(Dated: June 22, 2021)

We study the generalized version of the \( q \)-voter model with anticonformity in which agents can be in one of \( s \geq 2 \) states. As in the original model, which corresponds to \( s = 2 \), unanimous group of \( q \) agents can influence the chosen voter (conformity) or he can take one of values different than value of them (anticonformity). In our generalization we consider two types of disorder: (1) annealed, where voter act as anticonformist with probability \( p \) and with complementary probability \( 1 - p \) conform to others, and (2) quenched, where a fraction \( p \) of all voters are permanently anticonformists and the rest of them are conformists. We analyze the model on the complete graph analytically and via Monte Carlo simulations. We show, in contrast to common knowledge, that the model with quenched randomness can express discontinuous phase transitions for \( q > 1 \), whereas annealed scheme displays only continuous phase transitions.

I. INTRODUCTION

Both the existence and the distinction between different types of phase transitions seems to be in the field of big interest of many researchers. This topic was not only reviewed from theoretical point of view in dynamical like models [18] but it appears in real social systems [4, 8]. Through the need to establish certain universal laws, scientists are looking for factors which influence the appearance of discontinuous phase transitions. They pointed out the role of the structure [2, 9–11] or specific interactions between agents, like independence and anticonformity, where former support discontinuous phase transition whereas latter not [12–15].

Another property, which can play not trivial role in existence of specific phase transition is type of randomness. In statistical mechanics, two most common types of randomness are annealed and quenched. The first one is connected with process in which some properties of the system can vary in time. The latter express freezed properties in time, commonly randomly distributed at the beginning of the process [16–17]. Both of them are also visible in real social systems, know as person-situation debate, where decision making processes are carried out based on the personality and believes (quenched randomness) or based on some real life situations or circumstances (annealed approach) [18]. It seems that the type of randomness affects the transition point of continuous phase transition in some models, e.g. Galam [19, 20] or voter model with independence [12–21]. Moreover it can drastically change the behavior of the model. Namely the quenched disorder can round or completely destroy existence of discontinuous phase transition [21–24].

Similar high impact on the opinion dynamics models shows the number of states. It seems that the larger amount of states than typical two values support existence of discontinuous phase transitions. Such tendency was reported in Potts model, where existence of more than 4 states causes first order phase transition whereas for less than 4 only continuous phase transitions were observed [25, 26]. Similar behavior was visible also in both majority-vote model and \( q \)-voter model with independence. The former in binary regime shows only continuous phase transition [27–29], while in multi-state regime express discontinuous one [30, 31]. The latter shows both continuous and discontinuous phase transition based on the size of group of influence \( q \), which should be bigger than 5 [12], whereas after introducing more than 2 states the existence of discontinuous transitions expands to all values of \( q \) [32]. Interestingly transitions remain discontinuous even after introduction of quenched randomness, but they are less sharp in comparison to annealed model.

In this paper we try to check what will happen if we combine two properties which should support continuous phase transitions, anticonformity and quenched randomness. We show that connecting them with more than two states can support discontinuous phase transition, similarly as in [32, 33]. Moreover, in contrast to \( q \)-voter model with independence the discontinuity of phase transition is possible only under quenched approach, whereas they not occur under annealed randomness.

II. ANALYTICAL RESULTS AND MONTE CARLO SIMULATIONS

In this paper we propose a generalization of the original binary \( q \)-voter model with anticonformity [12]. Therefore, we consider a system of \( N \) nodes, also called agents or voters placed on the complete graph, which allows us a strict description with Mean-field approximation. In general, agents are describe with \( s \)-state variable \( \sigma_i \in \{0, 1, 2, 3, \ldots, s-1\} \) and can, with a given probability \( 1 - p \), be influenced by \( q \) neighboring agents if they are unanimous. If agent has the same opinion as
FIG. 1. Visualization of the elementary update for the multi-state $q$-voter model with anticonformity. Within annealed approach voter can act like anticonformist or conformist with complementary probabilities $p$ and $1-p$. Withing the quenched approach, a fraction $p$ of all voters are permanently anticonformists, whereas others are always conformists.

$q$ neighboring agents he can anticonform to them with probability $p$, namely take one of possible different values. Originally existence of anticonformity erase discontinuous phase transitions from the system. Similarly in existence of quenched disorder only continuous phase transition are possible in binary $q$-voter model in both versions, with independence and anticonformity [21]. We want to check how both, existence of anticonformist interactions and quenched disorder, will influence phase transition, thus we consider two approaches of generalized $q$ voter model with anticonformity:

- **Annealed approach**
  1. site $i$ is randomly chosen from the entire graph,
  2. a group of $q$ neighbors is randomly selected without repetitions,
  3. with probability $p$ chosen agent acts like anticonformist, i.e. if all $q$ neighbors are in the same state as chosen voter, he changes its opinion to randomly chosen state different than his state (each state can be chosen with the same probability $1/(s-1)$),
  4. with complementary probability $1-p$ chosen agent acts like conformist, i.e. if all $q$ neighbors are in the same state different than his state, he copies their state.

