Abstract

We report a new doorway mechanism for the dissociative electron attachment to genetic materials. The dipole-bound anion acts as the doorway for electron capture in the genetic material. The electron gets subsequently transferred to a sugar-phosphate or sugar-nucleobase bond, leading to their cleavage. The electron transfer is mediated by the mixing of electronic and nuclear degrees of freedom. The cleavage rate of the sugar-phosphate bond is higher than the breaking of the sugar-nucleobase bond, and both processes are considerably slower than the formation of a stable valence-bound anion.

Radiation therapy is one of the most popular means of treating cancer. It involves exposing the tumor cells to ionizing radiation such as X-, γ-, or β-radiations, which leads to DNA damage and ultimately to cell death. The high-energy photons interact with DNA and its aqueous environment in the cell. It results in the formation of reactive species such as free radicals, ions, secondary electrons, etc., which are potentially harmful to DNA. It is widely accepted that the contribution of the secondary products is higher than direct radiation-DNA interaction in causing damage. Among them, the role of secondary electrons in radiation damage to genetic material has attracted considerable attention recently. Once formed, the secondary electrons rapidly lose energy due to inelastic collisions with the solvent molecules. These Low energy electrons (LEE) with energies <20eV are then taken up by the DNA, which leads to single-strand breaks (SSB), double-strand breaks (DSB), or even clustered DNA damages. Even though it is widely accepted that LEEs cause DNA damage, the exact mechanism of this process is still not precisely understood. A deep insight into this process is vital for enhancing the efficiency of radiation therapy.

Sanche and coworkers’ pioneering work on the role of LEEs in DNA SSBs and DSBs ignited a series of exciting experimental and theoretical investigations regarding the process. They have reported that the LEEs with energies well below the ionization thresholds of DNA could induce strand breaks. Following this report, numerous attempts have been made to understand the mechanism of the dissociative electron attachment (DEA). A majority of them proposed the existence of short-lived shape resonance states located on nucleobase that lead to SSB. Nucleobase localized shape resonances lie in the energy range 0.1–2 eV and are accessible by the LEEs. The electron from the π*-MO shape resonance state subsequently gets transferred to C-O/C-N σ*-MO, which results in the rapture of the C-O/C-N bond. Sanche and coworkers concluded that this short-lived TNI could not result in the C-N bond rupture. It is the long-lived core excited resonance that causes the cleavage of the C-N bond. The sugar-phosphate bond rupture can also happen upon the direct electron attachment to the phosphate group, and Kumar et al. showed the existence of dissociative σ* levels accessible to electrons with energies >2eV from π* orbital of P=O bond. Many of these DNA bases have a sizeable dipole moment which can support dipole-bound anionic states in the gas phase. The dipole-bound state can act as a doorway to the valence-bound state of the nucleobases. The two states are clearly distinguishable because the extra electron density is located away from the nuclear framework in a dipole-bound state. Whereas in the valence-bound anion, which is of π* type, the extra electron density is localized on the nucleobase (figure 1). We have recently shown that the doorway mechanism is a generalized way to the formation of stable nucleobase anion, and this even exists in the condensed phase, where solvent-bound states act as a doorway state. This raises the possibility of a doorway mechanism for LEE-induced DEA process in genetic materials. Previous studies have shown that purine nucleobases have the highest VEA among the nucleobases. Between cytosine and thymine, the vertically bound anion of the former is more stable than that of the latter. Therefore, we have considered cytosine nucleotides as a simple model system. Figure 1 presents the dipole and valence-bound states of 3′-deoxycytididine monophosphate (3′-dCMPH). The difference in the location of the additional electron density leads to a striking contrast between the geometry of the two anionic states. Previous studies have shown that the geometry of the neutral molecules mostly remains unperturbed due to the formation of the dipole-bound anion. Hence, we have taken the structure of the neutral species as the dipole-bound anion’s geometry in this study. The valence-bound geometry, on the contrary, is visibly different relative to the neutral structure with an RMSD of 0.711 Å. The elongation of the bonds on the cytosine ring further confirms that the extra electron occupies the π*-antibonding molecular
orbital in the valence-bound state of 3′-dCMPH. When the VDE of both states are compared, the dipole-bound and valence-bound anions are vertically bound with values 0.106 and 1.089 eV, respectively. In terms of energetics, the dipole-bound anion is stable than the neutral molecule and the valence-bound anion. The energy of the valence-bound anionic state is higher by 84.37 meV with respect to the dipole-bound anion. However, one should expect the situation in an aqueous environment to be the opposite. The surrounding water molecules would stabilize the valence-bound anion to a greater extent due to the location of additional electron density on the nuclear framework.\(^3\)

