(Dated: June 21, 2021)

We demonstrate the transfer of $^{23}\text{Na}^{40}\text{K}$ molecules from a closed-channel dominated Feshbach-molecule state to the absolute ground state. The Feshbach molecules are initially created from a gas of sodium and potassium atoms via adiabatic ramping over a Feshbach resonance at 78.3 G. The molecules are then transferred to the absolute ground state using stimulated Raman adiabatic passage with an intermediate state in the spin-orbit-coupled complex $|c^2\Sigma^+, v = 35, J = 1\rangle \sim |B^2\Pi, v = 12, J = 1\rangle$. Our measurements show that the pump transition dipole moment linearly increases with the closed-channel fraction. Thus, the pump-beam intensity can be two orders of magnitude lower than is necessary with open-channel dominated Feshbach molecules. We also demonstrate that the phase noise of the Raman lasers can be reduced by filter cavities, significantly improving the transfer efficiency.

I. INTRODUCTION

In the last years, ultracold molecules have emerged as a promising tool of quantum metrology, quantum simulation, and quantum computation. The field is now growing rapidly as evidenced by the recent cooling of multiple new molecular species. However, the creation of ultracold molecules is still a significant undertaking. Streamlining of experimental methods is therefore an important goal. Here, we present an improved and simplified method for the creation of ultracold $^{23}\text{Na}^{40}\text{K}$ molecules in their absolute ground state.

Presently, the most controlled method for preparing samples of ultracold bialkali molecules is to first create a mixture of atoms and employ a Feshbach resonance to form molecules in a weakly bound spin-triplet state. These molecules exhibit only a small body-fixed dipole moment and are therefore typically transferred into the rovibrational ground state using stimulated Raman adiabatic passage (STIRAP). This method has been applied successfully to the species $^{40}\text{K}^{57}\text{Rb}$, $^{87}\text{Rb}^{133}\text{Cs}$, $^{23}\text{Na}^{40}\text{K}$, $^{23}\text{Na}^{87}\text{Rb}$, $^{23}\text{Na}^6\text{Li}$, and $^{23}\text{Na}^{39}\text{K}$. The $^{23}\text{Na}^{40}\text{K}$ molecule is a particularly interesting candidate for the creation of dipolar quantum gases due to its fermionic statistics and its comparatively large body-fixed dipole moment of 2.7 D.

STIRAP is still associated with considerable technical challenges as it requires two lasers with linewidths on the level of kilohertz or smaller, often at wavelengths not available with diode lasers. Furthermore, the transition dipole moments of the STIRAP transitions are small for some species, requiring high laser powers to reach adequate Rabi frequencies. For example, the first demonstration of STIRAP with $^{23}\text{Na}^{40}\text{K}$ was carried out with a Ti:sapphire laser for the pump pulse at 805 nm and a dye laser for the Stokes pulse at 567 nm. A later implementation used tapered amplifiers seeded by diode lasers in combination with second-harmonic generation. In our own previous work, we employed a different pathway with the pump pulse provided by a diode laser at 488 nm and the Stokes pulse by a dye laser at 652 nm.

Our new method enables a transfer efficiency of 80% using only two external-cavity diode lasers, an injection amplifier, and a single-pass second-harmonic generation module. This is possible due to an improved way of creating Feshbach molecules, allowing a larger overlap between the initial Feshbach-molecule state and the intermediate excited state. We also reduce off-resonant frequency components in the laser light by employing filter cavities with moderate finesse. Compared to the unfiltered laser light, this allows a significant increase in STIRAP transfer efficiency.