- **Quenched approach**
  1. site $i$ is randomly chosen from the entire graph,
  2. a group of $q$ neighbors is randomly selected without repetitions,
  3. if the voter is anticonformist (a fraction $p$ of all agents is permanently anticonformists), and all $q$ neighbors are in the same state different than his state then he changes its opinion to randomly chosen state different than his state (each state can be chosen with the same probability $1/(s-1)$),
  4. if the agents is conformist (a fraction $1-p$ of all agents is permanently conformists), and all $q$ neighbors are in the same state different than his state, he copies their state.

As usually time is measured with Monte Carlo Steps (MCS), and single step is $N$ elementary updates described by above algorithm and visualize in Fig. 1. Next to Monte Carlo simulation we want to describe our system by Mean-field approximation and with it express the relation between stationary values of the concentration $c_\alpha$ of agents with a given opinion $\alpha = 0, 1, 2, 3, \ldots, s-1$ and model’s parameters $p$ and $q$. The concentration $c_\alpha$ is defined as

$$c_\alpha = \frac{N_\alpha}{N},$$

(1)

where $N_\alpha$ denotes the number of agents with opinion $\alpha$. As usually, concentration of all states sum up to one:

$$\sum_{\alpha=0}^{s-1} c_\alpha = \frac{N_0 + N_1 + \cdots + N_{s-1}}{N} = 1$$

(2)

Based on the values of $c_\alpha$ we distinguish the following phases:

- The disordered phase, in which all opinions are equinumerous, i.e. $c_0 = c_1 = \cdots = c_{s-1} = 1/s$.
- The ordered phase, in which one or more opinions dominate over the others. A special case within this phase is the state of consensus, i.e. when all voters share the same opinion $c_\alpha = 1, c_\beta = c_\gamma = \cdots = 0$.
- The coexistence phase (possible only in case of discontinuous phase transitions), if both ordered and disordered phases can be reached depending on the initial state of the system.

Model is based on the random sequential updating in which a single update $\Delta t = 1/N$ consist change of the state of one agent. Thus, the total concentration of given state in the system $c_\alpha$ can increase or decrease by $1/N$ or
where \( F_\gamma \) probabilities remain constant according to the formulas for respective

The time evolution of the concentration of state \( \alpha \) in the mean-field limit is then given by the following equation

\[
\frac{dc_\alpha}{dt} = \gamma^+(c_\alpha) - \gamma^-(c_\alpha) = F(c_\alpha),
\]

where \( F(c_\alpha) \) can be interpreted as the effective force acting on the system [1][12].

### A. Annealed approach

First let us describe the annealed randomness within multi-state q-voter model. In this approach a system is homogeneous, i.e. all agents are indetical. Thus the transition rates are the same for all agents and Eq. \([4]\) takes the form:

\[
\frac{dc_\alpha}{dt} = -pc^\alpha_{q+1} + p\sum_{i\neq\alpha} \left[ \frac{c^i_{q+1}}{s-1} \right] + (1-p)\sum_{i\neq\alpha} [c_\alpha c^i_q - c_\alpha c^i_1].
\]

(5)

See Appendix [A1] for details. Above equation can be used to obtain trajectories, i.e. how the concentration of given state vary in time. To find stationary states we need to find solutions at which systems is constant in time, to achive it we need to fulfill the following condition

\[
\frac{dc_\alpha}{dt} = 0.
\]

(6)

One obvious solution of the above equation, valid for arbitrary value of \( p \), is \( c_0 = c_1 = \cdots = c_{s-1} = \frac{1}{s} \). All remaining solutions can be obtained by solving it numerically. However we are able to provide more general solution similarly as it was done for multi-state q-voter model with independence [32]. If initialy one opinion dominates over the others the system will reach an absorbing state in which this opinion still dominates over the others. Similarly, if initialy two or more equinumorous states dominate over the others the system reaches an absorbing state in which concentrations for these states are still equal and larger than the concentrations of others. Hence, at most two values of opinion’s concentrations are possible. Based on this observation we are able to rewrite all solutions in terms of a single variable \( c \), which will denote concentration of state 0, because of symmetricity of the system we can choose any of \( s \) states. Then all remaining states can be expressed with \( c \) by using condition [2]:

\[
c_0 = \cdots = c_{s-(\xi+1)} = c,
\]

\[
c_{s-\xi} = \cdots = c_{s-1} = \frac{1-(s-\xi)c}{\xi},
\]

