(Dated: June 22, 2021)

Being dispersionless, flat bands on periodic lattices are solely characterized by their macroscopically degenerate eigenstates: compact localized states (CLSs) in real space and Bloch states in reciprocal space. Based on this property, this work presents a straightforward method to build flat-band tight-binding models with short-range hoppings on any periodic lattice. The method consists in starting from a CLS and engineering families of Bloch Hamiltonians as quadratic (or linear) functions of the associated Bloch state. The resulting tight-binding models not only exhibit a flat band, but also multifold quadratic (or linear) band touching points (BTPs) whose number, location, and degeneracy can be controlled to a large extent. Quadratic flat-band models are ubiquitous: they can be built from any arbitrary CLS, on any lattice, in any dimension and with any number $N \geq 2$ of bands. Linear flat-band models are rarer: they require $N \geq 3$ and can only be built from CLSs that fulfill certain compatibility relations with the underlying lattice. Most flat-band models from the literature can be classified according to this scheme: Mielke’s and Tasaki’s models belong to the quadratic class, while the Lieb, dice and breathing Kagome models belong to the linear class. Many novel flat-band models are introduced, among which an $N = 4$ bilayer honeycomb model with fourfold quadratic BTPs, an $N = 5$ dice model with fivefold linear BTPs, and an $N = 3$ Kagome model with BTPs that can be smoothly tuned from linear to quadratic.

I. INTRODUCTION

The energy band structure associated to quantum mechanical particles on a periodic lattice is a fundamental building stone of solid state physics [1], and the concept can be naturally extended to artificial periodic systems, for example photonic crystals [2]. Currently, particular attention is paid to band structures that exhibit interesting features with regard to quantum geometry, topology and interactions. In this paper, we are particularly interested in two such features, namely (1) flat bands and (2) band touching points.

(1) A flat band is a completely dispersionless energy band. Flat bands have long been known to develop in a two-dimensional electron gas (2DEG) in the presence of a magnetic field (Landau levels) [3], and were first introduced in the context of lattice models in the seminal works of Sutherland, Lieb, Mielke and Tasaki [4–8].

Flat-band systems are interesting because, on the one hand, band flatness signifies the absence of an intrinsic energy scale (a band width), and on the other hand it implies the existence of macroscopically degenerate eigenstates. These two properties combined ensure that any perturbation may act non-perturbatively and profoundly modify the physics of the flat band. As an emblematic example, if electron-electron (Coulomb) interactions are added to a Landau-quantized 2DEG, the effect is known to be strongly non-perturbative, and the possibility for the existence of strongly correlated quantum phases arises (fractional quantum Hall states [9], Wigner crystal [10], etc.).

While the first works on flat-band lattices were mostly interested in ferromagnetism induced by the Hubbard interaction [11, 12], flat-band lattices are now widely studied in many electronic and artificial systems [13, 14]. Moreover, almost-flat bands can be found in Kagometype materials, see for instance Refs. [15–17], as well as in twisted bi- and multilayers of graphene and other quasi-2D crystals [18–20]. In the latter class of materials, an astonishing variety of different regimes emerges from the nearly-flat bands, ranging from quantum Hall to Mott insulating and superconducting phases.

The simplest approach to studying flat-band systems consists in considering periodic lattices in the tight-binding (TB) approximation: this is the framework adopted in the present work. In particular, many researchers have tried to develop schemes that systematically generate flat-band TB models. Such schemes make use of graph theory [6, 7, 21–23], Origami rules [24], repeated miniarrays [25], a bipartite lattice structure [26, 27], generic existence conditions [28, 29], or the extension of known flat-band lattices [29–31]. Also, over the last years, the close relation between flat bands and compact localized states (CLSs) [32] was increasingly exploited [33–39]. A CLS is a wave function strictly localized to some finite region of the lattice, with zero probability amplitude outside this region.

(2) A band touching point (BTP) is a point in the first Brillouin zone (FBZ) where two (twofold BTP) or more (multifold BTP) energy bands touch. Such defects generally entail geometrical and topological structures that have a measurable impact on physical observables. Accordingly, they have become a major focus of condensed matter research and are investigated in all kinds of setups, from graphene [40] to Dirac and Weyl semimetals [41] and even non-Hermitian systems [42]. Interestingly, the notions of flat bands and BTPs are not entirely independent. Some generic properties of BTPs in flat-band systems have been studied in Refs. [38, 43, 44].
Here, we are interested in families of tight-binding models that exhibit both features (1) and (2). In particular, we propose a systematic and simple procedure to design flat-band TB models, which at the same time offers considerable control over the existence and character of multifold BTPs. The key idea consists in an inverse approach: instead of directly searching for a real-space TB Hamiltonian corresponding to a superposition of all copies of the CLS translated by a Bravais vector, (ii) Impose a Bloch Hamiltonian \( H_k \) such that \( |f_k\rangle \) is a flat-band eigenstate:

\[
H_k |f_k\rangle = \epsilon_0 |f_k\rangle
\]

(H) \( H_k \) quadratic in \( |f_k\rangle \)

(iii) Build the real-space tight-binding model that corresponds to \( H_k \):

FIG. 1. Basics of our method to build flat-band lattice models. In step (i), the CLS wave function in real space is illustrated by the red shading. In step (ii), \( \epsilon_0 \) denotes the energy of the flat band. An example for a band structure with a quadratic (linear) BTP is sketched on the left (right). In step (iii), a schematic visualization of the final flat-band hopping model is shown.

Here, we are interested in families of tight-binding models that exhibit both features (1) and (2). In particular, we propose a systematic and simple procedure to design flat-band TB models, which at the same time offers considerable control over the existence and character of multifold BTPs. The key idea consists in an inverse approach: instead of directly searching for a real-space TB Hamiltonian with a flat band, we impose a form of the Bloch Hamiltonian \( H_k \) that forces a flat band to occur in its band structure. An appropriate real-space Hamiltonian can then be built in a second step from the knowledge of \( H_k \). This procedure is outlined in more detail in Fig. 1.

(i) On any lattice of choice, build any CLS \( |\Psi_{\text{CLS}}\rangle \), i.e. a linear combination of a finite number of atomic orbitals. The corresponding Bloch state \( |f_k\rangle \) is formed as a superposition of all copies of the CLS translated by a Bravais vector. (ii) Impose a Bloch Hamiltonian \( H_k(|f_k\rangle) \) such that \( |f_k\rangle \) is automatically a flat-band eigenstate. In particular, \( H_k(|f_k\rangle) \) can exhibit a quadratic or linear dependency on \( |f_k\rangle \), generically leading to models with quadratic or linear BTPs, respectively. (iii) Build the real-space TB Hamiltonian corresponding to \( H_k \), which will be a flat-band model by construction.

This method has several very convenient features. First, it allows to obtain arbitrarily many flat-band tight-binding models on any periodic lattice. Second, it is conceptually straightforward and fully analytic. Third, the required hoppings are generically short-ranged and do not require fine-tuning. Moreover, since \( H_k \) is obtained before the real-space model, the band structure can be directly controlled without the explicit need to construct the real-space model first. In particular, the flat band can be easily designed to be singular or non-singular [38], the dispersive bands can be widely tuned without destroying the flat band, and multifold BTPs with a tunable degree of degeneracy can be created. Finally, the method can be viewed as a new classification scheme, placing known models (Mielke, Tasaki, Lieb, dice, breathing Kagome, etc.) and the models we propose into quadratic or linear classes, based on the relation between the Bloch Hamiltonian and the CLS.

This paper is organised as follows. In Section II we first recall the important notion of a CLS and how to construct the corresponding Bloch state \( |f_k\rangle \) (Section II A). Second, the key idea of this work is introduced (Section II B): flat-band Bloch Hamiltonians can be engineered from any given CLS. This idea is developed for the case of a quadratic relation between \( H_k \) and \( |f_k\rangle \) in Section III, and for the case of a linear relation in Section IV. CLSs that allow to build linear flat-band models can also be used to build models that smoothly interpolate between the linear and quadratic case, as discussed in Section V. Conclusions are given in Section VI.

II. BUILDING FLAT-BAND HAMILTONIANS FROM COMPACT LOCALIZED STATES

A. Compact localized states and associated Bloch states

Consider a periodic lattice treated in the TB approximation [1], with \( N \) (atomic) orbitals per unit cell, i.e. with \( N \) sublattices labeled by \( \alpha = A, B, C, ..., \). On such a lattice, a compact localized state (CLS) centered at some localization center \( R_C \) can be formed as a linear combination

\[
|\Psi_{\text{CLS}}^{R_C}\rangle = \sum_{\alpha_i \in \text{CLS}} w_{\alpha_i} |\alpha_i\rangle
\]

of orbitals \( |\alpha_i\rangle \), where the complex number \( w_{\alpha_i} \) is the CLS amplitude on the respective orbital – takes a nonzero value only for a finite number of lattice sites around \( R_C \). Accordingly, the CLS wave function

\[
\Psi_{\text{CLS}}^{R_C}(r) \propto \langle r | \Psi_{\text{CLS}}^{R_C}\rangle
\]

is restricted to a finite region of the lattice, with strictly zero probability amplitude outside this region.

As an example, consider the CLS built on the square lattice \( (N = 2) \) shown in Fig. 2(a). It involves four orbitals labeled by \( \alpha = A, B \) and \( i = 1, 2 \), i.e.

\[
|\Psi_{\text{CLS}}^{R_C}\rangle = w_A |A_1\rangle + w_A |A_2\rangle + w_B |B_1\rangle + w_B |B_2\rangle.
\]
Similarly, the CLS on the Kagome lattice \((N = 3)\) shown in Fig. 2(b) involves six orbitals, i.e.

\[
|\Psi_{\text{CLS}}^{R_C}\rangle = w_{A_1} |A_1\rangle + w_{A_2} |A_2\rangle + w_{B_1} |B_1\rangle + w_{B_2} |B_2\rangle + w_{C_1} |C_1\rangle + w_{C_2} |C_2\rangle.
\]

The orbitals with nonzero amplitude \((w_{\alpha_i} \neq 0)\) are located at positions \(\delta_{\alpha_i}\), as measured from \(R_C\). For the CLS of panel (a), we have \(\delta_{A_{1,2}} = \pm \frac{1}{2}(1, -1)\) and \(\delta_{B_{1,2}} = \pm \frac{1}{2}(1, 1)\). For the CLS of panel (b), the positions are \(\delta_{A_{1,2}} = \pm \frac{1}{2}(1, -\sqrt{3})\), \(\delta_{B_{1,2}} = \pm \frac{1}{2}(1, \sqrt{3})\), and \(\delta_{C_{1,2}} = \pm (1, 0)\). Note that the lattice constant is taken as \(a = 1\) here and throughout.