II. ASSOCIATION OF FESHBACH MOLECULES

We begin our experiments by preparing a gas of $1 \times 10^5$ sodium atoms in the state $|F = 1, m_F = 1\rangle$ and $2 \times 10^5$ potassium atoms in $|F = 9/2, m_F = -9/2\rangle$, where $F$ denotes the total atomic angular momentum and $m_F$ its projection onto the magnetic field direction. The atomic mixture is prepared in a crossed-beam optical dipole trap with trap frequencies of $2\pi \times (50, 72, 191)$ Hz for Na and $2\pi \times (54, 88, 223)$ Hz for K in the $(x, y, z)$ directions, respectively, where the z-axis points along the direction of gravity. At the end of the preparation, we reach a temperature of about 300 nK at a magnetic field of 80.3 G, where the inter-species scattering length vanishes. We then ramp the magnetic field over a Feshbach resonance at 78.3 G in three steps to create about $4 \times 10^4$ weakly...
bound Feshbach molecules. The association procedure is shown in Fig. 1(a). In the first part, we quickly ramp the field to 79.2 G, slightly above the resonance, over 100 μs. The second ramp, where the actual association of Feshbach molecules happens, changes the field to 77.8 G within 470 μs. The duration and the end point of this ramp are chosen to optimize the association efficiency. However, at 77.8 G, the molecules are highly unstable against collisions with residual atoms, so we perform a third ramp to a final field of 72.4 G within 100 μs to minimize inelastic atom-molecule collisions. The value of the final field is chosen because the following STIRAP transfer is least sensitive to field fluctuations at this field. To achieve optimal stability for STIRAP and following experiments, the final ramp is performed with a feed-forward procedure, which is designed to minimize the effect of eddy currents in conductive parts of the apparatus close to the molecule sample. Finally, we apply a magnetic-field gradient of 40 G/cm for a duration of 20 ms, which removes residual atoms from the dipole trap while leaving the Feshbach molecules unaffected due to their lack of magnetic moment.

The Feshbach-molecule state |FB⟩ can be described as a superposition of the open-channel part, which corresponds to two unbound atoms, and the closed-channel part, which corresponds to the least-bound vibrational level of the electronic a3Σ− manifold. As shown in Fig. 2(b), the relative weight of the open- and closed-channel contributions depend on the magnetic field, with the closed-channel fraction becoming larger for the more deeply-bound Feshbach molecules far below the resonance.

III. STIRAP SETUP

The STIRAP pathway relies on an intermediate excited state |E⟩ in the complex |e3Σ+, ν = 35, J = 1⟩ ∼ |B3Π, ν = 12, J = 1⟩, the same which was previously used in [21] [26]. This state features strong mixing between triplet (64%) and singlet (36%) states [20], making it ideal for transfer from the triplet Feshbach-molecule state to the singlet ground state |G⟩ = |X1Σ+, ν = 0, J = 0⟩. Here, ν stands for the vibrational quantum number and J for the total angular momentumexcluding nuclear spin. The contribution of different nuclear spin states to the intermediate state is given in Table I.

To address this intermediate state, we generate light at 567 nm and 805 nm with the setup shown in Fig. 3. The setup is based on two external-cavity diode lasers (DLPro, Toptica) at wavelengths of 1134 nm and 805 nm, and an ultrastable, dual-wavelength optical cavity (Stable Laser Systems) of finesse \( F_{1134} = 3.530(6) \times 10^4 \) and \( F_{805} = 4.58(12) \times 10^4 \) at these wavelengths, respectively. The reference cavity spacer is made of ultra-low-expansion (ULE) material and is mounted inside a vacuum chamber at a pressure of \( 1.3 \times 10^{-6} \) mbar. The
We employ fiber-coupled EOMs (PM830 and PM1170, Jenoptik) to modulate sidebands at frequencies of up to 750 MHz onto each laser beam and subsequently lock these sidebands to the reference cavity using the Pound-Drever-Hall (PDH) locking technique [33]. In combination with the cavity’s free spectral range of 1.5 GHz, this allows us to stabilize the lasers to any frequency within their operation range. The fiber EOMs also exhibit very low residual amplitude modulation compared to bulk EOMs. We stabilize the input laser powers of the ULE cavity to minimize its thermal drift due to light absorption on the cavity mirrors. Using this lock, we achieve a long-term stability which is limited by the cavity spacer’s aging process, which initially causes a linear frequency drift on the order of $2\pi \times 5$ kHz per day. The drift slows down exponentially with a measured time constant of 375 days as the spacer approaches equilibrium [34, 35].