![Figure 1. The molecular orbital corresponding to the dominant transition in the EA-EOM-DLPNO-CCSD for (A) dipole-bound and B) valence-bound deoxycytidine-3′-monophosphate anion.](image)

The formation of the dipole-bound doorway anionic state of 3′-dCMPH can lead to the two distinct possible events. The electron may get transferred to the \(\pi^*\)-antibonding molecular orbital localized on nucleobase leading to the formation of valence-bound state. Alternatively, the electron may get transferred to the \(\sigma^*\)-MO of C-O/C-N, resulting in the dissociation of sugar-phosphate (C-O)/sugar-nucleobase (C-N) bonds. The transition between the diffuse dipole bound state to the \(\pi^*\)-antibonding molecular orbital is very feebly optically allowed. However, the process may be assisted by the vibrational degrees of freedom of the molecule. Modeling a potential energy surface (PES) to describe this process accurately is tricky due to the multidimensional nature of the problem. One can work around this issue by reducing its dimensionality. We have constructed a one-dimensional adiabatic PES along a linear trajectory between the dipole-bound and valence-bound states (See Figure 2). The geometrical parameters (bond length, bond angle, etc.) are varied linearly (according to Equation (1)) to obtain the intermediate geometries along the trajectory. The transition between the two electronic states leads to an avoided crossing in the adiabatic potential energy surface, where the Born-Oppenheimer approximation breaks down.\(^4\) We have modeled a diabatic surface by choosing the dipole-bound and valence-bound anionic states as the basis and calculated the coupling element using a two-state model Hamiltonian. The diagonal terms are approximated using Morse potential. The value of the coupling element between dipole- and valence-bound anions for 3′-dCMPH is 13.63 meV, which indicates the presence of weak coupling between the two states. One can use the Marcus theory to get an estimate of the rate of electron transfer.
from dipole-bound state to valence-bound state, which in the present case has been found to be $2.30 \times 10^7$ s$^{-1}$ at $T = 293$ K. It indicates that the dipole-bound state can act as a doorway to the valence-bound state in nucleotides.

Figure 2. a) Adiabatic and b) diabatic PES corresponds dipole-bound to valence-bound transition for 3′-dCMPH. $\lambda$ is the parameter varied from 0 to 1 to obtain the intermediate geometries.

Now, the formation of the dipole-bound anion can also be followed by C-O and/or C-N bond cleavage. Based on experimental studies, LEEs can cause various bond ruptures in DNA including sugar-phosphate (C-O), sugar-nucleobase (C-N), base-H, etc. However, the bulk of the experimentally observed DNA-LEE interaction products are due to the C-N and the two C-O bond cleavages. Previous theoretical studies on gas phase (and under implicit solvation) purine nucleotides have concluded that a transient negative ion (TNI) centered on the nucleobase is formed upon LEE attachment. The formation of the TNI is followed by the base release or the C-O bond rupture. Several mechanisms of DNA damage involving the nucleobase-centered anion, especially single-strand breaks, are available in the literature. The one proposed by Simon and coworkers states that the initial electron attachment leads to the formation of a shape-resonance state localized on cytosine in 3′-dCMPH. This is followed by a through-bond electron transfer from the nucleobase $\pi^*$-MO to C-O $\sigma^*$-MO, which results in the C-O bond rupture. Gu et. al, put forth a different pathway based on the transition state analysis on the purine nucleotides. They observed an atomic orbital overlap between the $C_6$ of pyrimidine and 3′C of sugar moiety in the transition state of 3′-dCMPH. Hence, the direct transfer of electron occurs from the $\pi^*$ antibonding MO of the nucleobase to 3′C of the ribose sugar, facilitating the C-O bond break. Both cases mentioned above have the extra electron density localized on the nucleobase, and therefore, the C-N $\sigma^*$ MO lies in close proximity to the orbital containing the additional electron. Still, a higher barrier is to be surmounted to break C-N bond as compared to C-O. Martin et. al, explained that the short-lived TNI could not result in the C-N bond rupture. They also proposed that the core excited resonances that have longer life time could cause the C-N bond cleavage. Experiments on DNA lesions in condensed phase as well as in gas-phase also reported a higher percentage yield for C-O fragmentation products.