(7)

where \( \xi = 1, 2, 3, \ldots, s-1 \) and \( \xi = 0 \) indicates solution, where all state are equinumorous \( c_0 = c_1 = \cdots = c_{s-1} = 1/s \). Combining above with Eq. \([5]\) and \([6]\) we obtain

\[
p \frac{\xi}{s-1} \left[ \frac{1-(s-\xi)c}{\xi} ight] \gamma^+_{q+1} - \gamma^+_{q+1}
\]

\[
+ (1-p)\xi \frac{1-(s-\xi)c}{\xi} \gamma^+_{q+1} - c \left( \frac{1-(s-\xi)c}{\xi} \right)^q = 0
\]

(8)

We are not able analytically derive the formula \( c_\alpha = c_{st}(p) \) for all stationary states different than trivial one mentioned before. However above equation is linear with the parameter \( p \), so we can derive the opposite relation \( p = p(c_{st}) \).
For \( s = 2 \) and \( \xi = 1 \) the above equation recovers the analytical solution for the original binary \( q \)-voter model with anticonformity [12]. For more states, namely \( s > 2 \) this relation produces \( s - 1 \) stationary solutions for \( \xi = 1, 2, \ldots, s - 1 \) respectively. The stability of given stationary state can be track by the sign of the first derivative of the effective force with respect to the stationary point \( c_{st} \). The steady state is stable if

\[
F'(c) = \left. \frac{dF(c)}{dc} \right|_{c=c_{st}} < 0,
\]

and unstable otherwise. Based on it we are able to derive the lower \( p_1^* \) and upper \( p_2^* \) spinodals which will express the existence of hysteresis in our system, namely in case of continuous phase transition and lack of the hysteresis this two points are equal \( p_1^* = p_2^* \), whereas for discontinuous phase transition they are not. The lower spinodal point \( p_1^* \) is the value of parameter \( p \) at which stationary solution \( c_{st} = 1/s \) loses stability. For the multi-state \( q \)-voter model with anticonformity we are able to derive it analytically (see Appendix [A2]).

\[
p_1^* = \frac{(s - 1)(q - 1)}{(s - 1)(q - 1) + q + 1}.
\]

FIG. 3. The dependence between the stationary concentration of agents in state 0 and probability of anticonformity \( p \) within the quenched approach for \( q = 5 \) and \( s = 3 \). Lines represent solutions of Eq. (19), solid and dashed lines correspond to stable and unstable steady states, respectively. Vertical dotted lines represent critical points \( p_{det}^* \) and \( p_{tr}^* \). Symbols represent the outcome from MC simulations for the system size \( N = 5 \times 10^5 \) performed from two initial conditions indicated in the legend. The results are averaged over ten runs and collected after \( t = 5 \times 10^5 \) MCS. The color shaded areas are obtained with analytical trajectories calculated with Eq. (12) and (14), where each pixel is initial condition. If trajectory converge to stationary state indicated by solid lane (ordered state) pixel is colored with pink color. If trajectory converge to disordered stationary state it is colored with green.

It is visible that above equation is increasing both with \( q \) and number of states \( s \), see Fig. 2 and limit of this when \( q \to \infty \) is \( 1 - \frac{1}{s} \). As expected, for binary model \( s = 2 \) above formula recovers analytical solution for the original \( q \)-voter model with anticonformity [12]. A upper spinodal as well as stability for other stationary solutions are calculated numerically. Similarly as in multi-state \( q \)-voter model with independence [32] and multi-state majority vote model [30] appears additional saddle solutions with more than one dominating opinion. And as for those models, they are visible in the analytical but not within Monte Carlo approach in which fluctuations seems to push the system into the attractive steady state with only one dominant opinion.

It was shown that under the annealed approach binary model with anticonformity shows only continuous phase transitions regardless of size of the group of influence \( q \). Even in the model with additional noise, the size of this group need to be sufficiently large to observe discontinuous phase transition [12]. To help overcome this behaviour we can introduce more states into the system. In the multi-state regime the model with noise recover discontinuous phase transition for all values of size of the influence group \( q > 1 \) [32]. Similar result was obtained for the majority-vote model, which with binary opinion displays only continuous phase transition [34], even if an additional noise is introduced [27, 29]. However introducing inertia into the system, by some external parameter [35] or by introducing more states [30, 36], can cause the discontinuous phase transition. Unfortunately this is not the case in multi-state model with anticonformity. As presented in Figs. 2 and 6 this model shows only continuous phase transition regardless to the size of the group of influence \( q \) and number of states \( s \). We observe such behavior both in Monte Carlo simulation and analytical results, with a very good agreement between these two, even in critical point given by Eq. (17).
formist agents. As in the annealed version we consider \( \gamma \) increases or decreases respectively in a single update and \( \alpha \) in result the mean-field dynamics, in contrast to an-annealed scheme we need to fullfill the following conditions

\[
\frac{dc_{\text{A},\alpha}}{dt} = -c_{\text{A},\alpha}c_{\alpha}^q + \sum_{i \neq \alpha} [c_{\text{A},i}c_{i}^q] / (s-1) \\
\frac{dc_{\text{C},\alpha}}{dt} = \sum_{i \neq \alpha} [c_{\text{C},i}c_{i}^q - c_{\text{C},\alpha}c_{\alpha}^q]
\]