For any CLS \((1)\) centered at some \(R_C\), there exists a macroscopic number of equivalent copies translated by some Bravais vector. Thus, for any given CLS, we can introduce a Bloch state of the CLS (BCLS) \(|f_k\rangle\), which is obtained as a (unnormalized) superposition of the CLS and all its translated copies:

\[
|f_k\rangle = \sum_{R_C} e^{-ik \cdot R_C} |\Psi_{\text{CLS}}^{R_C}\rangle = \sum_{\alpha} f_{\alpha}(k) |\alpha, k\rangle.
\]

In the second line, \(|\alpha, k\rangle\) are Bloch basis states \([45]\) and

\[
f_{\alpha}(k) \equiv \sum_{i \in \text{CLS}} w_{\alpha_i} e^{ik \cdot \delta_{\alpha_i}}.
\]

is completely specified by the positions and amplitudes of the orbitals contained in the associated real-space CLS. Hereafter, we work in the Bloch basis, where the BCLS simply takes the form of a column vector:

\[
|f_k\rangle = \begin{pmatrix} f_A(k) \\ f_B(k) \\ \vdots \end{pmatrix}.
\]

For example, the CLS of Fig. 2(a) gives rise to a BCLS

\[
|f_k\rangle = \begin{pmatrix} w_{A_1} e^{-\frac{i}{2}(k_x-k_y)} + w_{A_2} e^{\frac{i}{2}(k_x-k_y)} \\ w_{B_1} e^{-\frac{i}{2}(k_x+k_y)} + w_{B_2} e^{\frac{i}{2}(k_x+k_y)} \end{pmatrix},
\]

and the CLS of Fig. 2(b) corresponds to a BCLS

\[
|f_k\rangle = \begin{pmatrix} w_{A_1} e^{-ik_y} + w_{A_2} e^{ik_y} \\ w_{B_1} e^{ik_y} + w_{B_2} e^{-ik_y} \\ w_{C_1} e^{ik_x} + w_{C_2} e^{-ik_x} \end{pmatrix},
\]

where \(k_\pm \equiv \frac{1}{2}(k_x \pm \sqrt{3}k_y)\). In the same way, each arbitrarily designed CLS on any lattice uniquely corresponds to some BCLS \(|f_k\rangle\); the latter is an important quantity in our flat-band construction scheme, cf. Fig. 1.

Note that \(|f_k\rangle\) is called singular if there exists a point \(k_0\) in the FBZ such that \(|f_{k_0}\rangle = 0\), while it is called nonsingular otherwise \([38]\). The (non-)singularity of \(|f_k\rangle\) is a useful tool for characterizing the properties of BTPs at the flat-band energy.

### B. Bloch Hamiltonians from compact localized states

We now argue that for any arbitrarily shaped (input) CLS on any periodic lattice, it is possible to construct families of tight-binding Hamiltonians \(H\) such that this CLS and all its translated copies constitute a macroscopically degenerate set of eigenstates:

\[
H|\Psi_{\text{CLS}}^{R_C}\rangle = \epsilon_0 |\Psi_{\text{CLS}}^{R_C}\rangle, \quad \forall R_C.
\]

In order to find these tight-binding Hamiltonians \(H\), the strategy adopted in this work consists in designing Bloch Hamiltonians \(H_k\) \((N \times N\) matrices) for which the BCLS \(|f_k\rangle\) associated to the input CLS represents a flat-band eigenstate:

\[
H_k |f_k\rangle = \epsilon_0 |f_k\rangle.
\]

Once such matrices \(H_k\) are found, it is straightforward to obtain the real-space models \(H\) from them. Hereafter, we will take \(\epsilon_0 = 0\) without loss of generality.

To see how this Bloch Hamiltonian design can be done, let us write Eq. (11) explicitly in matrix form:

\[
\begin{pmatrix} H_{k,AA} & H_{k,AB} & \cdots \\ H_{k,BA} & H_{k,BB} & \cdots \\ \vdots & \vdots & \ddots \end{pmatrix} \begin{pmatrix} f_A(k) \\ f_B(k) \\ \vdots \end{pmatrix} = 0.
\]

Evidently, a flat band will automatically exist if the Bloch Hamiltonian is imposed to be an appropriate function \(H_k(|f_k\rangle)\) of the BCLS. More concretely, the matrix elements \(H_{k,\alpha\beta}\) should depend on the components \(f_{\alpha}(k)\) in such a way that \(\sum_{\beta} H_{k,\alpha\beta} f_{\beta}(k) = 0\) is fulfilled for every
orthogonal to
\[ |f_k\rangle \quad \text{and} \quad |\alpha\rangle \]

Thus, the task at hand consists in finding matrices \( H_k(|f_k\rangle) \) that fulfill Eq. (12). However, we have to be aware of an additional physical constraint:

\[ H_k \text{ must be a reasonable Bloch Hamiltonian,} \quad \text{(13)} \]
i.e. one has to choose \( H_k(|f_k\rangle) \) such that the real-space TB Hamiltonian \( H \) constructed from it makes sense on a lattice. This is not in general guaranteed for all matrices \( H_k(|f_k\rangle) \) that fulfill Eq. (12).

As it turns out, there are two different simple choices for matrices that fulfill condition (12):

- \( H_k \) is a \textit{quadratic} function of the \( f_\alpha(k) \)
- \( \rightarrow \) flat-band models with quadratic BTPs, Section III.
- \( H_k \) is a \textit{linear} function of the \( f_\alpha(k) \)
- \( \rightarrow \) flat-band models with linear BTPs, Section IV.

Designing quadratic Hamiltonians is possible for \( N \geq 2 \) and, conveniently, condition (13) is automatically fulfilled for any input CLS. In contrast, designing linear Hamiltonians requires \( N \geq 3 \) and condition (13) is only fulfilled for special input CLSs. For this reason, the quadratic case may be regarded as simpler and will be treated first.

III. FLAT-BAND MODELS WITH QUADRATIC BAND TOUCHING

The simplest scenario for a quadratic flat-band model is encountered in two-band \((N = 2)\) systems (Section III A). The procedure can then straightforwardly be generalized to \( N = 3 \) (Section III B), and finally to any \( N \) (Section III C).

A. Two-band models

Consider some CLS built on a lattice with two orbitals per unit cell:

\[ |\Psi_{\text{CLS}}^{R_c}\rangle = \sum_{i \in \text{CLS}} (w_A, |A_i\rangle + w_B, |B_i\rangle). \quad \text{(14)} \]

The corresponding BCLS has two components,

\[ |f_k\rangle = (f_A, f_B)^T, \quad \text{(15)} \]

where hereafter \( f_\alpha \equiv f_\alpha(k) \) for brevity. We now want to construct a matrix \( H_k \) orthogonal to \( |f_k\rangle \). The simplest way to do this consists in introducing a state

\[ |f_k^{AB}\rangle \equiv (-f_B^*, f_A^*)^T \quad \text{(16)} \]

orthogonal to \( |f_k\rangle \), as well as the matrix

\[ F_k^{AB} \equiv |f_k^{AB}\rangle \langle f_k^{AB}|. \quad \text{(17)} \]

Then a Bloch Hamiltonian defined as

\[ H_k \equiv \lambda_k^{AB} F_k^{AB} = \lambda_k^{AB} \begin{bmatrix} |f_B|^2 & -f_A f_B^* \\ -f_A^* f_B & |f_A|^2 \end{bmatrix} \quad \text{(18)} \]

will obviously have \( |f_k\rangle \) as an eigenstate of zero energy; in other words, Eq. (12) is fulfilled for any \( |f_k\rangle \). The band structure associated to Eq. (18) reads

\[ \epsilon_0(k) = 0, \quad \epsilon_1(k) = \lambda_k^{AB} (|f_A|^2 + |f_B|^2). \quad \text{(19)} \]

Here, \( \lambda_k^{AB} \) is an arbitrary real function with the periodicity of the FBZ. If it is taken positive (or negative) throughout, the flat band is gapped away from the dispersive band at all \( k \)-points where \( |f_k| \) does not vanish. In contrast, if \( \lambda_k^{AB} \) changes sign in the FBZ, the flat band will cross the dispersive band. For our purposes, it will suffice to take \( \lambda_k^{AB} = 1 \) from now on.

To see how flat-band tight-binding models can be designed from Eq. (18), let us discuss some examples. As a first example, consider again the square-like CLS used previously, shown in Fig. 3(a). We now simply insert the corresponding BCLS (8) into the Bloch Hamiltonian (18), to obtain

\[ H_k = \begin{bmatrix} H_{AA} & H_{AB} \\ H_{AB}^* & H_{BB} \end{bmatrix}, \quad \text{(20)} \]
where

\[
\begin{align*}
H_{AA} &= V_A + t_{12}^B e^{-i(k_x+k_y)} + t_{21}^B e^{i(k_x+k_y)}, \\
H_{BB} &= V_B + t_{12}^A e^{-i(k_x-k_y)} + t_{21}^A e^{i(k_x-k_y)}, \\
H_{AB} &= t_{11}^A e^{-ik_x} + t_{12}^B e^{-ik_y} + t_{21}^A e^{ik_x} + t_{22}^B e^{-ik_y}.
\end{align*}
\]

The real-space TB model \( H \) described by this Bloch Hamiltonian is depicted in Fig. 3(b). The hopping directions that appear can be directly understood from the shape of the CLS, as illustrated in Fig. 3(c): hoppings from site \( A \) to site \( B \) (\( B \) to \( A \), \( A \) to \( A \), \( B \) to \( B \)) are determined by all vectors that connect orbitals \( A \) to orbitals \( B \) (\( B \) to \( A \), \( B \) to \( A \), \( A \) to \( A \)) within the CLS (see Appendix A for details). As a consequence, the model (21) involves first- and second-neighbor hoppings.

The onsite energies \( V_A \equiv |w_{B1}|^2 + |w_{B2}|^2 \), \( V_B \equiv |w_{A1}|^2 + |w_{A2}|^2 \), inter-sublattice hopping parameters \( t_{ij}^A = -w_{a_i} w_{a_j} \), and intra-sublattice hopping parameters \( t_{ij}^{AA} = w_{a_i} w_{a_j} \) strongly depend on the CLS amplitudes. In particular, the existence of a BTP can be ensured by choosing \(|f_k|\) singular. For example, if the CLS amplitudes are such that \(|f_k| = 0\), a BTP at the \( X \) point of the FBZ appears, see Fig. 3(d). Similarly, there would be a BTP at the \( \Gamma \) point if \( w_{a_1} = -w_{a_2} \in \mathbb{R} \). In contrast, if \(|f_k|\) is chosen non-singular, the bands are gapped away from each other, see Fig. 3(e).

As a second example, consider the CLS on the honeycomb lattice shown in Fig. 4(a). It is straightforward to obtain the BCLS

\[
|f_k| = \begin{pmatrix} w_{A1} e^{-ik_x} + w_{A2} e^{ik_x} \\ w_{B1} e^{ik_x} + w_{B2} e^{ik_y} \end{pmatrix},
\]

where again \( k_x \equiv (k_x \pm \sqrt{3}k_y)/2 \). Inserting into Eq. (18), one obtains a TB model of the form (20), where now

\[
\begin{align*}
H_{AA} &= V_A + t_{12}^{BB} e^{i\sqrt{3}k_y} + t_{21}^{BB} e^{-i\sqrt{3}k_y}, \\
H_{BB} &= V_B + t_{12}^{AA} e^{-i(k_x+k_y)} + t_{21}^{AA} e^{i(k_x+k_y)}, \\
H_{AB} &= t_{11}^{AB} e^{-2ik_x} + t_{12}^{AB} e^{-ik_y} + t_{21}^{AB} e^{ik_x} + t_{22}^{AB} e^{ik_y},
\end{align*}
\]

with onsite energies and hoppings as defined above. This TB model is shown in Fig. 4(b). Due to the asymmetric shape of the input CLS, the hoppings are also distributed asymmetrically, as illustrated in Fig. 4(c). By an appropriate choice of the CLS amplitudes, the band structure can be freely designed to exhibit a BTP at the \( \Gamma \) point or at the \( K \) points, see Fig. 4(d) & (e), or to be gapped by taking \(|f_k|\) non-singular.

Proceeding in the same way, infinitely many different \( N = 2 \) flat-band models and their band structures can be designed. For any imaginable CLS (14), if one inserts the corresponding BCLS (15) into Eq. (18), one obtains a flat-band TB model with hopping directions that are determined by the shape of the CLS (i.e. the set of all vectors \( \delta_{a_i} \)), and hopping parameters as well as onsite energies that are determined by the CLS amplitudes \( w_{a_i} \).

As explained in more detail in Appendix A, the Bloch Hamiltonian (18) is indeed always reasonable [cf. condition (13)] due to its quadratic character. In fact, it is not only a reasonable flat-band Hamiltonian, but the only possible form for the Bloch Hamiltonian of any \( N = 2 \) flat-band model. This was already anticipated by Rhim and Yang [38] and can be easily understood from the spectral theorem, see Appendix B.

