The research field of magnonics proposes a low-energy wave-logic computation technology based on spin waves to complement the established CMOS technology and to provide a basis for emerging unconventional computation architectures, e.g. neuromorphic or quantum computing. However, magnetic damping is a limiting factor for all-magnonic logic circuits and multi-device networks, ultimately rendering mechanisms to efficiently manipulate and amplify spin waves a necessity. In this regard, parallel pumping is a versatile tool since it allows to selectively generate and amplify spin waves. While extensively studied in microscopic systems, nano-scaled systems are lacking investigation to assess the feasibility and potential future use of parallel pumping in magnonics. Here, we investigate a longitudinally magnetized 100 nm-wide magnonic nano-conduit using space and time-resolved micro-focused Brillouin-light-scattering spectroscopy. Employing parallel pumping to generate spin waves, we observe that a non-resonant excitation of dipolar spin-waves is favored over the resonant excitation of short wavelength exchange spin waves. In addition, we utilize this technique to access the effective spin-wave relaxation time of an individual nano-conduit, observing a large relaxation time up to (115.0 ± 7.6) ns. Despite the significant decrease of the ellipticity of the magnetization precession in the investigated nano-conduit, a reasonably small threshold is found rendering parallel parametric amplification feasible on the nano-scale.

I. INTRODUCTION

Spin-wave based computing attracts increasing attention in the view of a low-energy computation technology by replacing charge-based binary logic with a wave-based logic utilizing spin-waves as the information carrier [1, 2]. This potentially offers several advantages, e.g. energy efficiency due to the absence of Ohmic losses [3], multiple degrees of freedom (frequency and phase) [4], readily accessible nonlinear mechanisms [5, 6] and a device feature size with a sub-100 nm scaleability [7]. A variety of spin-wave based devices has already been realized, such as transistors [8], majority gates [9] or a directional coupler [10], with many more concepts proposed theoretically. For many of these proof-of-concept devices yttrium iron garnet (YIG) is used due to its record low magnetic damping, although the material has been limited to the macro- and microscale for a long time. Recent progress in the fabrication of high quality nanometer thin YIG films [11] and advanced structuring procedures revealed a long-range spin-wave propagation in transversely and longitudinal magnetized sub-100 nm YIG conduits, showing the feasibility of spin-wave computing on the nanoscale [7, 12]. Nonetheless, magnetic damping still remains a limiting factor for extended networks and all-magnonic circuits, ultimately rendering spin-wave amplifiers a necessity. Parametric amplification by parallel pumping (PP) has been proven to be a versatile tool in this context, which not only allows for the mere generation, but also for an amplification and manipulation of spin waves [13]. In this process, microwave photons are converted into correlated pairs of spin waves, providing a frequency- and mode selectivity, while conserving the phase. In this regard, PP is superior to other approaches of spin-wave amplification, e.g. the spin-transfer-torque amplification of spin waves [14], which are often lacking the necessary selectivity. The process of PP has been extensively studied in macroscopic and microscopic systems [13], but only theoretically [15–17] on the sub-micron or nano-scale or in completely quantized structures, e.g. ellipses [18] or nano-discs [19]. However, in open systems, e.g. conduits, the dissipation of propagating spin waves from the pumping source can dominate the pumping dynamics [20–22] and potentially impact the selectivity of the spin-wave generation and amplification. Additionally, a decreased PP efficiency is expected in nano-sized structures with an aspect ratio close to one due to a vanishing ellipticity of the magnetization precession. Thus, an investigation of PP in nano-scaled conduits is of great interest to assess its potential future use.

II. THEORETICAL BACKGROUND

Parallel pumping of spin waves is the interaction of a microwave pumping field $\mu_0h_p$ with a dynamic magnetization component, where both are oriented in parallel to the static magnetization of the system. Such a dynamic component arises due to an elliptic trajectory of
can propagate out of the pumping zone and thus constitute an additional loss channel. These losses are referred to as radiative damping, while the losses included in Eq. 2 are referred to as intrinsic damping. The associated parametric instability threshold, in the case of a quasi one-dimensional system (conduit) and negligible intrinsic losses, follows as [25]:

\[
\mu_0 h_{th}^{\text{rad}} = \frac{\alpha_n}{L k} \frac{\arccos(\alpha_n)}{\sqrt{1 - \alpha_n^2}}.
\]

(3)

