\bar{q}_i := \frac{\sum_{j=1}^{S_i} q^{(j)}_i}{S_i}. \tag{29}$$

Regarding $q^{(j)}_i$ as a random variable with a mean value of $\mu_i$ and a variance of $\sigma^2_i$, the mean and variance of $\bar{q}_i$ are written as

$$\mathbb{E}[\bar{q}_i] = \mu_i \tag{30}$$

$$\text{Var}[\bar{q}_i] = \frac{\sigma^2_i}{S_i}. \tag{31}$$

Now, the cost function $E_h$ in Eq. (11) is written using $\mu_i$, and is assumed to be estimated as follows using the approximated expectation values:

$$E_h = \frac{1}{2} \sum_{i=1}^m \frac{\mu_i^2}{\mu_i} \approx \frac{1}{2} \sum_{i=1}^m \frac{\bar{q}_i^2}{\mu_i} := g(\bar{q}_1, \ldots, \bar{q}_m), \tag{32}$$

with $g(\bar{q}_1, \ldots, \bar{q}_m)$ denoting the approximated cost function, where $m = 3$ for the periodic boundary condition, $m = 4$ for the Dirichlet boundary condition, and $m = 5$ for the Neumann boundary condition, which corresponds to the number of terms to be evaluated derived in Sec. 11B.

Note that sampling using quantum computers is performed independently for each term of the expectation, leading to $\text{Cov}(\bar{q}_i, \bar{q}_i') = 0$ for $i \neq i'$ where $\text{Cov}(\bar{q}_i, \bar{q}_i')$ is the covariance of $\bar{q}_i$ and $\bar{q}_i'$. Using the first-order Taylor series expansion of $g(\bar{q}_1, \ldots, \bar{q}_m)$ around $\mu_i$ for $i \in [1, m]$, the mean squared error $\varepsilon^2$ between $E_h$ and $g(\bar{q}_1, \ldots, \bar{q}_m)$ in Eq. (32) is then written as follows:

$$\varepsilon^2 = r^2_{\text{opt}} \left( \frac{\sigma_f^2}{S_1} + \frac{1}{4} r^2_{\text{opt}} \sum_{i=2}^m \frac{\sigma^2_i}{S_i} \right). \tag{33}$$

A detailed derivation of the above equation is provided in Appendix B. In the proposed method, for simplicity, we use the same number of shots, denoted by $S$, for all sampling processes, which yields

$$\varepsilon^2 \approx r^2_{\text{opt}} \left( \frac{\sigma_f^2}{S} + \frac{1}{4} r^2_{\text{opt}} \sum_{i=2}^m \frac{\sigma^2_i}{S} \right) \frac{1}{S}. \tag{34}$$

This equation implies that the mean square error is inversely proportional to the number of shots.

**E. Time complexity**

Here, we analyze time complexity of the proposed method in terms of state preparation, number of quantum circuits, number of shots, and the number of iterations required to optimize the parameter set $\theta$. Note that the time complexity of the classical computing parts, such as parameter initialization and update, depends on the classical implementation and optimizers; thus, it is omitted from this analysis.

The time complexity of state preparation represents the time required for setting up the quantum circuit before measurement to estimate a certain expectation value. Therefore, the time complexity of state preparation, denoted by $T_p$, can be estimated by the depth of
the quantum circuit of state preparation:
\[
T_P := \mathcal{O}(D_{\text{ansatz}} + D_{\text{enc}} + D_{\text{shift}}) \quad (35)
\]
\[
= \mathcal{O}(D_{\text{ansatz}} + D_{\text{enc}} + n^2) \quad (36)
\]
where \(D_{\text{ansatz}}, D_{\text{enc}},\) and \(D_{\text{shift}}\) denote the circuit depths of the ansatz, amplitude encoding, and shift operator, respectively.