To illustrate that the procedure outlined above indeed works for arbitrarily complicated input CLSs, we may consider the snowflake-shaped CLS displayed in Fig. 4(f). Of course, for such an extended input CLS, the real-space model that one obtains involves many further-neighbor hoppings and it is not useful to draw it explicitly. However, conveniently, the band structure (19)
A class of flat-band Bloch Hamiltonians is then obtained with corresponding matrices $w$ orbitals involved in the CLS, the dispersive band $\epsilon_1(k)$ strongly oscillates and exhibits a large peak at the $\Gamma$ point (not shown). If the amplitudes are flipped to $w_{\alpha i} = -1$ on three out of the six branches of the snowflake, see Fig. 4(g), then $\epsilon_1(k)$ exhibits six peaks arrayed hexagonally in the FBZ.

As we will show, an analogous procedure of flat-band model and band structure design is possible for $N > 2$. Additionally, the tunability turns out to be considerably increased.

B. Three-band models

Consider now a CLS built on a lattice with three orbitals per unit cell:

$$|\Psi_{\text{CLS}}^{Rc}\rangle = \sum_{i \in \text{CLS}} (w_A, |A_i\rangle + w_B, |B_i\rangle + w_C, |C_i\rangle).$$

(24)

The corresponding BCLS has three components,

$$|f_k\rangle = (f_A, f_B, f_C)^T.$$  

(25)

We can now introduce three states orthogonal to $|f_k\rangle$, namely

$$|f_{kAB}\rangle = (-f_B, f_A, 0)^T,$$

$$|f_{kAC}\rangle = (f_C, 0, f_A^*)^T,$$

$$|f_{kBC}\rangle = (0, -f_C^*, f_B^*)^T,$$

(26)

with corresponding matrices

$$F_{kAB}^{AB} = |f_{kAB}\rangle \langle f_{kAB}| = \begin{bmatrix} |f_B|^2 & -f_A f_B^* & 0 \\ -f_A f_B & |f_A|^2 & 0 \\ 0 & 0 & 0 \end{bmatrix},$$

$$F_{kAC}^{AC} = |f_{kAC}\rangle \langle f_{kAC}| = \begin{bmatrix} |f_C|^2 & 0 & -f_A f_C^* \\ 0 & 0 & 0 \\ -f_A f_C & 0 & |f_A|^2 \end{bmatrix},$$

$$F_{kBC}^{BC} = |f_{kBC}\rangle \langle f_{kBC}| = \begin{bmatrix} 0 & |f_C|^2 & -f_B f_C^* \\ 0 & 0 & 0 \\ -f_B f_C & 0 & |f_B|^2 \end{bmatrix}. $$

(27)

A class of flat-band Bloch Hamiltonians is then obtained as a linear combination:

$$H_k = \lambda_k^{AB} F_k^{AB} + \lambda_k^{AC} F_k^{AC} + \lambda_k^{BC} F_k^{BC},$$

(28)

where $\lambda_k^{AB}, \lambda_k^{AC}, \lambda_k^{BC}$ are arbitrary real functions with the periodicity of the FBZ. It will suffice to choose them as constants, $\lambda_k^{\alpha\beta} = \lambda_{\alpha\beta}$.

The Hamiltonian (28) is analogous to Eq. (18) in that it automatically verifies the desired conditions (12) & (13) for any conceivable input CLS, i.e. for any $|f_k\rangle$. Therefore, infinitely many flat-band models on any $N = 3$ lattice can be obtained from Eq. (28).

Moreover, there is an additional advantage compared to the $N = 2$ case, namely there are now three relative parameters $\lambda_{\alpha\beta}$, while the single parameter $\lambda_{AB}$ in the two-band Hamiltonian (18) only acts globally. As a consequence, the Hamiltonian (28) can be strongly tuned even if an input CLS completely fixed with regard to both shape and amplitudes is used. This represents an additional degree of freedom absent in the two-band case. In this context, it is crucial to realize that the states (26) are not eigenstates of the Hamiltonian (28). In fact, they form an overcomplete basis of the space orthogonal to $|f_k\rangle$. This redundancy is at the origin of the tunability provided by the $\lambda_{\alpha\beta}$. In contrast to the flat-band eigenstate $|f_k\rangle$, the dispersive-bands eigenstates of the Hamiltonian (28) do depend on the parameters $\lambda_{\alpha\beta}$.

The dependency on the choice of the input CLS (i.e. of the functions $f_\alpha$) and the tunability by the $\lambda_{\alpha\beta}$ are clearly reflected in the Hamiltonian’s band structure

$$\epsilon_0(k) = 0,$$

$$\epsilon_{1,2}(k) = \frac{1}{2} \left( C_1 \pm \sqrt{C_2 - C_1^2} \right),$$

(29)

where $C_n \equiv \text{Tr}(H_n^2)$ are given by

$$C_1 = (\lambda_{AB} + \lambda_{AC})|f_A|^2 + (\lambda_{AB} + \lambda_{BC})|f_B|^2 + (\lambda_{AC} + \lambda_{BC})|f_C|^2,$$

$$C_2 = (\lambda_{AB} |f_A|^2 + \lambda_{BC} |f_B|^2 + |\lambda_{AC}| |f_C|^2)^2 + (\lambda_{AB} |f_A|^2 + \lambda_{BC} |f_C|^2)^2 + 2(\lambda_{AB} |f_A|^2 |f_B|^2 + \lambda_{AC} |f_A|^2 |f_C|^2 + \lambda_{BC} |f_B|^2 |f_C|^2).$$

(30)

As an example, consider again the six-site CLS on the Kagome lattice used previously, shown in Fig. 5(a), with corresponding BCLS (9). Inserting into Eq. (28), one obtains a flat-band TB model

$$H_k = \begin{bmatrix} H_{AA} & H_{AB} & H_{AC} \\ H_{AB}^* & H_{BB} & H_{BC} \\ H_{AC}^* & H_{BC}^* & H_{CC} \end{bmatrix},$$

(31)

with diagonal matrix elements

$$H_{AA} = V_A + t_{12}^{A,BB} e^{2ik_+} + t_{21}^{A,BB} e^{-2ik_+} + t_{12}^{A,ACC} e^{2ik_+} + t_{21}^{A,ACC} e^{-2ik_+},$$

$$H_{BB} = V_B + t_{12}^{B,AA} e^{-2ik_-} + t_{21}^{B,AA} e^{2ik_-} + t_{12}^{B,ACC} e^{2ik_-} + t_{21}^{B,ACC} e^{-2ik_-},$$

$$H_{CC} = V_C + t_{12}^{C,AA} e^{-2ik_-} + t_{21}^{C,AA} e^{2ik_-} + t_{12}^{C,BB} e^{2ik_-} + t_{21}^{C,BB} e^{-2ik_-},$$

(32)
for $\lambda$ in (e) with $w$.

The corresponding band structure is shown for $d$ determined by the CLS shape. The corresponding band structure occurring in the flat-band TB model built from it, as shown in FIG. 5. (a) CLS on the Kagome lattice. (b) Hopping directions are determined by the CLS inter-sublattice hoppings $w$. Again, the hopping directions are determined by the CLS inter-sublattice hoppings $t$. The onsite energies $V_{\alpha} \equiv \sum_{\beta \neq \alpha} \lambda_{\alpha\beta} (|w_{\beta1}|^2 + |w_{\beta2}|^2)$, inter-sublattice hoppings $t_{ij}^{\alpha\beta} \equiv -\lambda_{\alpha\beta} w_{\alpha i} w_{\beta j}^*$ and intra-sublattice hoppings $t_{i}^{\alpha\beta} \equiv \lambda_{\alpha\beta} w_{\beta i}$ are strongly tunable by the six CLS amplitudes $w_{\alpha i}$ and the three parameters $\lambda_{\alpha\beta}$. This affords considerable control over the behavior of the dispersive bands, and in particular over the occurrence of BTPs. For example, the band structure can be chosen to exhibit a BTP at the $\Gamma$ point, and the position of the flat band with respect to the dispersive bands can be controlled by the $\alpha\beta$, see FIG. 5(c)&(d).

Similarly, the BTP can be placed at the $K$ points, and the position of the flat band can be controlled, see FIG. 5(e)&(f). Of course, the flat band can also be gapped out completely by an imbalance in the CLS amplitudes.

More generally, for three-band models of the form (28), a BTP of any degeneracy, and at various positions in the FBZ, can be designed without destroying the flat band. At $k = k_0$, there will be a twofold BTP if $2C_2(k_0) = C_1(k_0)[1 + C_1(k_0)]$, and a threefold BTP if $C_1(k_0) = C_2(k_0) = 0$. Clearly, this can be achieved in several different ways, with or without fine-tuning of the $\lambda_{\alpha\beta}$. All possible scenarios are listed in Appendix C.

C. N-band models

The arguments made above can be readily extended to any $N$. Consider a generic CLS (1) built on a lattice with $N$ orbitals per unit cell, with corresponding BCLS

$$|f_k \rangle = (f_A, f_B, f_C, \ldots)^T.$$  \hspace{1cm} (34)

We may now introduce $\binom{N}{2}$ states

$$|f_k^{\alpha\beta} \rangle \equiv (0, 0, 0, f_\alpha^*, 0, 0, f_\alpha, 0, \ldots, 0)^T$$  \hspace{1cm} (35)

orthogonal to $|f_k \rangle$, and the $N \times N$ matrices

$$F_{k}^{\alpha\beta} \equiv |f_k^{\alpha\beta} \rangle \langle f_k^{\alpha\beta}|$$  \hspace{1cm} (36)

constructed from them. A generic quadratic flat-band Bloch Hamiltonian is then obtained by forming a linear combination of these $\binom{N}{2}$ matrices:

$$H_k = \sum_{\alpha, \beta > \alpha} \lambda_{k}^{\alpha\beta} F_{k}^{\alpha\beta},$$  \hspace{1cm} (37)

where $\alpha, \beta \in \{A, B, C, \ldots\}$ and $\lambda_{k}^{\alpha\beta}$ is an arbitrary real function with the periodicity of the FBZ. We will assume $\lambda_{k}^{\alpha\beta} = \lambda_{\alpha\beta}$, such that the off-diagonal and diagonal matrix elements of the Hamiltonian (37) explicitly write

$$H_{k, \alpha\alpha} = -\lambda_{\alpha\beta} f_\alpha f_\beta^*,$$

$$H_{k, \alpha\alpha} = \sum_{\beta \neq \alpha} \lambda_{\alpha\beta} |f_\beta|^2.$$  \hspace{1cm} (38)

The Hamiltonian (37), which generalizes Eqs. (18) & (28) to any $N$, is the first main result of this paper. One can insert into it any arbitrary CLS built on any lattice, for any spatial dimension and any number of sites per unit cell. Since conditions (12) & (13) are automatically fulfilled, each such input CLS gives rise to a reasonable real-space tight-binding model with a flat band. One thus obtains arbitrarily many flat-band models on any lattice.

Of course, while Eq. (37) provides infinitely many flat-band models, it does not capture all possible flat-band models except in the $N = 2$ limit. In particular, flat-band models with a linear function $H_k(|f_k \rangle)$ exist for $N \geq 3$, see Section IV.
The flat-band models obtained from Eq. (37) are tunable by two independent knobs: the functions \( f_\alpha \) and the \( N(N-1)/2 \) parameters \( \lambda_{\alpha\beta} \). The latter tunability stems from the fact that the states (35) are not eigenstates of the Hamiltonian (37) and form an overcomplete basis of the space orthogonal to \( \ket{f_k} \).