Here, \(\alpha_n = |\text{sinc}(kL)|\) is the parameter of non-adiabacity, \(L\) the length of the pumping area and \(v_g\) the spin-wave group velocity. In the general case, the parametric instability threshold is not the mere sum of intrinsic and radiative thresholds but instead has to be determined from the following implicit equation [20, 22, 26]:

\[
\frac{\sqrt{(V_k \mu_0 h_{th})^2 - (\Gamma_k - \alpha_n V_k \mu_0 h_{th})^2}}{\Gamma_k - \alpha_n V_k \mu_0 h_{th}} = -\tan\left(\frac{\sqrt{(V_k \mu_0 h_{th})^2 - (\Gamma_k - \alpha_n V_k \mu_0 h_{th})^2} L}{v_g}\right). \tag{4}
\]

Under certain circumstances, a non-degenerate \((\omega_{k1} \neq \omega_{k2} \neq \frac{\omega_0}{2})\) with pumping frequency \(\omega_p = 2\pi f_p\) [27, 28] or even a non-resonant \((\omega_{k1} = \omega_{k2} \neq \frac{\omega_0}{2})\) splitting of the pumped spin-waves can be favorable [29, 30]. In the latter case the parametric instability threshold of Eq. 1 is modified as follows [13]:

\[
\mu_0 h_{th}^{\text{int}} = \sqrt{\frac{\Gamma_k^2 + (\omega_0 - \frac{\omega_p}{2})^2}{V_k^2}}. \tag{5}
\]

Please note, a description of the dynamics beyond the instability threshold in the regime of small supercriticalities \((h_p/h_{th})\) is given in Ref. [23], while for large supercriticalities far above the threshold, a strong nonlinear shift of the spin-wave dispersion and additional multi-magnon scattering effects have to be taken into account.

III. EXPERIMENTAL SETUP

In this study, a thin 44 nm-thick lanthanum-doped (111) YIG film is used, which was grown on top of a 500 µm thick gadolinium gallium garnet substrate by liquid phase epitaxy [11]. The film parameters were measured using vector network analyzer ferromagnetic resonance spectroscopy (VNA-FMR) [31] and micro-focused Brillouin-light-scattering (BLS) spectroscopy [32], revealing a saturation magnetization of \(M_s = (140.7 \pm 2.8) \text{ kA m}^{-1}\), a Gilbert damping parameter of \(\alpha = (1.75 \pm 0.08) \times 10^{-4}\), an inhomogeneous linewidth broadening of \(\mu_0 \Delta H_0 = (0.18 \pm 0.01) \text{ mT}\) and an exchange constant of \(A_{ex} = (4.22 \pm 0.21) \text{ pJ m}^{-1}\). Subsequently, micro and nano-sized waveguides with
a respective conduit width of \( w = 1000 \text{ nm} \) and \( w = 100 \text{ nm} \) were fabricated using a hard-mask ion beam milling procedure [7]. A titanium/gold single-strip antenna was added on top perpendicular to the long axis of the waveguides, with a thickness of 10 nm/150 nm and a width of \( L = 2 \mu \text{m} \) (see Fig. 1(a)). In the experiment, a bias magnetic field \( \mu_0 H_{\text{ext}} \) is applied along the conduits long axis, while microwave-frequency current pulses (pumping pulses) with a pulse length of 50 ns and a repetition time of 280 ns are fed into the antenna. The in-plane component of the resulting oscillating Oersted field of the antenna is oriented longitudinally to the conduits (in parallel to the internal static magnetization) and can thus act as the driving field for the PP process. The generated spin waves are investigated employing micro-focused BLS spectroscopy by focusing a single-frequency laser with a wavelength of 457 nm and 2 mW effective laser power through the substrate of the sample on the center of the pumping area using a compensating microscope objective (magnification 100×, numerical aperture NA = 0.85). In-plane spin-wave wavevectors up to \( k = 24 \text{ rad} \mu\text{m}^{-1} \) can be detected. To eliminate the influence of a varying microwave transmission characteristic of both, the antenna and the used equipment, the frequency of the pumping pulse is fixed to \( f_p = 7 \text{ GHz} \) and the external magnetic field is varied instead.