(14)

See Appendix B1 for details. Above equation together with relation given by Eq. (12) can be used to obtain trajectories. To find stationary states similarly as in annealed scheme we need to fulfill the following conditions

\[
\frac{dc_{\text{A},\alpha}}{dt} = 0 \\
\frac{dc_{\text{C},\alpha}}{dt} = 0.
\]

(15)

And as in the annealed approach we can express all stationary states by \( c \), namely the concentration of an arbitrarily chosen state, and by \( c_{\text{A}} \) and \( c_{\text{C}} \) concentration of anticonformist and conformist agents respectively:

\[
c_0 = \cdots = c_{s-(\xi+1)} = c, \\
c_{s-\xi} = \cdots = c_{s-1} = 1 - (s-\xi)c / \xi;
\]

\[
c_{\text{A},0} = \cdots = c_{\text{A},s-(\xi+1)} = c_{\text{A}}, \\
c_{\text{A},s-\xi} = \cdots = c_{\text{A},s-1} = 1 - (s-\xi)c_{\text{A}} / \xi;
\]

\[
c_{\text{C},0} = \cdots = c_{\text{C},s-(\xi+1)} = c_{\text{C}}, \\
c_{\text{C},s-\xi} = \cdots = c_{\text{C},s-1} = 1 - (s-\xi)c_{\text{C}} / \xi;
\]

\[
c = pc_{\text{A}} + (1-p)c_{\text{C}}.
\]

(16)

where \( \xi = 1, 2, 3, \ldots, s-1 \) and \( \xi = 0 \) indicates solution, where all state are equinumerous. Combining above with Eq. (14) and (15) we obtain

\[
\frac{\xi}{s-1} \left[ \frac{1 - (s-\xi)c_{\text{A}}}{\xi} \left( \frac{1 - (s-\xi)c}{\xi} \right)^q - c_{\text{A}}c^q \right] = 0 \\
\frac{\xi}{s-1} \left[ \frac{1 - (s-\xi)c_{\text{C}}}{\xi} \left( \frac{1 - (s-\xi)c}{\xi} \right)^q - c_{\text{C}}c^q \right] = 0.
\]

(17)

From above formulas we can derive following stationary solutions for concentration of anticonformist and conformist agents

\[
c_{\text{A},st} = \frac{\left( \frac{1 - (s-\xi)c_{st}}{\xi} \right)^q}{\left( \frac{1 - (s-\xi)c_{st}}{\xi} \right)^q + \xi c_{st}^q}
\]

\[
c_{\text{C},st} = \frac{\left( \frac{1 - (s-\xi)c_{st}}{\xi} \right)^q}{\left( \frac{1 - (s-\xi)c_{st}}{\xi} \right)^q + \xi c_{st}^q}.
\]

(18)

B. Quenched approach

Under the quenched approach system is not homogeneous, i.e. agents make decisions based on a prede-
determined type. The voter with probability \( p \) is set as an anticonformist permanently and with complementary probability \( 1 - p \) is set as a conformist one. Thus, we can distinguish two types of agents [21, 37] and for each type we introduce the concentration of agents in given state \( \alpha \) separately, \( c_{\text{A},\alpha} \) for anticonformist and \( c_{\text{C},\alpha} \) for conformist agents respectively. Therefore total concentration of voters in state \( \alpha \) is given by

\[
c_{\alpha} = pc_{\text{A},\alpha} + (1-p)c_{\text{C},\alpha}
\]

(12)

and in result the mean-field dynamics, in contrast to annealed version of the model, is given by two equations:

\[
\frac{dc_{\text{A},\alpha}}{dt} = \gamma^+_{\text{A}}(c_{\text{A},\alpha}) - \gamma^-_{\text{A}}(c_{\text{A},\alpha}) = F_{\text{A}}(c_{\text{A},\alpha}),
\]

\[
\frac{dc_{\text{C},\alpha}}{dt} = \gamma^+_{\text{C}}(c_{\text{C},\alpha}) - \gamma^-_{\text{C}}(c_{\text{C},\alpha}) = F_{\text{C}}(c_{\text{C},\alpha}).
\]

(13)

Symbols \( \gamma^+_{\text{A}}(c_{\text{A},\alpha}) \) and \( \gamma^-_{\text{A}}(c_{\text{A},\alpha}) \) are probabilities that the number of anticonformist agents in state \( \alpha \) increases or decreases respectively in a single update and \( \gamma^+_{\text{C}}(c_{\text{C},\alpha}) \) and \( \gamma^-_{\text{C}}(c_{\text{C},\alpha}) \) describe the same, but for conformist agents. As in the annealed version we consider dynamics on the complete graph thus the Eq. (13) takes the form