Although, for \( N > 3 \), there is no elegant closed-form solution for the energy bands, the existence of a flat band is always guaranteed, and BTPs with any degree of degeneracy (\( d = 1, ..., N \)) can be designed. The two most interesting classes of BTPs (not requiring fine-tuning of the \( \lambda_{\alpha\beta} \)) are the following. (1) If \( |f_{k_0}\rangle = 0 \) for some \( k_0 \), there will be an \( N \)-fold (singular) BTP at \( k_0 \). We have already seen examples for this in the two-band and three-band case, cf. Figs. 3–5. (2) If, at \( k_0 \), all except one component of \( |f_{k_0}\rangle \) vanish, say \( f_{\alpha_0}(k_0) \neq 0 \) and \( f_{\alpha\neq\alpha_0}(k_0) = 0 \), then the Hamiltonian (37) becomes locally diagonal with eigenvalues \( \{0, \lambda_{\alpha_0,\alpha\neq\alpha_0}|f_{\alpha_0}(k_0)|^2\} \).

Even though the CLS is completely fixed (shape and amplitudes), the flat-band Bloch Hamiltonian (37) built from it is still tunable by six parameters \( \lambda_{AB}, \lambda_{AC}, \lambda_{AD}, \lambda_{BC}, \lambda_{BD}, \lambda_{CD} \). To reduce the number of parameters, it is reasonable to set \( \lambda_{CD} = \lambda_{AB}, \lambda_{BC} = \lambda_{AD} \) and \( \lambda_{BD} = \lambda_{AC} \) for reasons of symmetry [cf. Fig. 6(a)]. We may then further set \( \lambda_{AC} = -c_\theta^2\lambda_{AB} \) and \( \lambda_{AD} = -s_\theta^2\lambda_{AB} \) to ensure a tight-binding model with zero onsite energies and no intra-sublattice hopping:

\[
H_k = \lambda_{AB} \begin{bmatrix}
0 & -g^2 & c_\theta^2|g|^2 & s_\theta^2|g|^2 \\
-g^*(2) & 0 & s_\theta^2(g^*)^2 & -c_\theta^2(g^*)^2 \\
c_\theta^2|g|^2 & s_\theta^2(g^*)^2 & 0 & -g^2 \\
s_\theta^2(g^*)^2 & c_\theta^2|g|^2 & -g^*(2) & 0
\end{bmatrix}.
\]

Here, the shorthand notation \( s_\theta \equiv \sin \theta \) and \( c_\theta \equiv \cos \theta \) is used. Physically, the parameter \( \theta \) quantifies the ratio between vertical (\( AC \) and \( BD \)) and diagonal (\( AD \) and \( BC \)) inter-layer hoppings. The band structure of the model (40) reads

\[
\epsilon_0(k) = 0, \quad \epsilon_1(k) = -2|g|^2, \quad \epsilon_2(k) = 2c_\theta^2|g|^2, \quad \epsilon_3(k) = 2s_\theta^2|g|^2,
\]

in units of \( \lambda_{AB} \). The upper two (lower two) bands are tunable by \( \theta \) if \( \lambda_{AB} \) is taken to be positive (negative), as shown in Fig. 6(b)–(e). Note that the system has a chiral symmetry for \( \theta = n\pi/2, \ n \in \mathbb{Z} \).

Finally, to illustrate that our flat-band model construction scheme indeed works for any dimension, an \( N = 4 \) flat-band model built from a CLS on the (3D) cubic lattice is discussed in Appendix D.

IV. FLAT-BAND MODELS WITH LINEAR BAND TOUCHING

The simplest scenario for a linear flat-band model is encountered in three-band (\( N = 3 \)) systems (Section IV A). This case will be studied in detail before generalizing to higher \( N \) (Section IV B).

A. Three-band models

Consider again some CLS built on a lattice with three orbitals per unit cell:

\[
|\Psi_{\text{CLS}}\rangle = \sum_{i \in \text{CLS}} (w_{Ai}|A_i\rangle + w_{Bi}|B_i\rangle + w_{Ci}|C_i\rangle),
\]

with corresponding BCLS

\[
|f_k\rangle = (f_A, f_B, f_C)^T.
\]

Our goal is now to construct \( N = 3 \) flat-band Bloch Hamiltonians \( H_k \) that are linear functions of \( |f_k\rangle \). To
achieve this, one cannot use a completely arbitrary input CLS, in contrast to the quadratic scenario. Instead, the CLS needs to have special properties. We can identify three cases that allow to build a linear $H_k$, namely the input CLS should be chiral, in which case $f_{A\beta\gamma}f_C = 0$; or anti-conjugate, in which case $f_{A\beta\gamma}f_C = (f_{A\beta\gamma}f_C)^*$; or conjugate, in which case $f_{A\beta\gamma}f_C = (f_{A\beta\gamma}f_C)^*$.

Flat-band models from chiral CLSs

The first possibility for building an $N = 3$ linear flat-band Hamiltonian arises if the input CLS (42) occupies two sublattices while vanishing on the third. Let $\tau \in \{A, B, C\}$ denote the unoccupied sublattice, then $f_{\tau} = 0$ and $f_{\alpha \neq \tau} \neq 0$. In this case we may call the CLS chiral, and we have $f_{A\beta\gamma}f_C = 0$. Any chiral CLS gives rise to a chiral BCLS

$$|f_k\rangle = |m_{r,k}^{ABC}\rangle,$$

$$|m_{A,k}^{ABC}\rangle \equiv (0, f_B, f_C)^T,$$

$$|m_{B,k}^{ABC}\rangle \equiv (f_A, 0, f_C)^T,$$

$$|m_{C,k}^{ABC}\rangle \equiv (f_A, f_B, 0)^T.$$  \hspace{1cm} (44)

It is easy to see that the matrix $M_{r,k}^{ABC}$, where

$$M_{A,k}^{ABC} \equiv \begin{bmatrix} 0 & -f_C & f_B \\ -f^*_C & 0 & 0 \\ f^*_B & 0 & 0 \end{bmatrix},$$

$$M_{B,k}^{ABC} \equiv \begin{bmatrix} 0 & -f_C & 0 \\ -f^*_C & 0 & f_A \\ 0 & f^*_A & 0 \end{bmatrix},$$

$$M_{C,k}^{ABC} \equiv \begin{bmatrix} 0 & 0 & -f_B \\ 0 & 0 & f_A^* \\ -f_B & f_A & 0 \end{bmatrix},$$

is orthogonal to $|m_{r,k}^{ABC}\rangle$. Consequently, any chiral CLS can be used to build a linear flat-band Bloch Hamiltonian

$$H_k = \lambda_k^{ABC} M_{r,k}^{ABC},$$

(46)

where $\lambda_k^{ABC}$ is any function with the periodicity of the FBZ. This Hamiltonian has a band structure

$$\epsilon_0(k) = 0,$$

$$\epsilon_{1,2}(k) = \pm \lambda_k^{ABC} \sqrt{|m_{r,k}^{ABC}|m_{r,k}^{ABC}}.$$  \hspace{1cm} (47)

The particle-hole symmetric character of the bands, \textit{i.e.} their symmetry about zero energy, is protected by an effective (global) chiral symmetry [46] $S H_k S = -H_k$, with a unitary matrix $S = \text{diag}(\sigma_A, \sigma_B, \sigma_C)$, where

$$\sigma_{\alpha \neq \tau} = 1 \text{ and } \sigma_{\alpha = \tau} = -1. \text{ Note that } \lambda_k^{ABC} = 1 \text{ in the following.}$$

Chiral CLSs can be easily found on any $N = 3$ lattice, since the functions $f_{\alpha \neq \tau}$ are completely unconstrained. As an example, consider the chiral CLS on the Kagome lattice shown in Fig. 7(a). Evidently, we have $\tau = B$, and the associated BCLS (44) is given by

$$f_A = w_A e^{-ik_x} + w_A e^{ik_x},$$

$$f_C = w_C e^{ik_x} + w_C e^{-ik_x}. $$  \hspace{1cm} (48)

Inserting into Eq. (46), we obtain a flat-band tight-
binding model

\[ H_k = \begin{bmatrix} 0 & H_{AB} & 0 \\ H_{AB}^* & 0 & H_{BC} \\ 0 & H_{BC}^* & 0 \end{bmatrix}, \quad (49) \]

where

\[ H_{AB} = t^A_B e^{-ikx} + t^A_B e^{ikx}, \]
\[ H_{BC} = t^B_C e^{-ikx} + t^B_C e^{ikx}. \quad (50) \]

This model has the topology of a Lieb lattice and is depicted in Fig. 7(b). Again, the hopping directions are determined by the shape of the CLS, i.e., by the position vectors \( \vec{\delta}_i \), although in a different fashion than for the quadratic models (see Appendix A). Similarly, the hopping parameters \( t_{AB}^A \equiv -w_{\alpha} \) and \( t_{BC}^B \equiv w_{\alpha} \) again depend on the CLS amplitudes, which allows to design the band structure. For instance, a BTP may be created at the \( \Gamma \) point [Fig. 7(c)] or at the \( K \) points [Fig. 7(d)], while the flat band can be gapped out by an imbalance in the CLS amplitudes.

As a more complicated example, consider the chiral CLS on the dice lattice shown in Fig. 7(e). The corresponding BCLS (44) is given by

\[ f_A = w_{A1} e^{ikx} + w_{A2} e^{ikx} + w_{A3} e^{-ikx} + w_{A4} e^{-2ikx}, \]
\[ f_C = w_{C1} e^{-ikx} + w_{C2} e^{-ikx} + w_{C3} e^{ikx} + w_{C4} e^{2ikx}, \quad (51) \]

and inserting into Eq. (46) leads to a flat-band TB model of the form (49), where now

\[ H_{AB} = t^A_B e^{ikx} + t^A_B e^{-ikx} + t^B_C e^{-ikx} + t^A_B e^{-2ikx}, \]
\[ H_{BC} = t^B_C e^{ikx} + t^B_C e^{-ikx} + t^C_D e^{-ikx} + t^B_C e^{-2ikx}, \quad (52) \]

with hopping parameters as defined above. This model is depicted in Fig. 7(f) and allows for different kinds of BTPs depending on the CLS amplitudes. For example, BTPs may appear at the \( \Gamma \) and \( M \) points [Fig. 7(g)], away from high-symmetry points [Fig. 7(h)], or the flat band may be gapped out by a suitable asymmetry. Finally, note that a similar construction works in any spatial dimension, since chiral CLSs can be easily built.

**Flat-band models from anti-conjugate CLSs**

The second possibility for building an \( N = 3 \) linear flat-band Hamiltonian arises if the input CLS (42) occupies all sublattices, but in such a way that the amplitudes \( w_{\alpha} \) are arranged in a certain (anti)symmetrical fashion with respect to the localization center. We may call such a CLS **anti-conjugate**. More precisely, any anti-conjugate CLS corresponds to an **anti-conjugate BCLS**

\[ |f_k\rangle = |\eta_{ABC}^k\rangle \equiv (f_A, f_B, f_C)^T, \]
\[ f^*_\alpha = \kappa_\alpha f_\alpha, \]
\[ \kappa_{ABK} \kappa_{BC} = -1, \quad (53) \]

i.e., each component \( f_\alpha \) is either real (\( \kappa_\alpha = 1 \)) or imaginary (\( \kappa_\alpha = -1 \)), and the three signs \( \kappa_\alpha \) are correlated such that \( f_A f_B f_C = -(f_A f_B f_C)^* \).