**IV. RESULTS AND DISCUSSIONS**

A. Parallel pumping in micron-sized systems

Figure 2(a) shows the spin-wave intensity as a function of the external magnetic field and the applied pumping power, referred to as the pump spectrum in the following, for a conduit width of \( w = 1000 \text{ nm} \). The extracted parametric instability threshold, displayed as the full black dots, resembles a commonly observed curve which is known as the "butterfly curve" and can be understood by taking the dependencies of the intrinsic and radiative losses into account [33]. The coupling parameter is basically a measure for the ellipticity of the magnetization precession, which decreases with increasing longitudinal wavevector \( k_x \) and with increasing width-mode order \( n \), thus resulting in intrinsic threshold minima for...
the respective $k^2 = 0$ points and an increasing threshold for smaller magnetic fields. Similarly, the radiative losses are minimized when the group velocity vanishes, which is the case at the respective modes’ band bottom. Thus, the dipolar regime of higher-order width modes features a smaller threshold than the exchange regime of lower order modes, which causes the distinct peculiarities and jumps observed in the butterfly curve. For magnetic fields $\mu_0 H_{ext} > 63 \, \text{mT}$, a cut-off of the spin wave manifold occurs, since the band bottom of the fundamental mode lies above $f_p / 2 = 3.5 \, \text{GHz}$ which renders a resonant pumping process impossible leading to a sharp increase of the threshold. Still, parallel pumping is observed which can be attributed to several effects. Effectively, at large powers, the dispersion can be shifted by a reduction of the effective magnetization due to Joule heating of the pumping pulse, as well as by a forced excitation driven by the out-of-plane field component of the pumping field. To specify the observed dynamics, the relative frequency shift of the pumped spin waves $\Delta f = f_k - f_p / 2$ is extracted and shown in Fig. 2(b). In addition, the frequency of the thermally excited spin waves of the fundamental mode ($n = 1$) is shown, which corresponds to the dipolar regime of small wavevectors. As expected, in the case of a small supercriticality, the parametric excitation always takes place at half the pumping frequency, even in the cut-off regime of the spin-wave manifold, thus confirming the aforementioned considerations of a dispersion shift in this regime. In the following, these findings provide a reference basis to assess and evaluate the dynamics of parallel pumping in the 100 nm-wide nano-conduit.

### B. Parallel pumping in magnonic nano-conduits

In Fig. 2(c) the pump spectrum is shown for the 100 nm-wide nano-conduit. In comparison to Fig. 2(a) the shape of the butterfly curve is noticeably different, as it does not exhibit several minima, but only one distinct threshold minimum. This is in agreement with the expectation, since the nano-conduit effectively represents a single-mode system as any higher order width or thickness modes are significantly lifted in frequency due to the strong quantization of the system [34]. The behaviour in the cut-off regime for magnetic fields $\mu_0 H_{ext} > 50.5 \, \text{mT}$ is very similar to Fig. 2(a), while the threshold increases continuously in the regime from $\mu_0 H_{ext} = 45 \, \text{mT} - 40 \, \text{mT}$, until the spin-wave intensity nearly vanishes for the maximal applied power. However, for even smaller magnetic fields a reduced threshold is observed and a noticeable spin-wave intensity is detected again. The pumped spin-waves above the cut-off of the spin-wave manifold are located at $f_p / 2$, but for smaller magnetic fields, the spin-waves are significantly shifted to smaller frequencies, contrary to the case of the 1000 nm-wide waveguide (see Fig. 2(d)). In principle, such a frequency shift is possible within the frequency uncertainty of the pumping pulse. However, it can be estimated to be on the order of ±50 MHz [35], which is insufficient to cause the experimental observation. Thus, apparently, a non-resonant pumping process is observed, which effectively pumps spin waves into the dipolar regime of the dispersion. In general, such a process is unfavorable with regard to the resonant generation of spin waves since it corresponds to an increase of the effective intrinsic threshold, as it can be seen from Eq. 5. However, the process can potentially be driven by a minimization of the radiative losses, which nearly vanish in the dipolar regime of the dispersion [36]. Unfortunately, the investigated case of non-resonant non-adiabatic pumping in nano-sized structures is not covered within current theoretical models. Hence, the observation cannot be supported theoretically. Still, the claim that the observed process is a non-resonant generation of spin waves by parallel pumping is supported by the fact that a threshold behavior is observed, as it is exemplary shown in Fig. 3. Please note, a threshold behavior could also be caused by multi-magnon scattering of resonantly excited spin waves at $f_p / 2 = 3.5 \, \text{GHz}$ into the dipolar regime. However, this process can be ruled out since no resonant generation of spin waves is observed in the first place.