In addition to the previously known resonance-based pathways, there is a possibility of a direct transfer of the electron from the doorway dipole bound state to the C-O or C-N $\sigma^*$-MO leading to bond cleavage. The most obvious way of studying the bond cleavage mechanism is by constructing a potential energy surface as a function of the bond length.
Figure 3 represents the PES for C-O elongation of 3′-dCMPH. The initial electron attached state is dipole-bound in nature. The stretching of the 3′C-O bond leads to the formation of σ* type valence-bound anionic state (See Figure 4), which tends to become the ground state anion with progressing increase in the bond length. The adiabatic potential energy curve shows an avoided crossing between the dipole-bound and σ* type valence-bound anionic state. Subsequently, the electron density gets transferred from the dipole-bound to C-O σ* type valence-bound state due to the mixing of electronic and nuclear degrees of freedom, and it leads to the rupture of the sugar-phosphate bond. While constructing the diabatic curve from the adiabatic picture, we had to choose the dipole-bound state and C-O σ* type valence-bound as the diabatic basis. Morse potential as a function of the bond length was used to model the diagonal terms in the simple avoided crossing model potential. The coupling constant has been found to be 35.07 meV, and the Marcus estimation of the rate of electron transfer was $1.46 \times 10^1 \text{s}^{-1}$. Therefore, the rate of electron transfer to C-O σ* leading to bond breaking is considered to be a much slower process than the formation of a stable anion.

Figure 4. The molecular orbital corresponding to the dominant transition in the EA-EOM-DLPNO-CCSD for the lowest energy anionic state (a) at neutral geometry (b) sugar-phosphate bond length at 1.5 times of its neutral equilibrium value (c) N-glycosidic length at 1.5 times of its neutral equilibrium value.
A similar doorway mechanism is observed for C-N bond breaking, where the electron transfer from the initial dipole bound state to the C-N $\sigma^*$ (See Figure 4(c)) leads to bond cleavage. Figure 5 shows the existence of an avoided crossing in the adiabatic potential energy surfaces corresponding to the C-N cleavage. We have performed a diabatization using the dipole bound and C-N $\sigma^*$ state as the diabatic basis, and the rate of electron transfer has been found to be $1.77 \times 10^{-14}$ s$^{-1}$. Therefore, the rate of electron transfer leading to C-O bond cleavage in the doorway mechanism is higher than that in the C-N bond cleavage, which consistent with the available experimental results.\textsuperscript{13}

Similar trends were observed for the 5′-deoxycytidine monophosphate (5′-dCMP), where the dipole-bound state acts as a doorway for electron capture, and the electron subsequently gets transferred to C-O or C-N $\sigma^*$ to bond breaking. From Figure S2 one can see that the adiabatic potential energy surfaces corresponding to C-O or C-N show avoided crossing, and the mixing of electronic nuclear degrees freedom leads to electron transfer. The rate of electron transfer to C-O $\sigma^*$ in 5′-dCMP is much higher than that to C-N $\sigma^*$, similar to the trend observed in 3′-dCMP.