To estimate the cost function value using a quantum computer, several quantum circuits are required, corresponding to the numerator of Eq. (11) and each term in Eqs. (22)–(24) in the denominator of Eq. (11). The required number of quantum circuits, \(T_C\), is
\[
T_C := \mathcal{O}(n^9) \quad (37)
\]
because \(T_C = 3\) for periodic boundary conditions, \(T_C = 4\) for Dirichlet boundary conditions, and \(T_C = 5\) for Neumann boundary conditions, independent of the scale of the problem, \(n\). Furthermore, when we use gradient-based optimizers, we need several quantum circuits, the number of which is proportional to the number of parameters in the parameter set \(\theta\), to evaluate the gradient of the cost function. As the number of parameters is \(\mathcal{O}(nD_{\text{ansatz}})\), the number of quantum circuits required, denoted by \(T_G\), is
\[
T_G := \mathcal{O}(nD_{\text{ansatz}}) \quad (38)
\]
To evaluate the cost function and its gradient, each quantum circuit must be run many times for the sampling required to estimate the expectation values. Based on the discussion in Sec. III D, the required number of shots is
\[
T_S := \mathcal{O}\left(\frac{1}{\varepsilon^2}\right) \quad (39)
\]
In the proposed method, the abovementioned evaluations of the cost function and its gradient through quantum circuits are repeated while the parameter set \(\theta\) is updated, as mentioned in Sec. III A. The number of iterations is strongly dependent on the classical optimization solver and the terminal condition setting. As the discussion of classical optimization solvers is beyond the scope of this paper, let \(T_{it}\) denote the number of iterations, for simplicity.

Consequently, the total time complexity can be derived as
\[
T := T_h T_P (T_C + T_G) T_S 
= \mathcal{O}\left(\frac{T_{it}}{\varepsilon^2} (D_{\text{ansatz}} + D_{\text{enc}} + n^2) nD_{\text{ansatz}}\right) \quad (40)
\]
The time complexity for solving the Poisson equation by classical computing is \(\mathcal{O}(N \log N)\) \cite{24}, where \(N\) is the size of the matrix \(A\), i.e., \(N = 2^n\). Thus, the proposed method has reduced time complexity compared with classical algorithms, as long as the number of optimization iterations \(T_{it}\), the depth of the ansatz \(D_{\text{ansatz}}\), and the depth of the quantum circuit for the amplitude encoding \(D_{\text{enc}}\) are relatively small, i.e., \(\mathcal{O}(\text{poly}(n))\).

The time complexity of the previous method \cite{21} can also be evaluated through a similar procedure. Here, only the result is provided: follows:
\[
T = \mathcal{O}\left(\frac{T_{it}(D_{\text{ansatz}} + D_{\text{enc}})n^2D_{\text{ansatz}}}{\varepsilon^2}\right) \quad (41)
\]
Hence, if either the depth of the ansatz or that of the amplitude encoding is greater than \(\mathcal{O}(n)\), the proposed method has reduced time complexity compared with the previous method. As for amplitude encoding, a depth of \(\mathcal{O}(n^2)\) is required for encoding arbitrary real-valued inputs \cite{24}, which implies that the proposed method has reduced time complexity compared with the previous method.

IV. NUMERICAL EXPERIMENTS

This section describes the results of several numerical experiments that demonstrate the validity of the proposed method. The proposed method was implemented in Qiskit ver 0.16.3 \cite{27}, an open-source framework for working with quantum computers. The statevector simulator backend in Aer, which is a high-performance quantum computing simulator operating with Qiskit, was used for the calculations, except for those reported in Sec. IV B 3 where the QASM simulator backend was used. As an optimizer for updating \(\theta\), we employed the Broyden–Fletcher–Goldfarb–Shanno method \cite{28–31}, with the gradient of the cost function evaluated by quantum computing. An analytic derivation of the expression for the gradient is provided in Appendix C.

In the experiments reported below, the unitary \(U_b\) for preparing \(|f\rangle\) was set as
\[
U_b = H^\otimes n X \otimes I^\otimes (n-1) \quad (42)
\]
where \(H\) represents a Hadamard gate. This unitary \(U_b\) prepares \(|f\rangle\) in the form of a step function from \(1/2^{n/2}\) to \(-1/2^{n/2}\). The number of layers of the ansatz was fixed to five.