### C. Limitations of parallel pumping in magnonic conduits

In the following, we discuss the limiting factors of PP regarding the generation of spin waves. While in micron-sized conduits a variety of different (even and odd) width modes can be easily selected and amplified, the resonant generation of exchange spin waves is restricted by the presence of dipolar spin-wave states of other width modes, which will always feature a smaller effective threshold. In this regard, the effective single-mode property of nano-sized conduits is very beneficial,
but non-resonant pumping processes as observed above seem to limit the versatility of PP. Thus, the development of advanced theoretical models is required to unravel the underlying mechanisms and to evaluate how a tuning of system parameters, e.g. the size of the pumping area, can be used to effectively model the accessible wavevector regime. We would like to point out that a pre-existing coherent spin-wave population, e.g. externally provided by a 2nd antenna, significantly impacts the dynamics of PP, since the effective energy gain is proportional to the pumped spin-wave group’s population [13, 37]. In this regard, the resonant amplification of exchange spin waves in nano-sized conduits might be favorable over the non-resonant generation of dipolar spin waves.

An additional limitation arises for nano-sized conduits approaching an aspect ratio of one, which is the significant decrease of the ellipticity and hence of the coupling strength due to the unpinning of the spin-wave modes [38]. With respect to the 1000 nm-wide conduit and for \( n = 1 \) and \( k_{x} = 0 \), the ellipticity coefficient drops by 87.4 % and the coupling parameter by 65.7 %. In this regard, a reasonably small threshold is found for the 100 nm-wide conduit rendering PP feasible in such systems.

D. Effective spin-wave relaxation time

In the following, we utilize PP not just as a mere tool to generate spin waves, but to gain access to the effective spin-wave relaxation time \( \tau_{\text{eff}} \) (similar to Ref. [18]) of a nano-sized conduit. In fact, PP provides direct access to this parameter rendering it superior in comparison to other methods, e.g. based on group velocity and decay length measurements. The time evolution of the spin-wave intensity \( n \) for small supercriticalities can be described using a simple exponential function [13]:

\[
n(t) = n_{0} \exp \left( \frac{t}{\tau_{\text{rise}}} \right).
\]  

Here, \( n_{0} \) denotes the initial spin-wave intensity (thermal population) and \( \tau_{\text{rise}} \) is the effective rise time, which, in the case of dominating intrinsic losses, follows as [13]:

\[
\tau_{\text{rise}}^{-1} = 2\mu_{0}h_{p}V_{k} - 2\Gamma_{\text{eff}} = \sqrt{PV_{k}'} - 2\tau_{\text{eff}}^{-1}.
\]

The pumping field \( \mu_{0}h_{p} \) can be considered as proportional to the square root of the applied pumping power \( P \), while any proportionality constant is absorbed into the effective coupling parameter \( V_{k} \). This allows to extract the effective relaxation time from a power dependent set of time traces [39]. Please note, these considerations are only valid if the radiative losses can be neglected or be considered much smaller than the intrinsic losses, which, for nano-sized conduits, holds true in the regime of small wavevectors. In the following, the applied pumping pulses are changed to 100 ns pulse length and 350 ns repetition time to provide a sufficient observation time of the rising spin-wave intensity. In addition, the laser power is increased to 5 mW, which causes a shift of the dispersion compared to Fig. 2(c). (b) Threshold curve and (c) time traces of the generated spin-wave pulses for different applied microwave powers \( P \) and \( \mu_{0}H_{\text{ext}} = 55.4 \) mT. Dashed lines: approximation of the rising edges.

FIG. 4. (a) Pump spectrum for a conduit width of \( w = 100 \) nm. Pumping pulse parameters are changed to 100 ns pulse length and 350 ns repetition time and laser power increased to 5 mW, causing a shift of the dispersion compared to Fig. 2(c). (b) Threshold curve and (c) time traces of the generated spin-wave pulses for different applied microwave powers \( P \) and \( \mu_{0}H_{\text{ext}} = 55.4 \) mT. Dashed lines: approximation of the rising edges.