FIG. 4. Relation between the size of influence group \( q \) and number of states \( s \). Solid black line describe situation when critical points \( p_{\text{det}} \) and \( p_{\text{tr}} \) are equal, given by Eq. (12). Pairs \((q,s)\) for which relation is opposite are marked by solid fill-color (green). Pairs for which relation is opposite are marked by solid fill-color pink.
The relation given by last formula of Eq. (16) is linear with parameter $p$. Hence combining it with above relations we are able to derive the formula for stationary solution $p = p(c_{st})$

$$p = \left( \frac{1 - (s - \xi) c_{st}}{\xi} \right)^{\frac{q}{s}} c_{st}^{2} - (1 + 2c_{st}c_{st}) (s - \xi) \right] + \xi c_{st}^{2 q} (s - \xi) - 1 \right] + c_{st} \xi (s - \xi) \left( \frac{1 - (s - \xi) c_{st}}{\xi} \right)^{2 q}$$

(19)

For $s = 2$ and $\xi = 1$ the above equation recovers the analytical solution for the original binary quenched $q$-voter model with anticonformity [21]. For more states, namely $s > 1$ this relation produces $s - 1$ stationary solutions for $\xi = 1, 2, \ldots, s - 1$ respectively similarly as for annealed scheme. The stability of given stationary point can be track by the determinant and trace of appropriate Jacobian matrix with respect to this point [31] [37] [38]

$$J(c_{A}, c_{B}) = \begin{bmatrix}
\frac{\partial F_{A}}{\partial A} & \frac{\partial F_{A}}{\partial C} \\
\frac{\partial F_{C}}{\partial A} & \frac{\partial F_{C}}{\partial C}
\end{bmatrix} \bigg| _{(c_{A}, c_{C}) = (c_{A}, c_{C})_{st}}$$

(20)

The steady state is stable if sign of the determinant is positive and sign of trace is negative. Based on this we are able to derive the condition for the lower spinodal point $p_{tr}^{s}$, see Appendix B2 for details

$$p_{det}^{s} = \frac{q - 1}{2q}$$

$$p_{tr}^{*} = 1 - \frac{1}{s} - \frac{1}{q}$$

(21)

The point $p_{det}^{s}$ is root of determinant which is strictly increasing function with $p$, while $p_{tr}^{*}$ is root of trace which is strictly decreasing function with $p$. It is clearly visible that critical point derived from determinant depends only on parameter $q$, while critical point derived from trace depends also on number of states $s$. Also for all values of size of the group of influence $q \geq 1$ in the binary model $s = 2$, the critical point $p_{tr}^{*}$ is lower than $p_{det}^{s}$. It means, that determinant is positive for $p > p_{det}^{s}$ while trace is negative, which follows the conclusion that solution $c = 1/2$ is attractive for $p > p_{det}^{s}$ and unstable otherwise. This agrees with original solution for binary $q$-voter model with quenched dynamics which also should be the same as the result for annealed model [21]. Addi- tionally we are able to derive point at which critical values $p_{det}^{s}$ and $p_{tr}^{*}$ are equal

$$s = \frac{2q}{q - 1} \text{ or } q = \frac{s - 2}{s - 2}$$

(22)

Both above equations give the same hyperbolic relation with asymptotes in $q = 1$ and $s = 2$, see Fig. 4. Below such curve (green fill in Fig. 4) point $p_{tr}^{s}$ is always lower than $p_{det}^{s}$, meaning determinant becomes positive when trace is negative, thus the point in which disordered solution changes stability, namely the lower spinodal line is $p_{det}^{s} = p_{det}^{s}$. Above curve given by Eq. (22) trace is bigger than determinant, thus solution $(c_{A}, c_{C}) = (1/s, 1/s)$ is stable for $p > p_{det}^{s}$ and for $p_{det}^{s} < p < p_{tr}^{*}$ oscillations which reaches attractive stable solution diffrent than $1/s$ as can be seen in Fig. 5. As in the annealed model stability for other stationary solutions is calculated numerically.