A. Solutions for three types of boundary conditions

First, we provide solutions obtained by the proposed method for the three types of boundary conditions to show the applicability of the proposed method to these basic types. Here, the statevector simulator backend in Aer was used to evaluate the proposed method in an ideal environment without any noise or sampling errors.

In this experiment, the optimization procedure was terminated when the norm of the gradients became less than the predetermined threshold value. The optimization was performed ten times from randomly set initial
FIG. 2. Distribution of solutions. The components of the solution vectors on each node are plotted.

parameters $\theta$ for each condition. When imposing the periodic or Neumann boundary conditions on both edges, a regularization term $\epsilon I$ with $\epsilon = 10^{-3}$ was added to the system matrix $A$ to prevent the matrix from becoming singular.

Figures 2(a)–(c) show the components of the solution vectors on each node from ten trials when $n = 5$. As shown in these figures, the solutions for the periodic and Dirichlet boundary conditions are similar to each other, whereas the Neumann boundary condition gives a totally different solution when the input vector $|f\rangle$ is prepared using the unitary operator in Eq. (42). Figures 2(a)–(c) also indicate that the proposed algorithm underestimates the norms of the solution vectors, although the directions of the solution vectors given by the proposed method are in good agreement with those from classical computing.

Figure 3 shows the trace distance $\varepsilon_{\text{tr}}$ between the solutions obtained by the proposed method and the classical computation when calculating $A^{-1}f$ with respect to the number of qubits. The trace distance $\varepsilon_{\text{tr}}$ between the trial state $|\psi(\theta)\rangle$ and the normalized ground-truth $|\bar{u}\rangle := |u\rangle / \sqrt{\langle u | u \rangle}$ is defined as

$$\varepsilon_{\text{tr}} := \frac{1}{2} \text{Tr} \left( \sqrt{\langle \psi | \psi \rangle - |\bar{u}\rangle \langle \bar{u}|} \right)^2 = \sqrt{1 - \langle \psi | \bar{u} \rangle^2}.$$  

(43)

The plots and error bars represent the mean values and the standard deviations of ten experiments. This figure shows that the trace distance $\varepsilon_{\text{tr}}$ is less than 0.01 for all cases, which results in the fidelity $|\langle \psi | \bar{u} \rangle|^2$ being greater than 0.9999. These trace distance and fidelity values compare favorably with those reported in previous research [20, 21]. Therefore, the errors between the solution vectors obtained by the proposed method and a classical approach are mainly caused by errors in the norms, and the directions of the solution vectors given by the proposed method actually agree with those from classical computing. Because the errors of the solution depend on the Hilbert space expressed by the ansatz, we hope to conduct future research on the ansatz that is most suitable for expressing the solutions of certain PDEs.
B. Comparison of the proposed method with the previous method

We now compare the proposed method with the previous approach [21] to evaluate the performance of the proposed method. In the previous method, the cost function to be minimized is formulated as

\[ E(\theta) = \langle \psi(\theta) | A (I - |f\rangle \langle f |) A | \psi(\theta) \rangle, \quad (44) \]

which corresponds to the maximization of the cosine similarity of \( A | \psi(\theta) \rangle \) and \( | f \rangle \). Because the cosine similarity does not take into account the norm information, the previous method cannot provide the norm. We also implemented the previous method using Qiskit, referring to the original paper.

In the following experiments, except those reported in Sec. IV B I, the proposed method used the Dirichlet boundary conditions imposed on both edges. The results are compared with those of the previous approach, which employed the Dirichlet boundary conditions.

1. Dependency of the number of circuit executions per cost function evaluation on the number of qubits

First, we examined the dependency of the number of circuit executions on the number of qubits to evaluate the scalability of the classical computing part of the proposed method. For randomly set parameters \( \theta \in [0, 4\pi] \), the number of circuit executions for evaluating a cost function value was recorded for both the proposed and previous methods.

Figure 4 illustrates the number of circuit executions per cost function evaluation on the number of qubits for both the proposed and previous methods [21]. This figure clearly shows that the proposed method significantly reduces the required number of expectation calculations on quantum computers.