The C-N bond rupture does not lead to SSB, but it can cause dangerous mutations in DNA. The C-O or sugar-phosphate bond, however, is on the DNA-backbone and its cleavage would cause strand break. Moreover, there are two different C-O sites – at 3′ (3′C-O) and 5′ (5′C-O) positions of the sugar. Knowing which one is more prone to dissociation will help us to understand the mechanism of strand breaks in the literature. Earlier theoretical studies using a simple sugar-phosphate-sugar model with nucleobase replaced by -NH2 group indicated a resonance-based pathway for bond-cleavage and the 5′C-O bond had been reported to be more susceptible to cleavage.\textsuperscript{48,49} However, Wagner and coworkers had experimentally shown that the 3′C-O bond is the favorable SSB site from the fragmentation pattern of thymidine nucleotide dimer\textsuperscript{20}, which contradicts the theoretically simulated results.
Figure 5. a) Adiabatic PES and b) diabatic PES for C-O and C-N bond cleavage for 3′-dCMP, respectively. The bond length are reported relative to their equilibrium value.

We have chosen a more realistic nucleoside-phosphate-nucleoside (NPN) model system with cytidine as the nucleoside to determine the favorable SSB site between the two sugar-phosphate bonds. The electron attachment at the neutral geometry leads to the formation of a dipole-bound state (See Figure 6(a)). This dipole bound state acts as a doorway for electron capture, and the additional electron subsequently gets transferred to the 3′C-O σ* or 5′C-O σ*, leading to bond cleavage. In Figure 7(a), we have plotted the adiabatic potential energy surface for the ground and the first excited state of the anion for the stretching of the 3′C-O and 5′C-O bond in the NPN model system. It shows the avoided crossing for the ground and excited state of the anion similar to that observed in 3′-dCMPH and 5′-dCMPH.

Figure 6. The molecular orbital corresponding to the dominant transition in the EA-EOM-DLPNO-CCSD for the lowest energy anionic state for NPN model system (A) neutral geometry, (B) fragments of 3C-O and (C) 5C-O bond cleavage.
We have employed a similar procedure mentioned earlier to model the diabatic PES using the dipole-bound anion and the C-O $\sigma^*$ anionic state as the basis. The coupling constants calculated for the 3′C-O bond and 5′C-O bond are 37.36 meV and 15.04 meV, respectively. The rates of electron transfer to 3′C-O $\sigma^*$ is $10^2$ higher than to 5′C-O $\sigma^*$ state (See Table 1). Our findings are consistent with the experimental results of Wagner and coworkers$^{20}$ and contradict earlier theoretical predictions.$^{48,49}$

![Figure 7](image_url)

**Figure 7.** a) Adiabatic PES and b) diabatic PES for 5′C-O and 3′C-O bond cleavage for NPN system, respectively. The bond length is reported relative to their equilibrium value.

For the cytosine nucleotide, the transition from dipole-bound to valence-bound anion is kinetically favored than bond break at SSB sites. However, the formation of the valence-bound anion does not eliminate the possibility of strand break. While considering the kinetics of this process, one should expect the rate to be lower because high rates of SSB, if possible, would render the DNA vulnerable to radiation-induced DEA. In such a scenario, the DNA repair mechanism will be overwhelmed with the number of strand breaks and would certainly fail. We have considered a two-step process (Figure 8), where the valence-bound state is first formed from the doorway dipole state. In the second step, the electron gets transferred from the $\pi^*$ valence-bound state to 3′C-O $\sigma^*$ orbital leading to bond cleavage. The second step is a three state process that involves the ground state, first excited state, and second excited state of the anion. Previous attempts to explain the mechanism of SSB have considered it as a single-state process involving the ground state of the anionic species.$^{27-29,47}$ However, our results shows that the multistate nature of DEA should be accounted for. We calculated the approximate rate of 3′C-O bond cleavage from the valence-bound anion to be $3.40 \times 10^{-11}$ s$^{-1}$. Thus, although the valence-bound 3′-dCMPH anion may also lead to 3′C-O bond cleavage in the gas-phase, the process is kinetically unfavorable. One should expect a further smaller rate for C-O bond dissociation in the condensed phase due to solvent stabilization of the anion.
Our calculations show the existence of a doorway mechanism in low-energy electron attachment induced bond breaking in short DNA oligomers in the gas phase. The initial electron attachment leads to the formation of a dipole-bound state, which acts as a doorway for electron capture. The electron subsequently gets transfer to a valence type anionic state leading to three competing processes (1) formation of a valence type $\pi^*$ anion, (2) formation of a C-O $\sigma^*$ type valence anion and subsequent C-O bond cleavage, and (3) formation of a C-N $\sigma^*$ type valence anion and subsequent C-N bond cleavage. The first process is kinetically favored over the other two, which explains the resilience of the genetic material in our cells to DEA inducers. We have shown that in the doorway mechanism, the phosphodiester bonds are more likely to be cleaved than the sugar-nucleobase bond, and the 3′C-O breaks easily than 5′C-O. Both of which are consistent with the available experimental results. The stability of the valence type $\pi^*$ anion has been known to drastically increase in the aqueous phase, which will result in the enhanced rate of formation of stable $\pi^*$ type valence-bound anionic state in the solvent phase. It will reduce the probability of the C-O and C-N bond cleavage on electron attachment in the aqueous phase and explain the suppression of single strand breaking in the aqueous phase compared to the gas phase.\textsuperscript{28,47} The doorway mechanism described above will be competitive to the already known resonance-based pathway of SSB. The consideration of both pathways is essential to get a complete understanding of the low-energy electron-induced SSB. It should be noted that the rate constant calculated using rigid potential energy surface scans in conjugation with Marcus theory is rather qualitative. One needs to perform non-adiabatic molecular dynamic simulation, including the effect of the surrounding environment, to get a quantitative description of the doorway mechanism for SSB. Work is in progress towards that direction.