However, a change of slope is observed in the rising edge of the spin-wave time traces (see Fig. 4(c)), thus the approximation of the rising edges according to Eq. 6 is only considered up to this intensity level. In Fig. 5(a) and (b), the extracted effective relaxation time as well as the effective coupling parameter are shown. We find a large relaxation time up to \( (115.0 \pm 7.6) \) ns in the regime of the dispersion band bottom. This is significantly larger than the
E. Dynamics in the regime of large supercriticality

In the following, the regime of large supercriticalities and the additional processes which are observed to take place are discussed. In Fig. 6(a) the relative frequency shift of the pumped spin waves is shown for the 1000 nm-wide conduit. We observe a deviation from $f_p/2$ for a large supercriticality and $\mu_0 H_{\text{ext}} > 42$ mT. In fact, a non-resonant pumping process to frequencies $f_k < f_p/2$ occurs, caused by the large spin-wave population achieved. This becomes evident from the associated spin-wave spectra, exemplary shown for $\mu_0 H_{\text{ext}} = 54.23$ mT in Fig. 7(a). For large magnetic fields, the spin-wave intensity will rise for powers above the threshold, but the spin-waves are located at $f_p/2$. At very large powers above the threshold, the pumped spin-waves shift in frequency, driven by the associated increasing nonlinear frequency shift. In addition, a further increase of the intensity is limited, likely by an induced dephasing of the pumped spin-waves and the pumping field, which reduces the effective energy gain of the system [13]. In contrast, for external fields $\mu_0 H_{\text{ext}} < 42$ mT, the frequency of the pumped spin waves relaxes to $f_p/2$ (see Fig. 6(a)) since the spin-wave population level is significantly decreased compared to larger fields and instead of a non-resonant pumping process, nonlinear scattering processes into the dipolar regime of the dispersion are observed. This is exemplary shown in Fig. 7(b) for $\mu_0 H_{\text{ext}} = 35.94$ mT, where the pumped spin waves are always found at $f_p/2$, even for the maximal supercriticality. However, the spin-wave population at $f_p/2$ saturates at a certain power, at which a sudden increase of the spin-wave population at lower frequencies is detected. This is a strong indication for the onset of a multi-magnon scattering process, which
FIG. 7. Power dependent BLS-spectra for (a) $\mu_0 H_{\text{ext}} = 54.23 \text{ mT}$ and (b) $\mu_0 H_{\text{ext}} = 35.94 \text{ mT}$ for the $w = 1000 \text{ nm}$-wide conduit. Please note, the method of BLS-spectroscopy induces a small frequency shift, thus $f_p/2 = 3.675 \text{ GHz} \neq 3.5 \text{ GHz}$ in the displayed spectra.

causes a population of the dipolar regime. However, due to the conservation of energy, three-magnon-splitting processes are excluded and necessarily spin waves have to be scattered to larger frequencies. These spin waves are not observed in the experiment since they are likely situated beyond the wavevector detection limit of the used setup.

Please note, Fig. 6(b) also shows the case of large supercriticalities for the 100 nm-wide conduit. Here, the pumping is already non-resonant for small supercriticalities and larger applied powers are only observed to introduce an additional frequency shift in the regime of $\mu_0 H_{\text{ext}} > 40 \text{ mT}$. Multi-magnon scattering cannot take place since the spin waves already populate the lowest energy states of the system and thus energy conservation cannot be fulfilled for any scattering processes into higher frequencies. However, a three-magnon confluence would be possible but although the pump spectrum saturates considerably for large supercriticalities we find no trace of such a process within the measured spectra.

effectively provide a single-mode system, rendering them superior to micron-sized systems in this regard. However, we observe non-resonant pumping processes to be favorable over the resonant generation of exchange spin waves, leading to a population of the dipolar regime in an extended regime of the pump spectrum, which is likely driven by a minimization of the radiative losses. The development of an advanced theoretical model is required to describe the investigated regime of non-resonant non-adiabatic parallel pumping and to unravel the underlying mechanisms. Still, despite the significant decrease of the ellipticity of the magnetization precession in the investigated nano-conduit (drop of the ellipticity coefficient by 87.4 % for $n = 1$ and $k_x = 0$ with respect to the 1000 nm-wide conduit), a reasonably small threshold was found rendering parallel pumping feasible in such systems.

V. CONCLUSION

To conclude, we presented an investigation of parallel pumping processes in yttrium iron garnet magnonic conduits. In micron-sized structures, a variety of different (even and odd) width modes can be amplified but the amplification of exchange spin waves is restricted due to the presence of the dipolar regime of higher order width modes. In contrast, nano-scaled conduits