Next, we examined the dependency of the number of optimization iterations on the number of qubits to evaluate the scalability of the classical computing part of the proposed method.

In this experiment, the terminal condition was based on the tolerance of the trace distance \( \varepsilon_{tr} \) between the trial state \( | \psi(\theta) \rangle \) and the normalized ground-truth \( | \bar{u} \rangle := | u \rangle / \sqrt{\langle u | u \rangle} \), which is the same criterion used in previous research [20]. Note that this metric only evaluates the difference in direction between the trial state and the true solution; the difference in the norm cannot be determined. In spite of this defect, we used the metric to compare the proposed method with the previous approach, which cannot provide the norm of the solution vector. The tolerance of the trace distance was successively set to \( \varepsilon_{tr} = 0.1, 0.03, 0.01 \).

For each condition, the optimization was run ten times, using randomly set initial parameters in \([0, 4\pi]\). Figure 5 shows the decadic logarithm of the number of optimization iterations with respect to the decadic logarithm of the number of qubits for both the proposed method and the previous method [21]. The plots and error bars represent the mean values and the standard deviations of ten experiments, respectively. This figure clearly shows that the number of iterations is positively correlated with the number of qubits. Although it is difficult to assert the time complexity of the number of iterations numerically because of the error bars, these plots were fitted to the lines that minimize the squared errors of fitting. The lines for the proposed method have slopes of 2.6 for \( \varepsilon_{tr} = 0.1 \), 2.3 for \( \varepsilon_{tr} = 0.03 \), and 2.5 for \( \varepsilon_{tr} = 0.01 \). This implies that \( T_{it} \) in Eq. (40) is at most \( O(n^{2.6}) \) in this experiment. For the previous method, the lines have slopes of 3.5 for \( \varepsilon_{tr} = 0.1 \), 3.6 for \( \varepsilon_{tr} = 0.03 \), and 4.2 for \( \varepsilon_{tr} = 0.01 \). Therefore, it seems that the number of iterations with respect to the number of qubits is of similar order in both the proposed method and the previous method.

3. Dependency of the sampling errors on the number of shots

Next, we examined the effect of the number of shots on the expectation estimations. The QASM simulator backend was used to evaluate the sampling errors in the environment without any noise.

For randomly set parameters \( \theta \in [0, 4\pi] \), the squared error between the ground-truth and the estimation value of the cost function was evaluated. The former was calculated by the statevector simulator and the latter by the QASM simulator (i.e., sampling). The cost function was evaluated ten times by sampling for each number of shots.

Figure 6 shows the decadic logarithm of the squared
FIG. 5. Decadic logarithm of the number of optimization iterations $T_{it}$ vs. the number of qubits $n$ for both the proposed and previous methods [21]. The points show the mean values of ten experiments and the fitted lines minimize the squared errors of fitting. The error bars represent the standard deviation of ten experiments.

FIG. 6. Decadic logarithm of the squared error $\epsilon^2$ vs. the number of shots $S$ for the proposed method. The optimization was run ten times with fixed parameters for each number of shots. The mean values are plotted, with the error bars representing the standard deviations. The mean and standard deviation of the slopes are $-1.11$ and $0.12$, respectively. The points show the mean values of the ten experiments and the error bars represent their standard deviations. Fitting lines are also provided in the plots. This figure clearly indicates that the squared error decreases as the number of shots increases. The mean and standard deviation of the slopes of the fitted lines are $-0.92$ and $0.16$, respectively. Although a comparison of the proposed and previous methods from these figures is difficult because of the different definitions of the cost function, it can be deduced that the mean squared error in the cost function evaluation has a similar dependency on the number of shots in both methods.

In addition to the cost function evaluation, it is also important to precisely evaluate the gradients when using a gradient-based optimization method. Therefore, we also evaluated the errors between the gradient evaluated by the sampling obtained using the QASM simulator and that computed by the statevector simulator with fixed parameters.