It is easy to see that the matrix

\[ N_{ABC}^k \equiv \begin{bmatrix} 0 & -f_C & f_B \\ -\kappa_C f_C & 0 & \kappa_C f_A \\ \kappa_B f_B & -\kappa_B f_A & 0 \end{bmatrix} \quad (54) \]

is orthogonal to \( |\eta_{ABC}^k\rangle \). Thus, any anti-conjugate CLS can be used to build a linear flat-band Bloch Hamiltonian

\[ H_k = \lambda_{ABC}^k N_{ABC}^k, \quad (55) \]

This Hamiltonian has a band structure

\[ \epsilon_0(k) = 0, \]
\[ \epsilon_{1,2}(k) = \pm \lambda_{ABC}^k \sqrt{|n_{ABC}^k| |n_{ABC}^k|}, \quad (56) \]

which is particle-hole symmetric due to an effective (global) charge conjugation symmetry \[ C^\dagger H^\dagger C = -H_k, \] with a unitary matrix \( C = \text{diag}(\kappa_A, \kappa_B, \kappa_C) \). Note that again \( \lambda_{ABC}^k = 1 \) hereafter.
Anti-conjugate CLSs cannot be found on all $N = 3$ lattices, since each sublattice involved in the CLS need to be (anti)symmetric with respect to the localization center. For example, an anti-conjugate CLS cannot exist on the dice lattice, but it can exist on the Kagome lattice. As an example, consider the CLS shown in Fig. 8(a), where we take the amplitudes $w_{α}$ to be real for concreteness. In order for the CLS to qualify as anti-conjugate, the three amplitudes $w_{α}$ have to be chosen as $w_{α} = κ_{α} w_{α}$, with $κ_{AB}κ_{C} = −1$. The corresponding BCLS (53) is given by

$$
\begin{align*}
    f_{A} &= w_{A_{1}} (e^{-ik_{y} + κ_{A}e^{ik_{x}}}),
    f_{B} &= w_{B_{1}} (e^{ik_{y} + κ_{B}e^{-ik_{x}}}),
    f_{C} &= w_{C_{1}} (e^{ik_{x} + κ_{C}e^{-ik_{y}}}).
\end{align*}
$$

(57)

Inserting into Eq. (55), we find a flat-band TB model

$$
H_{k} = \begin{bmatrix}
0 & H_{AB} & H_{AC} \\
H_{AB}^{*} & 0 & H_{BC} \\
H_{AC}^{*} & H_{BC}^{*} & 0
\end{bmatrix},
$$

(58)

where

$$
\begin{align*}
    H_{AB} &= t^{AB} (e^{ik_{x} + κ_{C}e^{-ik_{y}}}), \\
    H_{AC} &= t^{AC} (e^{ik_{y} + κ_{B}e^{-ik_{x}}}), \\
    H_{BC} &= t^{BC} (e^{-ik_{y} + κ_{A}e^{ik_{x}}}).
\end{align*}
$$

(59)

Here, the hopping parameters are $t^{AB} = −w_{C_{1}}$, $t^{AC} = w_{B_{1}}$, and $t^{BC} = κ_{C}w_{A_{1}}$. This model is shown in Fig. 8(b). Again, the band structure can be designed using the CLS amplitudes. An example with a BTP at the M point in Fig. 8(d). Finally, an example for a 3D anti-conjugate CLS is given in Appendix D.

**Flat-band models from conjugate CLSs**

The third possibility for building an $N = 3$ linear flat-band Hamiltonian arises if all three sublattices participate in the input CLS (42), but where now two sublattices are conjugates of one another, while the third sublattice (indicated by $τ$) is symmetric with respect to the localization center. We may call such a CLS conjugate. More precisely, any conjugate CLS corresponds to a conjugate BCLS

$$
\begin{align*}
    |f_{k}\rangle &= |o_{τk}^{ABC}\rangle, \\
    |o_{A_{k}}^{ABC}\rangle &= (f_{A}, −f_{C}, f_{C})^{T}, \\
    |o_{B_{k}}^{ABC}\rangle &= (f_{A}, f_{B}, −f_{A})^{T}, \\
    |o_{C_{k}}^{ABC}\rangle &= (−f_{B}, f_{C}, f_{B})^{T},
\end{align*}
$$

(60)

where the component $f_{τ}$ is real. Consequently, $f_{A}f_{B}f_{C} = (f_{A}f_{B}f_{C})^{*}$. It is easy to see that the matrix $O_{τk}^{ABC}$, with

$$
O_{A_{k}}^{ABC} = \begin{bmatrix}
0 & f_{C} & f_{C} \\
f_{C}^{*} & f_{A} & 0 \\
f_{C} & 0 & −f_{A}
\end{bmatrix},
$$

(61)

$$
O_{B_{k}}^{ABC} = \begin{bmatrix}
−f_{B} & f_{A} & 0 \\
f_{A}^{*} & f_{A} & 0 \\
0 & f_{B} & f_{B}
\end{bmatrix},
$$

$$
O_{C_{k}}^{ABC} = \begin{bmatrix}
f_{C} & 0 & f_{B} \\
0 & −f_{C} & f_{B} \\
f_{B} & f_{B} & 0
\end{bmatrix},
$$

(62)

is orthogonal to $|o_{τk}^{ABC}\rangle$. Thus, any conjugate CLS can be used to build a linear flat-band Bloch Hamiltonian

$$
H_{k} = λ_{k}^{ABC} O_{τk}^{ABC}.
$$

This Hamiltonian is in fact a spin-1 Hamiltonian, i.e. it can be written in the form $H_{k} = h_{x}(k)S_{x} + h_{y}(k)S_{y} + h_{z}(k)S_{z}$, with spin-1 operators that fulfill the algebra $[S_{i}, S_{j}] = ε_{ijk}S_{k}$. It has a band structure

$$
\begin{align*}
    ε_{0}(k) &= 0, \\
    ε_{1,2}(k) &= ± λ_{k}^{ABC} \sqrt{(o_{τk}^{ABC}|o_{τk}^{ABC})},
\end{align*}
$$

(63)

whose particle-hole symmetric character is protected by an effective (global) charge conjugation symmetry with a unitary matrix $C = e^{iπS_{x}}$, with diagonal matrix elements $C_{αα} = −δ_{ατ}$ and off-diagonal elements $C_{αβ} = 1 − δ_{ατ} − δ_{βτ}$. Again $λ_{k}^{ABC} = 1$ in the examples below.

Conjugate CLSs cannot be found on all $N = 3$ lattices due to the requirement of two sublattices being the conjugate of each other. For example, a conjugate CLS cannot exist on the Kagome lattice, but it can exist on the dice lattice. As an example, consider the CLS shown in Fig. 9(a), where we fix $w_{B_{1}}$ to be imaginary for concreteness. In order for the CLS to qualify as conjugate, we now have to take $w_{B_{2}} = −w_{B_{1}}$, such that $τ = B$, and $w_{C_{1}} = −w_{A_{1}}$. The corresponding BCLS (60) is then given by

$$
\begin{align*}
    f_{A} &= w_{A_{1}} e^{ik_{x}} + w_{A_{2}} e^{ik_{y}} + w_{A_{3}} e^{-ik_{x}}, \\
    f_{B} &= 2i w_{B_{1}} \sin(k_{x} + k_{z}).
\end{align*}
$$

(64)
FIG. 9. (a) A CLS on the dice lattice that is conjugate if the amplitudes are properly correlated. (b) Tight-binding model built from the CLS. The corresponding band structure is shown in (c) for \( w_A^1 = w_A^2 = w_A^3 = 1, w_B^1 = 1 \). (d) More extended conjugate CLS on the dice lattice, with \( w_A^i = \pm 1 \) and \( w_B^i = \pm i \) as shown. (f) Band structure for the corresponding TB model.

Inserting into Eq. (62), we find a flat-band TB model

\[
H_k = \begin{bmatrix}
H_{AA} & H_{AB} & 0 \\
H_{AB}^* & 0 & H_{BC} \\
0 & H_{BC}^* & H_{CC}
\end{bmatrix},
\]

(65)

where

\[
H_{AA} = -H_{CC} = 2it_{AA}^e \cos(k_x + k_z), \\
H_{AB} = H_{BC} = t_1^{AB} e^{ik_x} + t_2^{AB} e^{ik_y} + t_3^{AB} e^{ik_z},
\]

(66)

with hopping parameters \( t_{AA}^e = -w_B \) and \( t_{AB}^e = w_A \). The corresponding real-space TB model is shown in Fig. 9(b), and its band structure can be designed using the CLS amplitudes. An example with a BTP at the \( \Gamma \) point is shown in Fig. 9(c), and one with a BTP at the \( M \) point in Fig. 9(d). Note that BTPs at the \( K \) points could be created by taking an input CLS with six \( B \) orbitals arrayed hexagonally.

As a more complicated example, consider the extended conjugate CLS shown in Fig. 9(e). Inserting into Eq. (62) leads to a flat-band TB model with linear BTPs at the \( \Gamma \) and \( M \) points, as shown in Fig. 9(f).

Finally, an example for a 3D conjugate CLS is given in Appendix D.

**Conditions for reasonable linear flat-band models**

As discussed above, a given CLS has to possess special properties to qualify as chiral, anti-conjugate, or conjugate. However, even if some given CLS is, say, chiral, it is not automatically guaranteed that the chiral Hamiltonian (46) constructed from it will be reasonable, i.e. make sense when transformed to real space [cf. condition (13)]. The same is true for (anti-)conjugate CLSs.

In Fig. 7, we have seen chiral CLSs for which Eq. (46) does make sense on a lattice. As a counterexample, consider the CLS shown in Fig. 10(a). It perfectly qualifies as a chiral CLS with \( \tau = B \), however we can easily convince ourselves that the Bloch Hamiltonian obtained by inserting its BCLS into Eq. (46) does not correspond to a reasonable lattice model. Similarly, in Fig. 9, we have seen conjugate CLSs for which Eq. (62) makes sense on a lattice. As a counterexample, consider the CLS shown in Fig. 10(b), which perfectly qualifies as a conjugated CLS with \( \tau = A \) if \( w_A^1 = w_A^2 \) and \( w_C^i = -w_B^i \), but will not lead to a reasonable real-space model when its BCLS is inserted into Eq. (62).

There are thus two fundamental reasons that make the linear flat-band models much rarer than the quadratic models of Section III: (i) Only for certain classes of input CLSs it is possible to construct a linear matrix \( H_k \) that fulfills \( H_k \mid \psi_k \rangle = 0 \). (ii) Even if the input CLS belongs to such a special class, the position of the localization center and the arrangement of the sites around it need to be compatible with the underlying lattice, else the linear matrix \( H_k \) will not make sense in real space.

FIG. 10. (a) A chiral CLS on the dice lattice for which the linear Hamiltonian (46) is not physically reasonable. (b) A conjugate CLS on the dice lattice for which the linear Hamiltonian (62) is not physically reasonable.

**B. \( N \)-band models**

We now extend the notion of a linear flat-band Hamiltonian to any \( N \). Thus, consider again a CLS (1) built
on a lattice with $N$ orbitals per unit cell, associated to a BCLS

$$|f_k\rangle = (f_A, f_B, f_C, \ldots)^T. \quad (67)$$

The procedure that we will adopt for building a linear flat-band Hamiltonian from such a CLS is very similar in spirit to what was done in Section III for the quadratic flat-band models. There, we identified the $N = 2$ quadratic Hamiltonian (18) as a building block that allowed to construct $N \times N$ matrices $F^\alpha_\beta$, orthogonal to $|f_k\rangle$; the $N$-band quadratic Hamiltonian (37) was then formed as a linear combination of these matrices.

In exactly the same way, we can now regard the $N = 3$ linear Hamiltonians (46), (55) and (62) as building blocks that will allow to construct $N \times N$ matrices $F^\alpha_\beta$ orthogonal to $|f_k\rangle$. An $N$-band linear flat-band Hamiltonian can then be formed as a linear combination of these matrices,

$$H_k = \sum_{\alpha, \beta > \alpha, \gamma > \beta} \lambda^{\alpha \beta \gamma}_k F^\alpha_\beta F^\alpha_\gamma, \quad (68)$$

where $\lambda^{\alpha \beta \gamma}_k$ is an arbitrary function with the periodicity of the FBZ ($\lambda^{\alpha \beta \gamma}_k = \lambda^{\alpha \beta \gamma}_k$ hereafter).