Computational Details

The negative charge of 3'-dCMP and 5'-dCMP were neutralized by protonating the oxygen of the phosphate group (denoted as 5'-dCMPH and 3'-dCMPH). The neutral and anion geometries of both molecules were optimized at RI-MP2/def2-TZVP level of theory. A subsequent frequency calculation was performed for the optimized geometries. Obtained results shows no imaginary frequencies that ensure the geometry to be at the local minima. A rigid potential energy surface (PES) scan of the sugar-phosphate (C-O) and nucleobase-bond (C-N) cleavage was carried out for both 3'-dCMPH and 5'-dCMPH. C-O and C-N bonds were increased in steps of 0.1 Å to generate the intermediate geometries. The bond length in the final geometry was 1.5 Å longer than the equilibrium bond length. The vertical electron affinities were calculated using EA-EOM-DLPNO-CCSD level of theory with the aug-cc-pVDZ basis set. An additional 5s5p4d functions were added to the atom closest to the positive end of the molecular dipole moment vector. We have used a development version of ORCA to perform the calculations. The intermediate geometries in the linear transition between the dipole-bound and valence-bound anions are obtained using the following expression

\[ R = (1-\lambda)R_{DB} + \lambda R_{VB} \]  

Here, \( R \) represents a parameter of the intermediate geometry. It could be the bond length, bond angle, or dihedral angle. \( R_{DB} \) and \( R_{VB} \) are the value of geometric parameters in the dipole-bound and valence-bound geometries, respectively. \( \lambda \) is varied from zero to one, to obtain the intermediate geometries. The \( \lambda = 0 \) corresponds to dipole-bound geometry, and the valence-bound anion is obtained when the \( \lambda \) equals 1. The diagonal terms in the simple avoided crossing model potential are calculated using the Morse potential expression as a function of \( \lambda \):

\[ V_\lambda = \omega \left( 1 - e^{-a(\lambda-\lambda_0)^2} \right) + v_0^\lambda \]

We have calculated the approximate rate of dipole-bound to valence-bound transition and bond cleavage using Marcus theory as described in ref [34]. The expression for rate constant, \( k \) is as follows:

\[ k = \frac{2\pi}{\hbar} \left| W \right|^2 \frac{1}{4\pi k_B T \lambda_R} e^{-\left(\lambda_R^* + \Delta G^0\right)^2 / 4\lambda_R^* k_B T} \]

where \( \lambda_R \) is the reorganization energy, and \( \Delta G^0 \) is the free energy change between the valence-bound and dipole-bound states (\( E_{VB} - E_{DB} \)).

Supporting Information

The Supporting Information is available.

- Cartesian coordinates of the optimized neutral and anion geometry of 3'-dCMPH, and neutral geometries of 5'-dCMPH, NPN model system.
- Adiabatic and diabatic PES of C-O and C-N bond cleavage in 5'-dCMPH.