As a metric to evaluate the errors, we used the cosine similarity, which measures the similarity of directions, as the directions of the gradients are more important to optimizers than their norms. Figure 7 shows the decadic logarithm of “$1 - \cosine similarity$” with respect to the number of shots for both the proposed and previous methods. This figure clearly shows that the cosine similarity increases as the number of shots increases. The means and standard deviations of the slopes of the fitted lines are $-0.92$ and $0.17$ for our proposed method and $-0.97$ and $0.02$ for the previous method, respectively. Therefore, it seems that the gradient estimation for a given number of shots is of similar order in both the proposed and previous methods.

However, we can clearly observe that the proposed method has longer error bars, i.e., a larger standard devi-
FIG. 7. Decadic logarithms of cost function error $\varepsilon$ vs. the number of shots $S$ for the previous method [21] based on our implementation. The optimization was run ten times with fixed parameters for each number of shots. The mean values are plotted, with the error bars representing the standard deviations. The mean and standard deviation of the slopes of the fitted dashed line are $-1.01$ and $0.04$, respectively.

FIG. 8. Decadic logarithms of “$1 - \cosine similarity$” vs. the number of shots $S$ for the proposed and previous methods [21] based on our implementation. The optimization was run ten times with fixed parameters for each number of shots. The mean values are plotted, with the error bars representing the standard deviations. The means and standard deviations of the slopes of the fitted lines are $-0.92$ and $0.16$ for the proposed method and $-0.97$ and $0.02$ for the previous method, respectively.

V. CONCLUSIONS

This paper has presented a VQA for solving the Poisson equation based on the minimum potential energy. The main contributions of the present study are as follows: 1) we have provided an explicit decomposition of the system matrix for the Poisson equation into $O(n^0)$ terms consisting of simple observables, 2) the proposed method provides information about the norm of the solution vectors in addition to its direction, and 3) the time complexity of the proposed algorithm has been derived and verified. The first contribution implies that the proposed method only requires a small number of quantum measurements, compared with conventional approaches, at every iteration of the optimization procedure. The second contribution enhances the ability of VQAs to solve PDEs, because the norm information is essential when using the calculation results for engineering developments. As for the third contribution, we estimated the time complexity of the proposed method, and demonstrated that it has significant potential for reducing the computation time of classical computing algorithms. The number of optimization iterations and the depth of the ansatz depend on the classical optimization and the architecture of the ansatz, respectively. To derive the theoretical total time complexity, these aspects will be discussed in future work.

We believe the present study elevates the application of quantum computing to the field of computer-aided engineering and, moreover, design optimization.
FIG. 9. Example of tessellations for an 8-node cycle graph. Red and blue ellipses indicate the tessellations $T_{\text{even}}$ and $T_{\text{odd}}$, respectively.

Appendix A: Decomposition of stiffness matrix in finite element methods using graph theory

First, a one-dimensional problem is considered. Let us consider an $N$-node cycle graph $G = (V, E)$, where $V$ and $E$ represent node and edge sets, respectively. This $N$-node cycle graph corresponds to the one-dimensional finite element with a periodic boundary condition. A clique is defined as a subset of several nodes that form a complete subgraph. A tessellation $T$ is then defined as a set of cliques such that all nodes belong to one clique. The tessellation $T$ includes edges whose endpoints belong to the tessellation. Generally, several tessellations can be defined in a graph, and there exists a set of tessellations such that all edges of the graph are included in at least one tessellation. Such a set of tessellations is called a tessellation cover. Assuming that $N = 2^n$, two tessellations of the tessellation cover of the $N$-node cycle graph can be defined as

$$T_{\text{even}} := \{C_{2i} \mid i \in [0, 2^{n-1} - 1]\} \quad (A1)$$

$$T_{\text{odd}} := \{C_{2i+1} \mid i \in [0, 2^{n-1} - 1]\}, \quad (A2)$$

where $C_i := \{v_i, v_{i+1}\}$ is a clique consisting of the $i$-th node $v_i$ and the $(i+1)$-th node $v_{i+1}$. Note that we define $v_N := v_0$ to simplify the notation.

