(Dated: June 23, 2021)

In this work, we investigate the quantum phase transition of light in the dissipative Rabi-Hubbard lattice under the framework of the mean-field theory and quantum dressed master equation. The order parameter of photons in the low temperature and strong qubit-photon coupling regime is also derived analytically. Interestingly, it is able to locate the localization and delocalization phase transition very well in a wide parameter region. In the deep-strong qubit-photon coupling regime, the critical tunneling strength approaches zero regardless of the quantum dissipation, contrary to the previous results for the finite critical tunneling strength based on the standard Lindblad master equation.

I. INTRODUCTION

The microscopic interaction between light and quantum matter is ubiquitous in broad fields ranging from quantum optics \cite{1,2}, condensed matter physics \cite{3,4}, to quantum chemistry \cite{5,6}, and has attracted tremendous attentions in many years. It continues to be a hot topic due to the tremendous progress in the superconducting qubits \cite{7,8}, trapped ions \cite{9}, and the cold atoms \cite{10}. The simplest paradigm is composed by a two-level system interacting with a single-mode radiation field, theoretically characterized by the seminal quantum Rabi model \cite{11} and its restricted model after the rotating-wave approximation, known as the Jaynes-Cummings (JC) model \cite{12}. Recently, due to the significant development of circuit quantum electrodynamics (cQED) \cite{13,14}, the light-matter coupling now has reached the ultra-strong and even deep-strong coupling regimes, which invalids the rotating-wave approximation and spurs a plethora of inspiring works \cite{15,16,17,18}.

The quantum system would undergo the quantum phase transition (QPT) near the critical parameters due to the quantum fluctuations at zero temperature. The QPT has been extensively investigated in light-matter interacting systems \cite{21,22}. It was reported that the QPT can be even observed in finite-component quantum systems, e.g., the quantum Rabi model \cite{23,24} and Rabi-Stark model \cite{25}. While considering the interplay between the on-site light-matter interaction and intersite photon hopping lattice \cite{26}, the JC (Rabi)-Hubbard lattice system is the representative coupled cQED lattice model \cite{27,28}. One of the most intriguing effects for the light-matter interacting lattice is the QPT of light, i.e., the localization to delocalization transition of photons. Specifically, multiple Mott-to-superfluid transitions and a series of Mott lobes are exploited in the JC-Hubbard lattice system \cite{29,30,31,32,33,34,35,36}, whereas the Mott lobes are strongly suppressed and a single global boundary is unraveled to clarify the localized and delocalized phases in the Rabi-Hubbard lattice \cite{37,38,39}.

From the realistic view, quantum systems generally inevitably interact with the environment \cite{40}. For the single-site open Rabi model with phenomenological dissipation, the cooperation between the strong qubit-photon coupling and photon damping results in the dissipative phase transition \cite{41}. While for the dissipative JC-Hubbard lattice, the effective non-Hermitian model description leads to the suppression of Mott lobes and localization of photons \cite{42}. For the dissipative Rabi-Hubbard lattice described by the Lindblad master equation, the spin-spin correlation function and the phase transition of light is investigated \cite{43}. However, it was recently reported that as the qubit-photon interaction becomes strong, the light-matter hybrid system should be treated as a whole, which implies the breakdown of the Lindblad description \cite{44}. Consequently, the dressed master equation should be properly included to investigate the dissipative dynamics of the hybrid quantum systems, e.g., qubit-photon lattice system, from weak to strong hybridization strengths \cite{45,46,47}.

In this work, we apply the dressed master equation combined within the mean-field theory to study the steady-state phase diagram of the dissipative Rabi-Hubbard lattice model. The QPT of light are exhibited both at zero and finite temperatures. The nontrivial analytical expression of the order parameter is obtained, which relies on a comprehensive set of system parameters. Moreover, an improved boundary to characterize phase transition of photons is also achieved, compared to the previous work with Lindblad dissipation \cite{48}. The
paper is organized as follows: In Sec. II we briefly introduced the dissipative Rabi-Hubbard lattice model and the dressed master equation. In Sec. III we numerically show the phase diagram of the order parameter of photons, and analytical location of the phase boundary is also performed. Finally, we give a summary in Sec. IV.