The Hamiltonian (68) is the second main result of this paper. It is the linear analog of the $N$-band quadratic Hamiltonian (37). Several remarks about its construction and generic properties are in order.

In contrast to the quadratic Hamiltonian (37), which can be built from any input CLS, a linear Hamiltonian (68) can only be built from a CLS with special properties. In particular, the CLS must be decomposable into chiral, anti-conjugate and/or conjugate sub-CLSs,

$$|\psi^{\alpha \beta \gamma}_i\rangle = \sum_{i \in \text{CLS}} (w_{\alpha} |\alpha_i\rangle + w_{\beta} |\beta_i\rangle + w_{\gamma} |\gamma_i\rangle), \quad (69)$$

each of which involves only three sublattices ($\alpha, \beta, \gamma$) out of the $N$ sublattices. As described in detail in Appendix E, each sub-CLS contributes one term to the Hamiltonian (68), more precisely $F^\alpha_\beta \psi^{\alpha \beta \gamma}_i = M^\alpha_\beta \psi^{\alpha \beta \gamma}_i$, or $F^\alpha_\beta = O^\alpha_\beta$ if $|\psi^{\alpha \beta \gamma}_i\rangle$ is a chiral, anti-conjugate or conjugate sub-CLS, respectively.

The Hamiltonian (68) consists of only one term if $N = 3$; in this case, it is tunable only by the input CLS, just like the $N = 2$ quadratic models. In contrast, the $N \geq 4$ linear models obtained from Eq. (68) are, just like the $N \geq 3$ quadratic models, tunable by the input CLS and the parameters $\lambda^{\alpha \beta \gamma}_k$ that arise from the linear combination.

If only chiral matrices $M^\alpha_\beta$ contribute to the Hamiltonian (68), it exhibits an effective (global) chiral symmetry $S H_k S = -H_k$, with a unitary matrix $S = \text{diag}(\sigma_A, \sigma_B, \sigma_C, \ldots)$, where $\sigma_A = 1$ for all sublattices occupied by the CLS and $\sigma_A = -1$ for all unoccupied sublattices. Similarly, if only anti-conjugate matrices $N^\alpha_\beta$ contribute, $H_k$ exhibits an effective (global) charge conjugation symmetry $C H_k C = -H_k$, with a unitary matrix $C = \text{diag}(\kappa_A, \kappa_B, \kappa_C, \ldots)$, where $\kappa_A = 1$ if $f_A$ is real and $\kappa_A = -1$ if $f_A$ is imaginary. In the presence of either chiral or charge conjugation symmetry, the band structure of the Hamiltonian (68) takes a simple form for $N = 4$ and $N = 5$, respectively [48]:

$$\epsilon^{\alpha}(k) = \begin{cases} 0, \pm \frac{C_2}{2} \end{cases}, \quad \epsilon^{\alpha}(k) = \begin{cases} 0, \pm \sqrt{\frac{C_2}{4} \pm \frac{1}{2} \sqrt{C_4 - \frac{C_2^2}{4}}} \end{cases}, \quad (70)$$

where again $C_n \equiv \text{Tr}(H_{k_n})$.

In contrast, if only conjugate matrices $O^\alpha_\beta$ or matrices of different types contribute to the Hamiltonian (68), no chiral or charge conjugation symmetry will in general be present. In this case, there is no simple closed-form expression for the dispersive bands, but the existence of a flat band is always guaranteed.

![FIG. 11. (a) CLS on an $N = 5$ Kagome lattice. The $D$ orbitals are at the same sites as the $B$ orbitals but are unoccupied, as indicated by the black color. (b) Decomposition into three sub-CLSs. (c) & (d) Band structure of the corresponding TB model (72), with $\lambda_{ABC} = \lambda_{ADE} = 1$, $\lambda_{ACD} = 0$, for (c) $w_{\alpha_1} = w_{\alpha_3} = 1$ and (d) $w_{\alpha_1} = 2w_{\alpha_3} = 2$, where $\alpha = A, B, C, E$. (e) & (f) Same as (c) & (d) but with $\lambda_{ACD} = 1$. The insets show the deviation from particle-hole symmetry of the bands.](image-url)
Finally, just like the quadratic Hamiltonian (37), the linear Hamiltonian (68) vanishes at \( k_0 \) whenever \( |f_{k_0}\rangle = 0 \). As a consequence, there will be an \( N \)-fold (singular) BTP at \( k_0 \). More generally, in contrast to the quadratic BTPs of Section III, the linear BTPs encountered here can of course not be of any degeneracy, as they must involve an odd number of bands.

As an example that well illustrates many of these generic features, consider the CLS on the multi-orbital \((N = 5)\) Kagome lattice shown in Fig. 11(a). We take the orbitals on sublattices \( \alpha = A, B, C \) to be occupied antisymmetrically as \( \omega_{\alpha} = -w_{\alpha} \), \( \omega_{\alpha} = -w_{\alpha} \), sublattice \( D \) to be unoccupied, sublattice \( E \) to be occupied symmetrically as \( w_{E_2} = w_{E_4} = w_{E_5} \), and we will further assume \( w_{\alpha} \in \mathbb{R} \). The corresponding BCLS then takes the form \( |f_k\rangle = (f_A, f_B, f_C, 0, f_E)^T \), where

\[
\begin{align*}
&f_A = -2i[w_A, \sin k_x + w_{A_2} \sin (k_x + k_y)], \\
&f_B = -2i[w_B, \sin k_y + w_{B_2} \sin (k_x + k_y)], \\
&f_C = 2i[w_{C_2} \sin (3k_y)], \\
&f_E = 2i[w_{E_5} \cos k_x + w_{E_4} \cos (\sqrt{3} k_y)].
\end{align*}
\]

(71)

This CLS can be decomposed into three sub-CLSs, namely an anti-conjugate sub-CLS \( |\psi_{ABC}\rangle \) and two chiral sub-CLSs \( |\psi_{ACD}\rangle \) and \( |\psi_{ADE}\rangle \), as shown in Fig. 11(b) (see Appendix E for details). Accordingly, from this CLS, we can build an \( N = 5 \) linear flat-band Hamiltonian

\[
H_k = \lambda_{ABC}F_k^{ABC} + \lambda_{ACD}F_k^{ACD} + \lambda_{ADE}F_k^{ADE}
\]

(72)

where

\[
F_k^{ABC} = N_k^{ABC} \equiv \begin{bmatrix} 0 & -f_C & f_B & 0 & 0 \\ f_C & 0 & -f_A & 0 & 0 \\ -f_B & f_A & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \end{bmatrix},
\]

\[
F_k^{ACD} = M_k^{ACD} \equiv \begin{bmatrix} 0 & 0 & 0 & -f_C^* & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & f_A & 0 \\ -f_C & 0 & f_A & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \end{bmatrix},
\]

(73)

\[
F_k^{ADE} = M_k^{ADE} \equiv \begin{bmatrix} 0 & 0 & 0 & -f_E^* & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & f_A & 0 \\ -f_E & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & -f_A & 0 \end{bmatrix}.
\]

Two interesting cases (i.e. where no band is decoupled) can be identified, namely \( \lambda_{ABC}, \lambda_{ADE} \neq 0 \) with either \( \lambda_{ACD} = 0 \) or \( \lambda_{ACD} \neq 0 \). In the former case, the Hamiltonian has an effective charge-conjugation symmetry with \( C = \text{diag}(1, 1, 1, -1, -1) \), such that the energy spectrum is of the form (70). An example for this is shown in Fig. 11(c), where fivefold BTPs appear at the M points. They are connected by a threefold nodal line at \( f_A = 0 \). If some imbalance is introduced in the CLS amplitudes, the fivefold degeneracy is reduced to a threefold one and the nodal line is deformed, see Fig. 11(d). In the latter case, \( \lambda_{ACD} \neq 0 \), the charge conjugation symmetry is broken and the spectrum is no longer particle-hole symmetric. Examples for this are shown in Fig. 11(e) & f), where again a nodal line appears at \( f_A = 0 \).

As a second example, consider the CLS on the multi-orbital \((N = 5)\) dice lattice shown in Fig. 12(a). We take the orbitals on sublattice \( B \) to be occupied symmetrically as \( w_{B_4} = w_{B_5} = w_{B_6} = w_{B_6} \), sublattice \( C \) to be occupied oppositely to sublattice \( A \), \( w_{C_2} = -w_{A_i} \), sublattice \( E \) to be unoccupied, and we will further assume \( w_{\alpha} \in \mathbb{R} \). The corresponding BCLS takes the form

\[
|f_k\rangle = (f_A, f_B, f_C, 0, f_D)^T,
\]

where

\[
\begin{align*}
&f_A = w_{A_1} e^{ik_x} + w_{A_2} e^{ik_y} + w_{A_3} e^{-ik_x}, \\
&f_B = 2[w_{B_2} \cos(\sqrt{3} k_y) + w_{B_3} \cos(k_x + k_y) + w_{B_4} \cos(k_x + k_y)], \\
&f_C = -f_A^*, \\
&f_D = w_{D_1} e^{-ik_x} + w_{D_2} e^{-ik_y} + w_{D_3} e^{ik_x}.
\end{align*}
\]

Finally, just like the quadratic Hamiltonian (37), the linear Hamiltonian (68) vanishes at \( k_0 \) whenever \( |f_{k_0}\rangle = 0 \). As a consequence, there will be an \( N \)-fold (singular) BTP at \( k_0 \). More generally, in contrast to the quadratic BTPs of Section III, the linear BTPs encountered here can of course not be of any degeneracy, as they must involve an odd number of bands.
This CLS can be decomposed into three sub-CLSs, namely a conjugate sub-CLS $|\psi_{ABC}\rangle$ and two chiral sub-CLSs $|\psi_{ACE}\rangle$ and $|\psi_{ADE}\rangle$, as shown in Fig. 12(b) (see Appendix E for details). Accordingly, from this CLS, we can again build an $N = 5$ linear flat-band Hamiltonian as a linear combination of three matrices,

$$H_k = \lambda_{ABC} F_{k}^{ABC} + \lambda_{ACE} F_{k}^{ACE} + \lambda_{ADE} F_{k}^{ADE}, \quad (75)$$

where now

$$F_{k}^{ABC} = O_{B,k}^{ABC} \equiv \begin{bmatrix} -f_B & f_A & 0 & 0 & 0 \\ f_A & 0 & f_A & 0 & 0 \\ 0 & f_A & f_B & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \end{bmatrix},$$

$$F_{k}^{ACE} = M_{E,k}^{ACE} \equiv \begin{bmatrix} 0 & 0 & 0 & 0 & -f_C \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & f_A & 0 \\ -f_C & 0 & f_A & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \end{bmatrix}, \quad (76)$$

$$F_{k}^{ADE} = M_{E,k}^{ADE} \equiv \begin{bmatrix} 0 & 0 & 0 & 0 & -f_D \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & f_A & 0 \\ -f_D & 0 & 0 & f_A & 0 \end{bmatrix}.$$}

For all interesting cases (i.e. where no band is decoupled) the spectrum is not particle-hole symmetric, due to the mixing of chiral and conjugate building blocks. In Fig. 12(c) & (d), the spectrum is shown for different amplitudes of the input CLS. In particular, fivefold BTPs can be created at the K points or at the $\Gamma$ point. Of course, the bands are also tunable by the three parameters $\lambda_{\alpha\beta\gamma}$.

V. INTERPOLATING BETWEEN LINEAR AND QUADRATIC BAND TOUCHING

From the previous discussion we know that all CLSs allow to build quadratic flat-band models, while only special CLSs allow to build linear ones. In other words, each such special CLS can be used to create both a linear and a quadratic flat-band model; both models will have a zero-energy flat band and an identical flat-band eigenstate. In this way, we can construct tight-binding models that allow to interpolate smoothly between multifold linear and quadratic BTPs, without moving the BTP or destroying the flat band.