Figure 9 illustrates an example of these tessellations for an 8-node cycle graph, where the red line represents a tessellation $T_{\text{even}}$ and the blue dashed-dotted line represents the other tessellation $T_{\text{odd}}$.

The decomposed matrices $A_{T_{\text{even}}}$ and $A_{T_{\text{odd}}}$ in Eqs. (17) and (18) can then be expressed as the sums of the element stiffness matrices related to elements in each tessellation $T_{\text{even}}$ and $T_{\text{odd}}$, respectively.

The above discussion can easily be extended to two-dimensional problems. Let us consider the finite element method in the two-dimensional Poisson equation. For a first-order quadrilateral element of length 1 in Fig. 10(a) the element stiffness matrix is described as

$$A_e := \frac{1}{6} \begin{bmatrix}
4 & -1 & -1 & -2 \\
-1 & 4 & -2 & -1 \\
-1 & -2 & 4 & -1 \\
-2 & -1 & -1 & 4
\end{bmatrix}$$

Now, let us describe the total stiffness matrix for the mesh in Fig. 10(b) using the Pauli operators. Here, for simplicity, we assume that periodic boundary conditions are imposed on all edges of the mesh. Let $N_x$ and $N_y$ denote the number of columns and rows of nodes, respectively. That is, the number of nodes is $N = N_x \times N_y$. For example in Fig. 10(b) $N_x = 4$ and $N_y = 4$.

We now define a graph corresponding to the mesh, as shown in Fig. 10(c). Each node $v_i$ of the graph corresponds to node $i$ of the mesh, and the graph has edges between nodes within the same elements. Because of the periodic boundary conditions, nodes corresponding to the edges of the mesh are also connected, e.g., $v_0$ and $v_3$, $v_0$ and $v_12$, and so on. For clear visibility, nodes with dashed circles are added on the upper and right sides.

Assuming that $N_x = 2^{n_x}$ and $N_y = 2^{n_y}$, four tessellations in the tessellation cover of the $N$-node graph can be defined as

$$T_0 := \{C_{2i_x+2i_yN_x} \mid i_x \in [0, 2^{n_x} - 1], i_y \in [0, 2^{n_y} - 1]\} \quad (A4)$$

$$T_1 := \{C_{2i_x+2i_yN_x + 1} \mid i_x \in [0, 2^{n_x} - 1], i_y \in [0, 2^{n_y} - 1]\} \quad (A5)$$

$$T_2 := \{C_{2i_x+2i_yN_y} \mid i_x \in [0, 2^{n_x} - 1], i_y \in [0, 2^{n_y} - 1]\} \quad (A6)$$

$$T_3 := \{C_{2i_x+2i_yN_y + 1} \mid i_x \in [0, 2^{n_x} - 1], i_y \in [0, 2^{n_y} - 1]\}, \quad (A7)$$

respectively.

Let $|i\rangle$ be the quantum state corresponding to node $v_i$ of the graph. The quantum state $|i\rangle$ consists of two quantum registers, $|i_x\rangle$ and $|i_y\rangle$, for each direction, as $|i\rangle := |i_y\rangle |i_x\rangle$, where $|i_x\rangle$ and $|i_y\rangle$ consist of $n_x$ and $n_y$
qubits, respectively. The sum of the element stiffness matrix for the elements related to the tessellation \( T_0 \), denoted as \( A_{T_0} \), can then be expressed as

\[
A_{T_0} = \frac{1}{6} \left( 4(I \otimes n_y - 1) \otimes (I \otimes n_x - 1) - (I \otimes n_y - 1) \otimes (I \otimes n_x - 1) X \right)
\]

\[
- (I \otimes n_x - 1) \otimes (I \otimes n_y - 1) X - 2(I \otimes n_x - 1) \otimes (I \otimes n_y - 1) X)
\]

where \( P_y \) is a shift operator in the \( y \)-direction defined as

\[
P_y := \sum_{i_y \in [0, 2^n-1]} |i_y \rangle \langle i + 1 | \langle i |.
\]

Consequently, the total stiffness matrix \( A \) can be described as the sum of the stiffness matrices related to each tessellation:

\[
A = A_{T_0} + A_{T_1} + A_{T_2} + A_{T_3}.
\]

For Dirichlet and Neumann boundary conditions, we just have to add terms to adjust the stiffness matrices of edge elements.