We characterize the quality of the laser lock by the power spectrum of the in-loop PDH error signal. From this, the phase noise power spectral density $\mathcal{L}(\omega)$ can be determined as described in Ref. [36], see Fig. 4. At sufficiently high frequencies and small modulation, the integral of $\mathcal{L}(\omega)$ is equal to the total power in the phase noise pedestal $P_\phi$. The servo bumps of the PDH lock are at frequencies of $2\pi \times 1.2$ MHz. The integrated power of the laser’s phase noise pedestal is almost exclusively in these servo bumps and is about 0.6% of the total laser power. As described in section [VC] the servo bumps are in a frequency range which is especially problematic for STIRAP efficiency. Hence we reduce the power in the servo bumps using two optical filter cavities with finesse $F = 4430(14)$ and $F = 5110(30)$ for the 1134-nm and the 805-nm light, respectively. Using piezo-driven mirrors, the filter cavities are PDH-locked to achieve optimal transmission. Sending the light through these cavities is
expected to reduce the servo bumps by 22 dB. A Faraday isolator is used before the filter cavity input to block detrimental back-reflection into the ULE-cavity setup.

The 1134-nm light is then injection-amplified to a total power of 105 mW using an anti-reflection-coated gain chip (GC-1180-100-TO-200-B, Innolume), and frequency-doubled in a single-pass periodically-poled lithium-niobate waveguide (HC Photonics) to create 3 mW of 567-nm light. Both beams are sent to the experimental chamber through shutters and acousto-optical modulators, which allow us to create the desired pulse shape for STIRAP. As previously discussed in Refs. [25, 37, 38], we use a pulse shape given by

\[
I(t) = \begin{cases} 
I_0 \cos^2 \left( \frac{\omega t}{2} \right), & -\tau < t < \tau \\
0 & \text{otherwise}
\end{cases}
\]  

(1)

with the peak intensity \(I_0\), see Fig. 1(b). The beam intensities are independently chosen to achieve comparable Rabi frequencies of around \(2\pi \times 2.5\) MHz for each beam. For the transfer to the ground state, the Stokes pulse precedes the pump pulse by \(\tau\), for the reverse transfer they are interchanged. For both pump pulses, one half is cut off, which simplifies our experimental control with no impact on the STIRAP itself.

IV. RESULTS

A. Spectroscopy of the pump and Stokes transitions

We performed photoassociation spectroscopy on Feshbach-molecule samples to identify our target intermediate state as previously described in the work of Park et al. [20]. We found the STIRAP intermediate state at a pump laser frequency of \(2\pi \times 372\,554\,391(1)\) MHz, as determined using a beat note with an optical frequency comb. In the following, the pump laser frequency is given as a detuning \(\Delta_p\) relative to this transition.

To find the correct frequency for the Stokes beam, we performed dark-state spectroscopy of the ground state. For this, the Feshbach molecules were illuminated with both the pump and Stokes beam simultaneously for 200 \(\mu\)s. The intensities were 5 W/cm\(^2\) and 4 mW/cm\(^2\) for the pump and Stokes beam, respectively, at a beam waist of 30 \(\mu\)m \(\times\) 100 \(\mu\)m for both beams. The pump light was kept on resonance with the intermediate state while the Stokes beam frequency was scanned. With the Stokes beam away from resonance, the pump beam power is sufficient to photoassociate all Feshbach molecules during the illumination time. However, when the Stokes beam becomes resonant, the light shift of the excited state prevents photoassociation, thus showing up as increased remaining molecule numbers. We scanned the hyperfine structure of the rovibrational ground state for both horizontal and vertical polarization of the Stokes beam and assigned the observed peaks to find the absolute ground state (see Fig. 5). This state has \(m_F = -5/2\) character and we determined the Stokes transition frequency to be \(2\pi \times 528\,805\,718(1)\) MHz. The detuning of the Stokes laser from this frequency is denoted by \(\Delta_S\). As the pump frequency remained the same throughout the measurement, the two-photon detuning \(\delta = \Delta_S - \Delta_p\) was changed together with the Stokes detuning, and the one-photon detuning \(\Delta = \Delta_p\) was always zero. In combination with the photoassociation data, these measurements yielded a binding energy of the absolute ground state of \(5212.044\,43(3)\) cm\(^{-1}\), relative to the hyperfine center of mass of the free atoms, consistent with the value found in Ref. [20].