As a simple example, consider again a six-site CLS on the Kagome lattice, where we now fix $w_{A_1} = -w_{B_1} = \ldots = -w_{C_2}$ and $w_{A_2} = w_{B_2} = \ldots = w_{C_1}$.

\[ H_k = (1 - \lambda)H_{\text{lin}} + \lambda H_{\text{quad}}, \quad (77) \]

which gives rise to a tight-binding model that can be smoothly tuned from linear to quadratic by the parameter $\lambda \in [0, 1]$, without the flat band and its eigenstate being affected in any way. This is illustrated in Fig. 13(b)–(d).

In the same way, all the linear BTPs encountered in Section IV can be smoothly tuned to become quadratic, simply by interpolating the respective linear flat-band model with the quadratic model (37) built from the same CLS.

VI. CONCLUSIONS

It has been known for a long time that, for any given flat-band tight-binding (TB) model $H$ on a periodic lattice, it is possible to find a macroscopic number of compact localized states (CLSs) as eigenstates of $H$.

Conversely, in the present work, we have shown that for any given (input) CLS $\psi_{RCL}$ on any periodic lattice, it is possible to engineer one or several families of TB Hamiltonians $H$ for which this CLS and all its translated copies are eigenstates. We have provided a precise procedure to find such TB Hamiltonians, which are flat-band models by construction. Since infinitely many
different CLSs can be constructed on any lattice, this represents an efficient flat-band construction scheme: it yields infinitely many flat-band TB models on any periodic lattice.

This procedure is most conveniently carried out in reciprocal space, as explained in Section II. First, we exploited the fact that there is a one-to-one correspondence between any given CLS $\Psi_{\text{CLS}}^\text{RC}$ and the associated Bloch state, the BCLS $|f_k\rangle$. Flat-band Bloch Hamiltonians $H_k$ can then conveniently be engineered as a function of the BCLS. Once $H_k$ is determined, the real-space model $H$ is straightforwardly obtained.

For any arbitrarily designed input CLS, it is always possible to construct a flat-band model $H_k$ as a quadratic function of the BCLS, as discussed in Section III. This generic quadratic Hamiltonian, which works for any number of bands $N \geq 2$, is provided in Eq. (37) and gives rise to TB models with quadratic multifold BTPs at the flat-band energy. In contrast, if the input CLS has certain special properties, it can be used not only to build quadratic models, but also to construct a Bloch Hamiltonian $H_k$ as a linear function of the BCLS, as discussed in Section IV. This generic linear Hamiltonian, which works for any number of bands $N \geq 3$, is given in Eq. (68) and provides TB models with linear multifold BTPs at the flat-band energy.

The generic quadratic Hamiltonian (37) is based on $N = 2$ building blocks of the form (18). Similarly, the generic linear Hamiltonian (68) is based on $N = 3$ building blocks of the form (46), (55) & (62). Due to this superposition principle, our models can not only be designed by choice of the input CLS, but also are widely 
tunable by a set of completely free parameters. For the quadratic flat-band models, there are exactly $N_f = \frac{(N)}{2}$ free parameters $\lambda_{\alpha\beta}$, independently of the input CLS. In contrast, for the linear models, the precise number $N_f \leq \frac{(N)}{3}$ of free parameters $\lambda_{\alpha\beta\gamma}$ depends on the input CLS. Importantly, for both classes of models, the flat band and its eigenstate are independent of the free parameters, while the dispersive bands and their eigenstates depend on them.

Since our flat-band models are tunable by these two knobs, the input CLS and the free parameters, they allow for extensive control over the existence, degeneracy and location of multifold BTPs. This is perhaps most strikingly illustrated by the discussion of Section V: from any CLS that leads to a linear flat-band model, we can also construct TB models with BTPs whose low-energy dispersion can be smoothly interpolated from linear to quadratic.

In closing this work, let us mention some perspectives. First, while our method allows to build infinitely many flat-band TB models, and while it captures most models described in the literature, it can be generalized in several ways. For example, a more general version of the quadratic Hamiltonian (37) reads

$$H_k = \sum_{\alpha\beta\gamma} \sum_{\delta\epsilon} \lambda_{\alpha\beta\gamma\delta} \langle f^{\alpha\beta}_{k} | f^{\gamma\delta}_{k} \rangle |f_k\rangle,$$

where $\lambda_{\alpha\beta\gamma\delta} = \lambda_{\gamma\delta\alpha\beta}$. Moreover, it is clear that not all flat-band models are governed by Bloch Hamiltonians that are simply linear or quadratic functions of the flat-band eigenstate $|f_k\rangle$. As a prominent example, consider the ordinary nearest-neighbor TB model on the ($N = 3$) Kagome lattice. At the $\Gamma$ point, its flat-band eigenstate vanishes, $|f_{k=0}\rangle = 0$, and the band structure exhibits a twofold BTP. A situation of this kind cannot be captured by our Hamiltonians (37) or (68), since they locally vanish whenever $|f_k\rangle$ vanishes, implying the presence of an $N$-fold BTP. Indeed, it seems that the Bloch Hamiltonian for the simple Kagome model cannot be written as an analytic function of the flat-band eigenstate. Thus, it would be rewarding to establish all possible relations between $H_k$ and $|f_k\rangle$, and to develop a classification scheme of flat-band systems based on these relations.

Second, we have only used strictly localized states as an input for the Hamiltonians (37) and (68), in order to obtain short-range TB models with an exactly flat band. This implies that all flat bands presented in this work have a first Chern number $C_1 = 0$ [49]. It might be worthwhile to study the models obtained by using infinitely extended states (e.g. with some power-law decay) as an input for our Hamiltonians, in particular with regard to a possible topological character of the flat bands.

Third, the flat-band construction scheme discussed here exclusively for lattice models can be immediately applied to low-energy (continuum) models as well. Two cases may be distinguished in this regard. On the one hand, for any flat-band lattice model built from some given CLS, the low-energy theory around some point in the FBZ can be obtained simply by linearizing the BCLS components $f_{\alpha}(k)$, which will preserve the flat band by construction. On the other hand, one can also make a general ansatz $f_{\alpha}(k) = v_{\alpha} \cdot k$ without having in mind a concrete lattice model, and study the generic properties of the continuum models obtained from the Hamiltonians (37) or (68).

Finally, it would be interesting to investigate the quantum geometric (and possibly topological) structures associated to our multifold BTPs. In particular, the chiral, anti-conjugate and conjugate classes of flat-band Hamiltonians introduced in Section IV are expected to correspond to different kinds of topological defects.

ACKNOWLEDGEMENTS

We thank Mateo Uldemolins for fruitful discussions.

Appendix A: Relation between input CLSs and real-space tight-binding models

In order to determine the real-space tight-binding model corresponding to the Bloch Hamiltonian $H_k$ built from some input CLS, we write the off-diagonal matrix
each orbital with respect to the localization center is relevant. (b) For linear flat-band models, only the position of the localization center is relevant. FIG. 14. (a) For quadratic flat-band models, only the relative distance between each pair of orbitals within the CLS is relevant. (b) For linear flat-band models, only the position of each orbital with respect to the localization center is relevant.

For the linear flat-band models described by Eq. (68), the exact form of the matrix elements depends on the input CLS. However, since all matrix elements are linear in \( f_\alpha \), it is clear from Eq. (6) that they always contain phase factors of the form \( \exp[i\mathbf{k} \cdot \delta_{\alpha_i}] \). Generically, the hopping directions \( r_{\alpha}^{\alpha \beta} \) are given by the positions of some orbitals of a third kind \( \gamma \) with respect to the localization center. This is well visible in Figs. 7–9. Thus, for linear flat-band models, the position of the localization center is very important, cf. Fig. 14(b). This is why linear flat-band models can only be built from CLSs that fulfill certain compatibility relations with the underlying lattice. For the linear flat-band models, all onsite energies are zero. The hopping parameters are functions both of the CLS amplitudes and of the parameters \( \lambda_{\alpha \beta \gamma} \).

Appendix B: Two-band Bloch Hamiltonian with a flat band

To find a \( 2 \times 2 \) matrix \( H_k \) with a (unnormalized) flat-band eigenstate \( |f_k\rangle \), we may first assume that \( |f_k\rangle \) is such an eigenstate. Evidently, this uniquely determines the corresponding eigenprojector

\[
P_0(k) = \frac{|f_k\rangle \langle f_k|}{\langle f_k| f_k \rangle} = \frac{1}{|f_A|^2 + |f_B|^2} \begin{bmatrix} f_A f_B^* & f_A f_B \end{bmatrix}
\]

but, crucially, it also fixes the orthogonal eigenprojector

\[
P_1(k) = 1 - P_0(k) = \frac{1}{|f_A|^2 + |f_B|^2} \begin{bmatrix} |f_B|^2 & -f_A f_B^* \\ -f_A^* f_B & |f_A|^2 \end{bmatrix}
\]

This latter property is unique to the two-band case. According to the spectral theorem, the desired flat-band Hamiltonian now necessarily takes the form

\[
H_k = \epsilon_0 P_0(k) + \epsilon_1(k) P_1(k) = \epsilon_0 1 + (\epsilon_1(k) - \epsilon_0) P_1(k),
\]

with the flat-band energy \( \epsilon_0 \). Without loss of generality, we may now take \( \epsilon_0 = 0 \), such that Eq. (B3) turns into Eq. (18) of the main text. In summary, all two-band models with a flat band are of the form (18).

Appendix C: Band touching scenarios for the quadratic three-band Hamiltonian

Consider the three-band Hamiltonian (28) with band structure (29). For any given point \( \mathbf{k}_0 \) in the FBZ, one can distinguish four possibilities for the behavior of |\( f_{\mathbf{k}_0} \rangle|:

1. If |\( f_{\mathbf{k}_0} \rangle| = 0 \), there is a threefold (singular) BTP.
If $\lambda (f)$ be trivially decoupled. The possibility should be ignored since the flat band would now be controlled by the parameters $\lambda_{\alpha\beta}$. If $\lambda_{\alpha\beta}$ and $\lambda_{\alpha\beta}$ are nonzero, the flat band is fully gapped. If $\lambda_{\alpha\beta} = 0$ or $\lambda_{\alpha\beta} = 0$, there is a twofold BTP. If $\lambda_{\alpha\beta} = \lambda_{\alpha\beta} = 0$, there is a threefold BTP, however this possibility should be ignored since the flat band would be trivially decoupled.

(3) If one out of the three components of $|f_{k_0}|$ vanishes (say $f_{C}(k_0) = 0$ for concreteness), the degeneracy of the BTP is again tunable by the $\lambda_{\alpha\beta}$. For most values of the $\lambda_{\alpha\beta}$, all bands will be gapped from each other at $k_0$, but choosing $\lambda_{\alpha\beta} = 0$ leads to $\epsilon_0(k_0) = \epsilon_2(k_0) = 0$, $\epsilon_1(k_0) = \lambda_{AC}|f_A(k_0)|^2 + \lambda_{BC}|f_B(k_0)|^2$, and similarly choosing $\lambda_{AC}|f_A(k_0)|^2 + \lambda_{BC}|f_B(k_0)|^2 = 0$ leads to $\epsilon_0(k_0) = \epsilon_2(k_0) = 0$, $\epsilon_1(k_0) = \lambda_{AB}|f_A(k_0)|^2 + |f_B(k_0)|^2$. By a proper choice of the $\lambda_{\alpha\beta}$, one can thus obtain a twofold BTP and even a threefold BTP without trivially decoupling the flat band.

(4) If none of the components of $|f_{k_0}|$ vanishes, a threefold BTP is impossible, but a twofold BTP can be achieved by $\lambda_{AB}\lambda_{AC}|f_A(k_0)|^2 + \lambda_{AB}\lambda_{BC}|f_B(k_0)|^2 + \lambda_{AC}\lambda_{BC}|f_C(k_0)|^2 = 0$.