II. MODEL AND METHOD

A. The Rabi-Hubbard lattice model

The Rabi-Hubbard lattice system, which is composed by the on-site quantum Rabi model and photon tunneling between the nearest-neighboring sites with the rate $J$, is described as

$$ H = \sum_n H_n^{Rabi} - J \sum_{(m,n)} (a_m^\dagger a_n + a_n a_m^\dagger), $$

where $H_n^{Rabi}$ denotes the Hamiltonian of the Rabi model at the $n$th site, which describes the interaction between a qubit and a single mode photon field. The Hamiltonian is specified as

$$ H_n^{Rabi} = \omega_0 a_n^\dagger a_n + \frac{\varepsilon}{2} \sigma_z^n + g \sigma_z^n (a_n + a_n^\dagger) $$

where $a_n$ and $a_n^\dagger$ are the annihilation and creation operator of cavity field at the $n$th site, $\sigma_z$ and $\sigma_z^n$ are the Pauli operators of qubit at the $n$th site, $\omega_0$ denotes the frequency of cavity field, $\varepsilon$ is the energy splitting of qubit, and $g$ is the qubit-cavity coupling strength.

Then, we adopt the mean-field theory to simplify the Rabi-Hubbard lattice model to an effective single site. The Hamiltonian of mean field Rabi-Hubbard lattice model is given by

$$ H_{MF} = \omega_0 a^\dagger a + \frac{\varepsilon}{2} \sigma_z + g \sigma_z (a + a^\dagger) - \frac{z}{2} J \psi (a + a^\dagger), $$

where $z$ is the number of nearest neighboring sites, and $\psi$ is a the average value of annihilation operator $a$ and can be calculated as

$$ \psi = \text{Tr} \{ \rho_s a \}, $$

with $\rho_s$ the steady state density matrix. In this work, $\psi$ can be regarded as the order parameter. Note that the subindex $n$ is ignored for all sites, because each site shares the same Hamiltonian in the mean-field framework. The emergence of the nonzero order parameter $\psi$ can be used to characterize the QPT of light in the Rabi-Hubbard lattice, i.e., the localization phase to delocalization phase transition [29, 30].

B. Quantum dressed master equation

We take quantum dissipation into consideration in this work. Specifically, we include local dissipation where the $n$th site mean-field Rabi model is coupled to two individual bosonic thermal baths. Hence, the total Hamiltonian under the mean-field theory can be expressed as

$$ H_t = H_{MF} + H_B + \nu. $$

The bosonic thermal baths are described as

$$ H_B = \sum_{q,c} \sum_{\omega_k} b_{q,k} b_{q,k}^\dagger + \sum_{\omega_k} b_{c,k} b_{c,k}^\dagger, $$

where $b_{q,k}$ and $b_{c,k}^\dagger$ are the annihilation and creation operators of the boson with the frequency $\omega_k$ in the $n$th bath. The interactions between the Rabi-Hubbard lattice model and bosonic thermal baths are given by

$$ V_q = \sum_{\omega_k} \lambda_{q,k}^+ (b_{q,k} + b_{q,k}^\dagger) \sigma_x, $$

$$ V_c = \sum_{\omega_k} \lambda_{c,k} (b_{c,k} + b_{c,k}^\dagger) (a + a^\dagger), $$

with $\lambda_{q,k}^+ (\lambda_{c,k})$ the coupling strength between the qubit (photon) and the corresponding thermal bath. The system-bath interaction is characterized as the spectral function $G_{q,c}(\omega) = 2\pi \sum_{\omega_k} |\lambda_{q,c,k}|^2 \delta(\omega - \omega_k)$. In this work, we select the Ohmic case to quantify the thermal bath, i.e., $G_q(\omega) = \gamma_q \omega / \varepsilon \exp(-\omega / \omega_c)$ and $G_c(\omega) = \gamma_c \omega / \omega_0 \exp(-\omega / \omega_c)$, where $\gamma_q(\omega)$ is the dissipation strength and $\omega_c$ is the cutoff frequency. $\omega_c$ is considered to be large enough, so the spectral functions are simplified as $G_q(\omega) = \gamma_q \omega / \varepsilon$ and $G_c(\omega) = \gamma_c \omega / \omega_0$.