In the binary case quenched model gives exactly the same result as annealed version [21]. Surprisingly in the multi-state version this two approaches give different outcomes. While in the annealed version phase transition is still continous, quenched model shows discontinuous transition for $q > 1$ if the number of states is larger than two, see Figs. 2 and 6. The size of the hysteresis seems to increases with $q$ and reaches maximum in point where determinant and trace are equal, namely Eq. (22). There exist only two such integer solution $(q = 3, s = 3)$ and $(q = 2, s = 4)$, see Fig. 4. The stationary solution given by Eq. (19) wrongly predicts lower spinodal, because it shows stationary point in critical value where determinant becomes zero $p_{det}^{s}$, while real lower spinodal can be predict by additional sign of trace as we described above. Despite this inconvenience we still observe good agreement between Monte Carlo simulations and analytical predictions, see Figs. 3 and 5. Unfortunately we are not able to compare this results with majority-vote model, while to our best knowledge multi-state majority vote model was not studied with quenched anticonformity. It was studied on quenched networks and in such case only a continous phase transition where observed [30] [39]. A discontinuous phase transition in such networks was observed only by introducing external parameter which stands for the level of inertia [40].

Taking into account above consideration we can state that one main difference between multi-state $q$-voter model with anticonformity under quenched and annealed approach is existence of discontinuous phase transition. But generally both models behave in very similar way, clearly seen in Figs. 2 and 6. Both models give exactly the same result in binary opinion regime and both models
increase with \( q \) to the limit \( 1 - \frac{1}{2} \).

### III. CONCLUSIONS

We compared two versions of the multi-state \( q \)-voter model with anticonformity: with annealed and quenched disorder. Mean-field analysis together with Monte Carlo simulations revealed difference between this two approaches. At first glance this two models seems to behave in very similar way. Moreover in binary regime they give exactly the same result. But the main difference lay in the existence of discontinuous phase transition. Which in contrast to \( q \)-voter model with independence shows existence of such transition only under quenched approach, whereas for annealed shows only continuous phase transitions. This result is not only suprising and novel but also open doors to new scientific questions. One of them is already hot topic in both social and physics world, namely if there is universality in existence of discontinuous phase transition and hysteresis among different model of opinion dynamics like voter models [1, 2, 12, 14, 21, 37, 41–49] or the majority-vote models [27, 30, 33, 35, 50, 53]. Such universality can be seen if we compare majority-vote model with \( q \)-voter model with independence, where introducing just 3 states result in discontinuous phase transition. The second universality is visible in case of the considered anticonformity model, which for annealed model in complete graph make all transition continuous. Which is not the case in quenched approach. What lead us to another scientific question, namely if quenched approach always as anticonformity destroy discontinuous phase transitions? And as we show in this work, this is not always true, what can lead to more interesting scientific challenges.

### Appendix A: Annealed scheme

#### 1. Transition rates

The total concentration of voters in state \( \alpha \) can increase by \( 1/N \) if we pick an agent in different state and he will change his state to \( \alpha \). Choosig agent with different state than \( \alpha \) takes place with probability \( P(i) \), where \( i \) is state \( i \neq \alpha \). Then this chosen voter can act like anticonformist with probability \( p \) or conformist with probability \( 1 - p \). In the conformity case randomly (without repetitions) lobby consist of \( q \) neighbors is choosen and to increase the total concentration of voters in state \( \alpha \) this lobby need to be unanimous with this state. Collecting such lobby can happen with probability \( P^q(\alpha|i) \), where \( P(\alpha|i) \) is the conditional probability of picking a neighbor in state \( \alpha \) given that a chosen target voter is in state \( i \). In the anticonformity case chosen lobby need to be in the same state as a target voter. Such lobby can be collected with probability \( P^q(i|i) \). Due to anticonformity he can change his state to one of remaining states from the system, each with equal probability \( 1/(s-1) \). Analogous reasoning can be carried out for situations where the total concentration of voters in state \( \alpha \) decrease. Whereby the transition rates can be expressed explicitly as:

\[
\gamma^+(c_\alpha) = \sum_{i \neq \alpha} P(i) \left[ p \frac{P^q(i|i)}{s-1} + (1 - p)P^q(\alpha|i) \right]
\]

\[
\gamma^-(c_\alpha) = \sum_{i \neq \alpha} P(\alpha) \left[ p \frac{P^q(\alpha|\alpha)}{s-1} + (1 - p)P^q(i|\alpha) \right]
\]

(A1)

In case of a complete graph, events of picking a voter in a given state \( \alpha \) and a neighbor in a state \( \beta \) are independent so all conditional probabilities \( P(\alpha|\beta) \) are equal to \( P(\alpha) \). If we asume also, that \( P(\alpha) = c_\alpha \), which is true also in complete graph regime, we end up with formulas given by equations:

\[
\gamma^+(c_\alpha) = \sum_{i \neq \alpha} c_i \left[ p \frac{c^q}{s-1} + (1 - p)c^q_\alpha \right]
\]

\[
\gamma^-(c_\alpha) = \sum_{i \neq \alpha} c_\alpha \left[ p \frac{c^q_\alpha}{s-1} + (1 - p)c^q_i \right].
\]

(A2)