In summary, the band structure of the Hamiltonian (28) can exhibit a gapped flat band, a twofold or a threefold BTP, depending on the interplay between the BCLS $|f_k|$ and the parameters $\lambda_{\alpha\beta}$.

Appendix D: Examples for 3D flat-band models

Quadratic flat-band models can be built from any CLS on any $d$-dimensional lattice. For example, consider the CLS on the simple 3D cubic lattice shown in Fig. 15(a). The corresponding BCLS reads

$$|f_k| = \psi_{ABC}^A = (f_A, f_B, f_C),$$

where

$$f_A = -2i[w_{A_1}\sin(k_- - k_z) + w_{A_2}\sin(k_- + k_z),$$

$$f_B = 2i[w_{B_1}\sin(k_+ + k_z) + w_{B_2}\sin(k_- + k_z) + w_{B_3}\sin(k_+ - k_z),$$

$$f_C = 2i[w_{C_1}\sin(k_+ + k_z) + w_{C_2}\sin(k_- + k_z) + w_{C_3}\sin(k_z - k_-)].$$

Inserting into Eq. (37), one obtains flat-band models tunable by the CLS amplitudes and six parameters $\lambda_{\alpha\beta}$.

The simplest linear flat-band models on a 3D lattice are three-band models built from chiral, anti-conjugate or conjugate CLSs. A chiral CLS can be easily found on any lattice. Finding (anti-)conjugate CLSs is much more difficult, but a simple way consists in forming a 3D lattice by stacking up appropriate 2D layers. Importantly, the localization center must be chosen within one of the 2D layers. For example, an anti-conjugate CLS can be found on the 3D-stacked Kagome lattice, see Fig. 15(b), where $w_{\alpha+3} = -w_{\alpha}, \in \mathbb{R}$. The corresponding BCLS reads

$$|f_k| = \psi_{ABC}^A = (f_A, f_B, f_C),$$

where

$$f_A = -2i[w_{A_1}\sin(k_- - k_z) + w_{A_2}\sin(k_- + k_z),$$

$$f_B = 2i[w_{B_1}\sin(k_+ + k_z) + w_{B_2}\sin(k_- + k_z) + w_{B_3}\sin(k_+ - k_z),$$

$$f_C = 2i[w_{C_1}\sin(k_+ + k_z) + w_{C_2}\sin(k_- + k_z) + w_{C_3}\sin(k_z - k_-)].$$

Inserting into Eq. (37), one obtains another linear 3D flat-band model.
Appendix E: Construction of linear $N > 3$ flat-band Hamiltonians by CLS decomposition

As a first step to obtain a linear flat-band Hamiltonian (68) from a given CLS on a lattice with $N > 3$, decompose the CLS into chiral, anti-conjugate and/or conjugate sub-CLSs. This is most conveniently done by identifying in the BCLS (67) all chiral, anti-conjugate and/or conjugate sub-BCLSs.

A chiral sub-BCLS $|m_{\alpha, \beta, \gamma}^{\alpha, \beta, \gamma}\rangle$ is a three-component sub-vector

$$
|m_{\alpha, \beta, \gamma}^{\alpha, \beta, \gamma}\rangle = (0, f_\beta, f_\gamma)^T,
$$

$$
|m_{\beta, \gamma, \alpha}^{\alpha, \beta, \gamma}\rangle = (f_\alpha, 0, f_\gamma)^T,
$$

$$
|m_{\gamma, \alpha, \beta}^{\alpha, \beta, \gamma}\rangle = (f_\alpha, f_\beta, 0)^T.
$$

An anti-conjugate sub-BCLS is a three-component sub-vector

$$
|m_{\alpha, \beta, \gamma}^{\alpha, \beta, \gamma}\rangle = (f_\alpha, f_\beta, f_\gamma)^T,
$$

$$
\kappa_\alpha \kappa_\beta \kappa_\gamma = -1,
$$

where a sign $\kappa_\delta = 1$ ($\kappa_\delta = -1$) is assigned to each real (imaginary) component of the BCLS (67). A conjugate sub-BCLS $|o_{\alpha, \beta, \gamma}^{\alpha, \beta, \gamma}\rangle$ is a three-component subvector

$$
|o_{\alpha, \beta, \gamma}^{\alpha, \beta, \gamma}\rangle = (f_\alpha, -f_\beta^*, f_\gamma)^T,
$$

$$
|o_{\beta, \gamma, \alpha}^{\alpha, \beta, \gamma}\rangle = (f_\alpha, f_\beta, -f_\gamma^*)^T,
$$

$$
|o_{\gamma, \alpha, \beta}^{\alpha, \beta, \gamma}\rangle = (-f_\alpha, f_\beta, f_\gamma)^T.
$$

If no chiral, anti-conjugate or conjugate sub-BCLSs can be found, then the input CLS is not suitable for building a linear flat-band model.

As a second step, for each sub-BCLS found from the above decomposition, one can now construct a matrix orthogonal to $|m_k\rangle$. For each chiral sub-BCLS, write down a corresponding $3 \times 3$ matrix $M_{\alpha, \beta, \gamma}^{\alpha, \beta, \gamma}$, where

$$
\hat{N}_{\alpha, \beta, \gamma} = \begin{bmatrix}
0 & -f_\gamma & f_\beta \\
-f_\gamma^* & 0 & 0 \\
f_\beta & 0 & 0
\end{bmatrix},
$$

$$
\hat{O}_{\alpha, \beta, \gamma} = \begin{bmatrix}
0 & f_\gamma^* & f_\beta \\
f_\gamma & 0 & -f_\alpha \\
-f_\beta & -f_\alpha & 0
\end{bmatrix},
$$

$$
\hat{O}_{\alpha, \beta, \gamma} = \begin{bmatrix}
0 & f_\gamma^* & -f_\beta \\
f_\gamma & 0 & f_\alpha \\
-f_\beta & f_\alpha & 0
\end{bmatrix}.
$$

where

$$
\begin{bmatrix}
0 & -f_\gamma & f_\beta \\
f_\gamma & 0 & 0 \\
\bar{f}_\beta & f_\alpha & 0
\end{bmatrix}.
$$

Extend each such matrix to an $N \times N$ matrix $M_{\alpha, \beta, \gamma}^{\alpha, \beta, \gamma}$ by adding zeros in all rows and columns not indicated by $(\alpha, \beta, \gamma)$. Similarly, for each anti-conjugate sub-BCLS, write down a corresponding $3 \times 3$ matrix

$$
\hat{O}_{\alpha, \beta, \gamma} = \begin{bmatrix}
0 & f_\gamma^* & f_\beta \\
f_\gamma & 0 & -f_\alpha \\
-f_\beta & -f_\alpha & 0
\end{bmatrix},
$$

and extend each such matrix to an $N \times N$ matrix $O_{\alpha, \beta, \gamma}^{\alpha, \beta, \gamma}$.

Finally, for each conjugate sub-BCLS, write down a corresponding $3 \times 3$ matrix $O_{\alpha, \beta, \gamma}^{\alpha, \beta, \gamma}$, where

$$
\hat{O}_{\alpha, \beta, \gamma} = \begin{bmatrix}
0 & f_\gamma^* & f_\beta \\
f_\gamma & 0 & f_\alpha \\
-f_\beta & f_\alpha & 0
\end{bmatrix},
$$

$$
\hat{O}_{\alpha, \beta, \gamma} = \begin{bmatrix}
0 & f_\gamma^* & f_\beta \\
f_\gamma & 0 & f_\alpha \\
-f_\beta & f_\alpha & 0
\end{bmatrix},
$$

and extend each such matrix to an $N \times N$ matrix $O_{\alpha, \beta, \gamma}^{\alpha, \beta, \gamma}$.

The idea is now to form a linear combination out of all the $N \times N$ matrices found from this procedure. However, for getting a reasonable Bloch Hamiltonian, we have to recall the discussion of Section IV A: not all chiral, anti-conjugate or conjugate CLSs lead to linear $N = 3$ Hamiltonians that make sense on a lattice. Similarly, among all the sub-CLSs into which a given CLS on a lattice with $N$ orbitals can be decomposed, not all will lead to matrices $M_{\alpha, \beta, \gamma}^{\alpha, \beta, \gamma}$, $N_{\alpha, \beta, \gamma}^{\alpha, \beta, \gamma}$, and $O_{\alpha, \beta, \gamma}^{\alpha, \beta, \gamma}$ that are physically reasonable. We will thus only retain physically reasonable matrices.

As a last step to obtain a linear flat-band Hamiltonian, form a linear combination

$$
H_k = \sum_{\alpha, \beta, \gamma, \lambda} \lambda_{\alpha, \beta, \gamma} F_{\alpha, \beta, \gamma}^{\alpha, \beta, \gamma}.
$$
we get
\[
M^{ABD}_{D,k} = \begin{bmatrix}
0 & 0 & 0 & -f_B^* & 0 \\
0 & 0 & f_A^* & 0 & 0 \\
0 & 0 & 0 & 0 & 0 \\
-f_B & f_A & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 
\end{bmatrix},
\]
\[
M^{ACD}_{D,k} = \begin{bmatrix}
0 & 0 & 0 & -f_C^* & 0 \\
0 & 0 & 0 & 0 & 0 \\
0 & 0 & f_A^* & 0 & 0 \\
-f_C & f_A & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 
\end{bmatrix},
\]
respectively. The former matrix is not physically reasonable, as can be seen in the following way: if it contributed to \(H_k\), then in the real-space tight-binding model there would have to be a hopping from \(A\) to \(D\) orbitals along directions \(\pm \frac{1}{2}(e_x + \sqrt{3}e_y)\) and \(\pm \frac{1}{2}(3e_x - \sqrt{3}e_y)\). Clearly, such hoppings are not compatible with the lattice, cf. Fig. 11(a). Thus, the sub-CLS \(|\psi_{ABD}\rangle\) is not physically reasonable. In contrast, the hoppings arising when \(M^{ACD}_{D,k}\) contributes to \(H_k\) make sense on the lattice. Thus, the sub-CLS \(|\psi_{ACD}\rangle\) is physically reasonable. Proceeding in the same way, one finds that there are three reasonable sub-CLSs, shown in Fig. 11(b), and therefore the Hamiltonian (72) is a linear combination of the three corresponding matrices.

Similarly, for the CLS of Fig. 12(a), with corresponding BCLS (74), we can identify six chiral sub-BCLSs, namely \(|m_{AE}\rangle\), \(|m_{BE}\rangle\), \(|m_{CE}\rangle\), \(|m_{ABE}\rangle\), \(|m_{BCE}\rangle\) and \(|m_{ACE}\rangle\), and one conjugate sub-BCLS \(|\phi_{ABC}\rangle\). Among these, there are three reasonable sub-CLSs, shown in Fig. 12(b), and the linear Hamiltonian (75) can be built from the corresponding matrices.

[23] C. V. Morfonios, M. Röntgen, M. Pyzh, and
[45] The Bloch basis states used here may be written as $|\alpha, k\rangle \equiv \mathcal{N}^{-1/2} \sum_m e^{-i \mathbf{k} \cdot (\mathbf{R}_m + \mathbf{r})} |m, \alpha\rangle$. The sum $\sum_m$ runs over all lattice vectors, $\mathcal{N}$ is the total number of unit cells and $\mathbf{R}_m + \mathbf{r}$ is the position vector of the orbital $|m, \alpha\rangle$, i.e. the orbital of type $\alpha$ in unit cell $m$. Note that the BCLS was introduced in a similar way in Ref. [38], where the authors work in the "tight-binding basis II" such that the Bloch Hamiltonian has the periodicity of the FBZ. In contrast, here we work in the "tight-binding basis II" [50].