Next, we assume the weak coupling between the quantum system and bosonic thermal baths. Regarding the system-bath interactions Eq. (3) and Eq. (7) as perturbations, we obtain the dressed quantum master equation under Born-Markov approximation, which is expressed as [13, 44, 47]

$$ \frac{\partial \rho_{MF}}{\partial t} = -i[H_{MF}, \rho_{MF}] $$

$$ + \sum_{j, k > j} \{ \Gamma_{jk}^u \left( 1 + n_u (\Delta_{kj}) \right) D[|\phi_j\rangle \langle \phi_k|], \rho_{MF} \} $$

$$ + \Gamma_{jk}^c n_u (\Delta_{kj}) D[|\phi_k\rangle \langle \phi_j|], \rho_{MF}], $$

where the dissipator is $D[O, \rho_{MF}] = \frac{1}{2} (2O\rho_{MF}O^\dagger - O^\dagger O\rho_{MF} - \rho_{MF}O^\dagger O)$, $\Delta_{kj} = E_k - E_j$ is the transition frequency of two energy levels, with $E_k$ and $|\phi_k\rangle$ the eigenenergy and eigenstate of the mean-field Rabi model, i.e., $H_{MF}[\phi_k] = E_k |\phi_k\rangle$, $n_u (\Delta_{kj}) = 1/\left[ \exp(\Delta_{kj} / k_BT_u) - 1 \right]$ is the occupation number with frequency $\Delta_{kj}$ in the $u$th thermal bath, and the effective dissipative rates $\Gamma_{jk}^q$ and $\Gamma_{jk}^c$ thus read

$$ \Gamma_{jk}^q = \frac{\gamma_q \Delta_{kj}}{\varepsilon} \frac{|\langle \phi_j | (\sigma_- + \sigma_+) | \phi_k \rangle|^2}{}, $$

$$ \Gamma_{jk}^c = \frac{\gamma_c \Delta_{kj}}{\omega_0} \frac{|\langle \phi_j | (a + a^\dagger) | \phi_k \rangle|^2}{}. $$

With the dressed master equation, we can self-consistently solve the steady state of the Rabi-Hubbard lattice model. To be more specific, we initially set the order parameter to be an arbitrary reasonable value, then
we find a temporary steady state and calculate the next order parameter using Eq. (14). This procedure can be repeated until the converged steady state and order parameter are achieved. All physical quantities can be calculated within the final steady state.

III. RESULTS AND DISCUSSIONS

A. Numerical analysis of QPT

We first apply the dressed master equation combined with mean-field theory to numerically investigate the steady-state phase diagram of photons of the Rabi-Hubbard lattice model. By calculating the order parameter $|\psi|$ with Eq. (11) at zero temperature, the sharp phase transition from the localization to the delocalization phase is clearly exhibited in Fig.1. The localization phase with vanished order parameter (i.e., $|\psi| = 0$) is denoted by the dark blue region, whereas the delocalization phase, characterized as significant excitation of the order parameter, locates at light green and yellow regions. The present phase transition corresponds to the $Z_2$ symmetry breaking. Moreover, as the inter-site photon tunneling strength $J$ increases, the critical on-site qubit-photon coupling strength $g$, separating the delocalization and localization phases decreases gradually.

These numerical results are qualitatively consistent with the previous ones observed in the QPT of light at both the steady state [38] and the ground state [39], where the competition between the inter-site photon tunneling and the on-site qubit-cavity coupling are also considered. In the next subsection, we will analytically explain the global boundary through the order parameter of photons.

B. Analytical solution of QPT

Since the phase boundary located by numerical calculation in Fig.1 is just in the deep-strong coupling regime where the analytical adiabatic approximation can be applicable [38], we may also derive an analytical solution of the order parameter $|\psi|$ at steady state in the critical regime. In the limiting regime of low temperature and weak excitation of the order parameter, we approximately treat the eigensate $|\phi_k\rangle$ of the mean-field Rabi model at Eq. (8) as the counterpart $|\phi_{k0}\rangle$ of the standard Rabi model $\hat{H}_{\text{Rabi}}$ by ignoring $\psi$ at Eq. (3). Moreover, we confine the complete Hilbert space to the subspace only spanned by the ground state $|\phi_{00}\rangle$ and the first excited state $|\phi_{10}\rangle$. Then, the dressed master equation is simplified as

$$\frac{\partial \rho_{10}}{\partial t} = -i\beta t (2\rho_{00} - 1) - \frac{\Gamma(\Delta)}{2} (2n_B(\Delta) + 1)|\rho_{10} - i\Delta\rho_{10}|,$$

$$\frac{\partial \rho_{00}}{\partial t} = i\beta (\rho_{01} - \rho_{10}) + \frac{\Gamma(\Delta)}{2} \{1 - [2n_B(\Delta) + 1](2\rho_{00} - 1)\},$$