Above transition rates combining with Eq. (3) gives us

\[
\frac{dc_\alpha}{dt} = -pc^{q+1}_\alpha + p \sum_{i \neq \alpha} \left[ \frac{c^{q+1}_i}{s-1} + (1 - p) \sum_{i \neq \alpha} (c_i c^q_\alpha - c_\alpha c^q_i) \right].
\]

(A3)
FIG. 6. Dependence between the stationary concentration of agents in state 0 and probability of anticonformity $p$ within the annealed (upper panels) and quenched (bottom panels) approach for different values of the influence group size $q = \{2, 3, 4, 5, 6\}$. Arrows in the bottom right corners of subplots indicate the direction in which $q$ increases. The number of states $s = 2$ (left column), $s = 3$ (middle column) and $s = 4$ (right column). Lines represent solutions of Eq. (9) and (19): solid and dashed lines correspond to stable and unstable steady states, respectively. Symbols represent the outcome from MC simulations for the system size $N = 5 \times 10^5$ performed from initial condition $c_0 = 1, c_1 = c_2 = 0$. The results are averaged over ten runs and collected after $t = 5 \times 10^4$ MCS. Symbols above the line $c = 1/s$ correspond to the concentration of state 0, whereas symbols below the line $c = 1/s$ represent concentration of all others.

2. Lower spinodal

To determine the lower spinodal for the annealed randomness, we want to calculate the derivative of the effective force

$$F'(c) = (1 - p) \left[ qe^{q-1} - (s - \xi)(q + 1)c^q \right. + cq(s - \xi) \left( \frac{1 - (s - \xi)c}{\xi} \right)^{q-1} - \xi \left( \frac{1 - (s - \xi)c}{\xi} \right)^{q} \right] - p \frac{(q + 1)}{s - 1} \left[ (s - \xi) \left( \frac{1 - (s - \xi)c}{\xi} \right)^{q} + \xi c^q \right].$$

(A4)

which for $c_{st} = 1/s$ gives

$$F' \left( \frac{1}{s} \right) = \left( \frac{1}{s} \right)^q \left[ (1 - p)s(q - 1) - psq + \frac{1}{s} \right].$$

(A5)

We see that above derivative is equal 0 at point

$$p_1^* = \frac{(s - 1)(q - 1)}{(s - 1)(q - 1) + q + 1},$$

(A6)

while values for $q$ and $s$ are set. It has positive sign where $p < p_1^*$ (unstable solution) and negative when $p > p_1^*$ (stable solution). Thus $p_1^*$ is point at which stationary point $c = 1/s$ loses stability.

Appendix B: Quenched

1. Transition rates

In the quenched approach two groups of agents exist: conformists and anticonformists. The total concentration of anticonformist voters in state $\alpha$ can increase by $1/N$ if we pick anticonformist agent in different state and he will
change his state to $\alpha$. Choosing such agent takes place with probability $P_{A}(i)$, where $i$ is state $i \neq \alpha$. Then lobby consist of $q$ neighbors is chosen. Anticonformist agent will change his opinion only if this lobby is unanimous and have the same state as him. Such lobby can be collected with probability $P^{+}(ii)$, where $P(i)$ is the conditional probability of picking a neighbor in state $i$ given that a chosen target voter is in state $i$. Then this agent can pick randomly on of remaining states, each with equal probability $1/(s - 1)$. Similarly, the total concentration of conformist agents in state $\alpha$ can increase by $1/N$ if we pick conformist agent in different state and he will change his state to $\alpha$. Choosing such agent takes place with probability $P_{C}(i)$, where $i$ is state $i \neq \alpha$. Then the chosen $q$ lobby need to be unanimous and have state $\alpha$. Such lobby is collected with probability $P^{+}(ai)$. Analogous reasoning can be carried out for situations where the total concentration of anticonformist and conformist voters in state $\alpha$ decrease. Hence the transition rates can be expressed explicitly as

$$
\gamma_{A}^{+}(c_{i,\alpha}) = \sum_{i \neq \alpha} \left[ \frac{P_{A}(i)P^{+}(ii)}{s - 1} \right],
$$

$$
\gamma_{A}(c_{i,\alpha}) = \sum_{i \neq \alpha} \left[ \frac{P_{A}(\alpha)P^{+}(\alpha|\alpha)}{s - 1} \right],
$$

$$
\gamma_{C}^{+}(c_{i,\alpha}) = \sum_{i \neq \alpha} \left[ P_{C}(i)P^{+}(ai) \right],
$$

$$
\gamma_{C}(c_{i,\alpha}) = \sum_{i \neq \alpha} \left[ P_{C}(\alpha)P^{+}(i|\alpha) \right], \quad \text{(B1)}
$$