B. Determination of Rabi frequencies

Next, we performed two-photon spectroscopy on Feshbach-molecule samples to determine the Rabi frequencies associated with the two transitions. To obtain the spectra, Feshbach molecules were illuminated with the Stokes beam at a high intensity of around 50 W/cm\(^2\). Its frequency was kept close to the previously determined value for the transition, i.e. \(\Delta_S \approx 0\). Hence, for this measurement, the condition \(\delta = \Delta\) was always fulfilled. While the Stokes beam remained on, the pump beam was added for 50 \(\mu\)s at various detunings. Note that we kept the convention of naming the transitions “pump” and “Stokes”, as is typical for STIRAP, even though in the context of the measurements in this section, they are usually called “probe” and “coupling”, respectively [39]. After the illumination, we measured the number of remaining molecules. The resulting spectrum features a dark state of the system where no molecules are lost when both lasers are on resonance, i.e. \(\Delta = 0\). Tuning \(\Delta\) reveals two dips, which are split by the Stokes laser Rabi frequency \(\Omega_S\). The shape of the entire feature is
described by \[ N = N_0 \exp \left( -\Delta \Omega_p^2 / \Omega_s^2 + 2i \delta \left( \gamma + 2i \Delta \right) \right), \] (2)

where \( N \) and \( N_0 \) are the remaining and initial molecule numbers, respectively, \( \gamma \) is the linewidth of the intermediate state \(|E\rangle\), and \( t \) is the duration of the pump pulse. Since in our case \( \gamma \approx \Omega_s \), we are in an intermediate regime between electromagnetically induced transparency (EIT), which results purely from interference, and Autler-Townes splitting, which results from a light shift due to the strong Stokes beam \[39\].

We then prepared Feshbach molecules at different magnetic background fields by performing an additional magnetic field ramp after the completion of the clearout. This allowed us to vary the closed-channel fraction of molecules and investigate its effect on the transition dipole moments of the pump and Stokes transitions. To this end, we determined the normalized Rabi frequencies \( \Omega_p = \Omega_p / \sqrt{T_p} \) and \( \Omega_s = \Omega_s / \sqrt{T_s} \) by fitting Eq. (2) to the obtained spectra. The normalized Rabi frequencies are directly proportional to the respective transition dipole moments. Here, \( I_p \) (\( I_s \)) stands for the intensity of the pump (Stokes) beam. As the results in Fig. 6 show, \( \Omega_p \) is approximately proportional to the closed-channel fraction. This is expected because only the closed-channel part of the Feshbach-molecule state couples with the excited state.

For near-zero closed-channel fractions, we find \( \Omega_p = 2 \pi \times 0.8 \text{kHz}/\sqrt{\text{mW/cm}^2} \), which is comparable to the value previously reported in Ref. \[20\] using Feshbach molecules created via radiofrequency association. In contrast, \( \Omega_s \) remains essentially constant, as the states \(|E\rangle\) and \(|G\rangle\) are only weakly affected by the magnetic field. At \( B = 72.4 \text{G} \), which corresponds to a closed-channel fraction of 0.84, we find \( \Omega_p = 2 \pi \times 6.3(4) \text{kHz}/\sqrt{\text{mW/cm}^2} \) and \( \Omega_s = 2 \pi \times 142(8) \text{kHz}/\sqrt{\text{mW/cm}^2} \). The measured excited-state linewidth is \( \gamma = 2 \pi \times 11(1) \text{MHz} \). Thus, the transition dipole moment of the pump transition at \( B = 72.4 \text{G} \) is 14 times larger than was demonstrated in Ref. \[20\] with a closed-channel fraction of a few percent. This means the same STIRAP efficiency can be achieved with two orders of magnitude lower laser intensity, making amplification of the pump laser unnecessary. The summary of the performance achieved with previous STIRAP setups shown in Table \[11\] provides some context to this result.
TABLE II. Overview of experimentally investigated STIRAP schemes from Feshbach states to $X^1\Sigma^+$ rovibrational ground states of bialkali molecules. 1 kHz/√mW/cm² corresponds to a transition dipole moment of $9.0 \times 10^{-7}$ $\text{cm mW}$. The pump and Stokes laser wavelengths are denoted by $\lambda_p$ and $\lambda_S$, respectively. Note that STIRAP has not yet been demonstrated for some of the listed transition pairs.