where the reduced density matrix element is $\rho_{ij} = \langle\phi_{k0}^\dagger \phi_{ij}^\dagger \phi_{ij} \phi_{k0}\rangle (i,j = 0,1)$, the coefficient is $\beta = -zJ\psi_t (\phi_{k0}^\dagger (a + a^\dagger) |\phi_{k0}\rangle \psi_t)$ with the time-dependent order parameter $\psi_t = \text{Tr}(\rho_{k0}(a^\dagger)\rho_{k0}) \approx \text{Tr}(\rho_{k0}(a^\dagger))$, the dissipation rate becomes $\Gamma(\Delta) = \gamma_c \Delta |\langle\phi_{k0}^\dagger (a + a^\dagger) |\phi_{k0}\rangle|^2/\omega_0 + \gamma_q |\langle\phi_{k0}^\dagger (\sigma_+ + \sigma_-) |\phi_{k0}\rangle|^2/\epsilon$, the Bose–Einstein distribution function is $n_B(\Delta) = 1/\exp(\Delta/k_B T) - 1$, and the energy gap is $\Delta = E_{10}^{\text{Rabi}} - E_{00}^{\text{Rabi}}$.

In the deep strong qubit-photon coupling regime, the ground state and the first excited state of the standard Rabi model are nearly degenerate, which can be approximately expressed as [48]

$$|0\rangle \approx \frac{1}{2} \left( |\alpha\rangle - |\alpha\rangle, |\alpha\rangle - |\alpha\rangle \right)^T,$$

$$|1\rangle \approx \frac{1}{2} \left( |\alpha\rangle + |\alpha\rangle, |\alpha\rangle + |\alpha\rangle \right)^T,$$

where $|\alpha\rangle$ is the coherent state with the displaced coefficient $\alpha = g/\omega_0$. At steady state $(d\rho_{ij}/dt = 0)$, the order parameter is approximated as $\psi \approx g(\rho_{10}^\dagger + \rho_{10})/\omega_0$, the coefficient is given by $\beta = -2g^2 Z J (\rho_{10}^\dagger + \rho_{10})/\omega_0^2$, and the transition rate is reduced to

$$\Gamma(\Delta) \approx \Delta \left( \frac{4g^2 \gamma_c}{\omega_0^2} + \frac{\gamma_q}{\epsilon} \right).$$
Therefore, the order parameter $|\psi|$ at steady state with finite temperature can be obtained as

$$|\psi| \approx \sqrt{\frac{4g^2zJ\Delta}{(2n_B(\Delta) + 1)\omega_0^2} - \Delta^2 - \left[\frac{(2n_B(\Delta) + 1)\Gamma(\Delta)}{4}\right]^2} \times \frac{\omega_0}{2\sqrt{2gzJ}},$$

(16)

where the gap becomes $\Delta = \varepsilon \exp(-2g^2/\omega_0^2)$ \[49\]. While in the zero temperature limit, the order parameter is reduced to $|\psi| \approx \frac{\omega_0}{2\sqrt{2gzJ}} \sqrt{\frac{4g^2zJ\Delta}{\omega_0^2} - \Delta^2 - \frac{1}{\Gamma(\Delta)}}$. We will show below that this analytical result can well characterize the phase boundary obtained by numerical calculation in the last subsection in Fig. 1. Moreover, at finite temperature, we can also predict the critical tunneling strength as $zJ_c = \omega_0^2\Delta(2n_B(\Delta, T) + 1)[1 + (2g^2\gamma_c/\omega_0^2 + \gamma_q/2\varepsilon)^2]/4g^2$, which may be useful to investigate the finite temperature phase transitions of photons.

IV. CONCLUSION

In the paper, we study the QPT of light in the Rabi-Hubbard lattice with local dissipation under the framework of the mean-field and quantum dressed master equation. The steady state phase diagram of photons are numerically composed, which clearly classifies the localization and delocalization phases. We then analytically obtain an approximate expression of the order parameter in the low temperature and strong qubit-photon coupling regime, where the mean-field Rabi model is reduced to the effective near-degenerate two-level system. We further analyze the boundary between two difference phases, which is characterized as the critical tunneling strength. The expression of critical tunneling strength can be naturally reduced to the previous work in the absence of the quantum dissipation. While by tuning on the quantum dissipation, it is found that the critical tunneling strength approaches zero as the qubit-photon coupling strength becomes deep strong. This result is distinct from the previous work based on the Lindblad equation, which has finite minimal critical tunneling. Moreover, we also predict the critical tunneling strength at finite temperature, which may be helpful to study the phase transition of light at thermal equilibrium in the future.