Appendix B: Derivation of the mean squared error between the exact cost function and that estimated by sampling

Here, the mean squared error between the exact cost function value and that estimated by sampling is derived
using the Taylor series expansion. The first-order Taylor
series expansion of $g(\bar{q}_1, \ldots, \bar{q}_m)$ around $\mu_i$ for $i \in [1, m]$ is given as

$$g(\bar{q}_1, \ldots, \bar{q}_m) = E_h + \sum_{i=1}^{m} \frac{\partial g}{\partial \bar{q}_i} \bigg|_{\bar{q}_i = \mu_i} (\bar{q}_i - \mu_i) + o ((\bar{q}_i - \mu_i)^2), \quad (B1)$$

where

$$g(\bar{q}_1, \ldots, \bar{q}_m) = \frac{1}{2} \sum_{i=2}^{m} \frac{\bar{q}_i^2}{\mu_i}.$$  

(B2)

Assuming that $\text{Cov}(\bar{q}_i, \bar{q}_j) = 0$ for $i \neq j$, the mean squared error between the exact cost function value and that estimated by sampling can be evaluated as follows:

$$\varepsilon^2 = \mathbb{E}[(g - E_h)^2]$$

$$\approx \mathbb{E} \left[ \left( \sum_{i=1}^{m} \frac{\partial g}{\partial \bar{q}_i} \bigg|_{\bar{q}_i = \mu_i} \frac{\partial g}{\partial \bar{q}_j} \bigg|_{\bar{q}_j = \mu_j} (\bar{q}_i - \mu_i)(\bar{q}_j - \mu_j) \right)^2 \right]$$

$$= \sum_{i=1}^{m} \sum_{j=1}^{m} \frac{\partial g}{\partial \bar{q}_i} \bigg|_{\bar{q}_i = \mu_i} \frac{\partial g}{\partial \bar{q}_j} \bigg|_{\bar{q}_j = \mu_j} \mathbb{E}[(\bar{q}_i - \mu_i)(\bar{q}_j - \mu_j)]$$

$$= \sum_{i=1}^{m} \left( \frac{\partial g}{\partial \bar{q}_i} \bigg|_{\bar{q}_i = \mu_i} \right)^2 \sigma_i^2 \frac{\mu_i^2}{(\sum_{i=2}^{m} \mu_i^2 S_i^2) + \frac{1}{4} \sum_{i=2}^{m} \sum_{j=2}^{m} \sigma_i^2 S_j^2}$$

$$= \frac{\mu_i^2 \sigma_i^2}{(\sum_{i=2}^{m} \mu_i^2 S_i^2) + \frac{1}{4} \sum_{i=2}^{m} \sum_{j=2}^{m} \sigma_i^2 S_j^2}$$

$$= r_{\text{opt}}^2 \left( \frac{\sigma_i^2}{S_i^2} + \frac{1}{4} r_{\text{opt}}^2 \sum_{i=2}^{m} \frac{\sigma_i^2}{S_i^2} \right), \quad (B3)$$

where $\delta_{ij}$ is Kronecker’s delta. The assumption that $\text{Cov}(\bar{q}_i, \bar{q}_j) = 0$ for $i \neq j$ is based on the assumption that, in quantum computers, each shot is mutually independent. In the last transformation, we have used the following equation:

$$r_{\text{opt}} = \frac{\langle f, \psi \mid X \otimes I^\otimes n \mid f, \psi \rangle}{\langle \psi \mid A \mid \psi \rangle}$$

$$= \frac{\mu_1}{\sum_{i=2}^{m} \mu_i}. \quad (B4)$$

Appendix C: Derivative of the cost function

The gradient of the cost function in Eq. (11) is now derived. The partial derivative of the cost function with respect to the parameters $\theta$ yields