| a | A Feshbach state with a strong singlet contribution was used, avoiding the need for singlet-triplet mixing in the intermediate state. |
| b | This efficiency was achieved with off-resonant Raman scattering rather than with STIRAP. |
| c | Ref. [45] reported a different value of $\gamma = 2\pi \times 35(3)$ kHz. |

### C. STIRAP and laser noise reduction

Finally, we used STIRAP to transfer Feshbach molecules into the absolute ground state $X^1\Sigma^+$, $v = 0$, $|J, m_J, m_I, m_N, m_{I,K}, l_K\rangle = |0, 0, 3/2, -4\rangle$. For this lasers were tuned to $\Delta = \delta = 0$ and the previously discussed pulse sequence was applied. Initially, we attempted STIRAP without the use of filter cavities and observed a strong dependence of the one-way STIRAP efficiency $\eta$ on the pulse duration $\tau$, as well as an overall low one-way efficiency of $\eta = 64\%$.

This poor result can be explained with the theoretical framework developed in Refs. [37, 38] to describe the effect of laser noise on STIRAP efficiency. Following this theory, we expect a STIRAP efficiency described by

$$\eta = \exp\left(-\frac{\pi^2 \gamma}{\Omega^2 \tau} - \frac{D}{4} + \frac{\Omega^2 G P_n}{8G^2 + 4G \gamma + 2D^2}\right).$$

Here, $D$ stands for the full-width at half-maximum laser linewidth and $G$ for the width of the laser noise pedestal. The total noise power, i.e., the sum of phase and intensity noise power, is denoted $P_n$. The first term inside the exponential function corresponds to loss caused by non-perfect adiabaticity of the transfer. The second term corresponds to the noise contribution from finite laser linewidth. The third term accounts for losses caused by the presence of a wide noise pedestal. To obtain this equation from Refs. [37, 38], we assumed that $G$, $P_n$ and $\Omega$ of the pump and Stokes lasers are equal.

According to Eq. 3 noise at frequencies close to the Rabi frequency is especially detrimental to the transfer efficiency, and this effect becomes stronger at long pulse durations. This problem can be partially mitigated by increasing Rabi frequencies or choosing smaller values of $\tau$. However the line-broadening caused by this can cause other problems such as unwanted addressing of off-resonant hyperfine levels [26]. Therefore, a reduction of the servo bumps should be an effective method to improve STIRAP efficiency. We tested this hypothesis by adding filter cavities as described in section 11.1. This indeed led to an improvement to $\eta = 80\%$. In addition, the optimal value of $\tau$ was increased from 15 $\mu$s to 25 $\mu$s.

Even though the model in Eq. 3 is built on the as-
We have demonstrated that, by using magnetoassociation on the Feshbach resonance at $B = 78.3$ G, the closed-channel fraction of Feshbach molecules of $^{23}$Na$^{40}$K can be increased to up to 90%. This leads to increased pump transition strengths for STIRAP to the absolute ground state and allows us to achieve equal or better transfer efficiencies than previously demonstrated with a simpler setup. We have also shown that the use of filter cavities is an effective method to reduce detrimental laser noise and to increase STIRAP efficiency. The analytical model developed by Yatsenko et al. offers a simple and effective way to estimate the improvement that can be achieved by noise reduction. In future work, it may be possible to further improve the transfer efficiency by increasing the Rabi frequencies and reducing the intensity noise of the filter-cavity transmission. In the case of RbCs and NaRb, molecules with a narrow linewidth intermediate state, where Feshbach states with a relatively large closed-channel fraction have previously been employed, conversion efficiencies of 90% or better have been demonstrated with low Rabi frequencies. We therefore expect that noise reduction, for example with filter cavities, in a STIRAP scheme with a narrow-linewidth intermediate state will allow reaching near-unit efficiencies. This is an important requirement for high-fidelity state preparation and detection for future molecule quantum gas microscopes as well as quantum computation with molecule arrays.

**V. CONCLUSION**

We thank Eberhard Tiemann for providing a coupled-channel calculation of the Feshbach resonance and Fengdong Jia for his help with the cavity vacuum setup. We also thank Xiangliang Li and Fabian Schmid for insightful discussions. We gratefully acknowledge support from the Max Planck Society, the European Union (PASQuanS Grant No. 817482) and the Deutsche Forschungsgemeinschaft under grants No. 390814868 and FOR 2247.