If as in the annealed case we can asume that all conditional probabilities $P(\alpha|\beta)$ are equal to $P(\alpha)$ and $P(\alpha) = c_{\alpha}$, which is true in complete graph regime, we end up with formulas:

$$
\gamma_{A}^{+}(c_{i,\alpha}) = \sum_{i \neq \alpha} \left[ \frac{c_{i,\alpha}^{i}q^{i}}{s - 1} \right],
$$

$$
\gamma_{A}(c_{i,\alpha}) = \sum_{i \neq \alpha} \left[ \frac{c_{i,\alpha}^{i}c_{\alpha}^{i}}{s - 1} \right],
$$

$$
\gamma_{C}^{+}(c_{i,\alpha}) = \sum_{i \neq \alpha} \left[ c_{i,\alpha}^{i}q_{\alpha}^{i} \right],
$$

$$
\gamma_{C}(c_{i,\alpha}) = \sum_{i \neq \alpha} \left[ c_{i,\alpha}^{i}c_{\alpha}^{i}q_{i}^{i} \right]. \quad \text{(B2)}
$$

Including above into Eq. (13) leads us to

$$
\frac{dc_{i,\alpha}}{dt} = -c_{i,\alpha}^{2}c_{\alpha}^{i} + \sum_{i \neq \alpha} \left[ \frac{c_{i,\alpha}^{i}q^{i}}{s - 1} \right],
$$

$$
\frac{dc_{i,\alpha}}{dt} = -c_{i,\alpha}^{2}c_{\alpha}^{i} + \sum_{i \neq \alpha} \left[ c_{i,\alpha}^{i}c_{\alpha}^{i}q_{i}^{i} \right]. \quad \text{(B3)}
$$

### 2. Lower spinodal

To calculate lower spinodal point for model with quenched randomness we need to calculate determinant and trace of such Jacobian matrix:

$$
J_{(c_{A},c_{C},\alpha)} = \begin{bmatrix}
\frac{\partial F_{A}}{\partial c_{A}} & \frac{\partial F_{A}}{\partial c_{C}} \\
\frac{\partial F_{C}}{\partial c_{A}} & \frac{\partial F_{C}}{\partial c_{C}}
\end{bmatrix} \quad \text{(B4)}
$$

To achieve it first let us derive appropriate derivatives

$$
\frac{\partial F_{A}}{\partial c_{A}} = qp \left[ \frac{s - \xi}{\xi(s - 1)} \frac{1 - (1 - (s - \xi)c)^{q-1}}{\xi} \right] - \frac{\xi}{s - 1} c_{A} \xi^{q-1},
$$

$$
\frac{\partial F_{C}}{\partial c_{A}} = q(1 - p) \left[ \frac{s - \xi}{\xi(s - 1)} \frac{1 - (1 - (s - \xi)c)^{q-1}}{\xi} \right],
$$

$$
\frac{\partial F_{A}}{\partial c_{C}} = \xi \frac{\xi^{q-1}}{s - 1} (s - \xi)c_{C} \xi^{q-1} - c_{A},
$$

$$
\frac{\partial F_{C}}{\partial c_{C}} = -(s - \xi)c_{C} - \xi \left[ \frac{1 - (1 - (s - \xi)c)^{q}}{\xi} \right] + q(1 - p) \left[ \frac{c^{q-1} - (s - \xi)c_{C} \xi^{q-1}}{s - 1} - c_{A} \xi^{q-1} \right]. \quad \text{(B5)}
$$

Base on above derivatives we are able to calculate the determinant and the trace for the stationary solution ($c_{A,t} = 1/s$, $c_{C,t} = 1/s$):

$$
\det[J_{(1/s,1/s,s)}] = \frac{\partial F_{A}}{\partial c_{A}} \frac{\partial F_{C}}{\partial c_{C}} - \frac{\partial F_{A}}{\partial c_{A}} \frac{\partial F_{C}}{\partial c_{A}},
$$

$$
\text{tr}[J_{(1/s,1/s,s)}] = \frac{\partial F_{A}}{\partial c_{A}} + \frac{\partial F_{C}}{\partial c_{C}}, \quad \text{(B6)}
$$

which gives us

$$
\det[J_{(1/s,1/s,s)}] = \left( \frac{1}{s} \right)^{2q} \frac{s^{2}}{s - 1} [q(2p - 1) + 1]
$$

$$
\text{tr}[J_{(1/s,1/s,s)}] = \left( \frac{1}{s} \right)^{q-1} \left[ q - s(qp + 1) \right]. \quad \text{(B7)}
$$

It easy to observe that determinant increases with $p$ while trace decreases. The solution is stable if sign of trace is negative while positive for determinant. Thus to determine stability of point ($c_{A,t} = 1/s$, $c_{C,t} = 1/s$) we only need to find roots of determinant and trace, namely

$$
p_{\text{det}}^{*} = \frac{q - 1}{2q},
$$

$$
p_{\text{tr}}^{*} = 1 - \frac{1}{s} - \frac{1}{q}. \quad \text{(B8)}
$$