$$\frac{\partial E_h}{\partial \theta} = - \left( \langle f, \psi(\theta) \mid X \otimes I^\otimes n \mid f, \psi(\theta) \rangle \right) \frac{\partial}{\partial \theta} \left( \langle f, \psi(\theta) \mid X \otimes I^\otimes n \mid f, \psi(\theta) \rangle \right) \frac{\partial}{\partial \theta} \langle \psi(\theta) \mid A \mid \psi(\theta) \rangle$$

$$+ \frac{1}{2} \left( \langle f, \psi(\theta) \mid X \otimes I^\otimes n \mid f, \psi(\theta) \rangle \right)^2 \frac{\partial}{\partial \theta} \langle \psi(\theta) \mid A \mid \psi(\theta) \rangle^2.$$

(C1)

Recalling that $|\psi(\theta)\rangle = U(\theta)|0\rangle^\otimes n$, where $U(\theta)$ is a sequence of parameterized quantum gates, the following holds for the $i$-th parameter $\theta_i$:

$$\frac{\partial}{\partial \theta_i} |\psi(\theta)\rangle = \frac{\partial}{\partial \theta_i} U(\theta)|0\rangle^\otimes n$$

$$= \frac{1}{2} U(\theta_1, \theta_2, \ldots, \theta_i + \pi, \ldots) |0\rangle^\otimes n, \quad (C2)$$
under the assumption that the parameterized gates consist of either $R_X$, $R_Y$, or $R_Z$ gates. Note that
\[
|\psi(\theta),i\rangle := U(\theta_1, \theta_2, \ldots, \theta_i + \pi, \ldots) |0\rangle^\otimes n
\] (C3)
is a quantum state because $U(\theta_1, \theta_2, \ldots, \theta_i + \pi, \ldots)$ is a unitary operator.

Now, recall that $|f, \psi(\theta)\rangle := (|0\rangle |f\rangle + |1\rangle |\psi(\theta)\rangle) / \sqrt{2}$, which yields
\[
\frac{\partial}{\partial \theta_i} \langle f, \psi(\theta) | X \otimes I^\otimes n | f, \psi(\theta) \rangle
= \frac{1}{4} (\langle \psi(\theta),i | f \rangle + \langle f | \psi(\theta),i \rangle)
= \frac{1}{2} \langle f, \psi(\theta),i | X \otimes I^\otimes n | f, \psi(\theta),i \rangle,
\] (C4)
where $|f, \psi(\theta),i\rangle := (|0\rangle |f\rangle + |1\rangle |\psi(\theta),i\rangle) / \sqrt{2}$. The following equation also holds:
\[
\frac{\partial}{\partial \theta_i} \langle \psi(\theta),i | A | \psi(\theta) \rangle
= \frac{1}{2} \left( \langle \psi(\theta),i | A | \psi(\theta) \rangle + \langle \psi(\theta) | A | \psi(\theta),i \rangle \right)
= \langle \psi(\theta),i, \psi(\theta) | X \otimes A | \psi(\theta),i, \psi(\theta) \rangle,
\] (C5)
where $|\psi(\theta),i, \psi(\theta)\rangle := (|0\rangle |\psi(\theta),i\rangle + |1\rangle |\psi(\theta)\rangle) / \sqrt{2}$.

Substituting Eqs. (C4) and (C5) into Eq. (C1), the gradient of the cost function is derived as
\[
\frac{\partial E_h}{\partial \theta_i} = \frac{1}{2} \frac{\langle f, \psi(\theta),i | X \otimes I^\otimes n | f, \psi(\theta) \rangle \langle f, \psi(\theta),i | X \otimes I^\otimes n | f, \psi(\theta),i \rangle}{\langle \psi(\theta) | A | \psi(\theta) \rangle}
+ \frac{1}{2} \frac{\langle f, \psi(\theta) | X \otimes I^\otimes n | f, \psi(\theta) \rangle^2 \langle \psi(\theta),i, \psi(\theta) | X \otimes A | \psi(\theta),i, \psi(\theta) \rangle}{\langle \psi(\theta) | A | \psi(\theta) \rangle^2}.
\] (C6)
