We present a theoretical investigation of the resonant elastic scattering of twisted light, carrying angular momentum, by partially striped ions. Special emphasis is placed on the question of whether the scattered radiation is also twisted. In order to investigate such an “angular momentum transfer” we develop the approach, that allows us to find the vector potential of scattered radiation without projecting it onto detector states. The general expression for this so-called excited state of outgoing radiation is derived and it can be used to analyze the resonant scattering by any ion, independently of its shell structure. Here, we illustrate our approach with strong electric dipole $nS_0 \rightarrow n'P_1 \rightarrow nS_0$ transitions, which play an important role for the Gamma Factory project at CERN. We show, for the incident Bessel light, that the scattered radiation is in a superposition of twisted modes with the projections of the total angular momentum $m_f = 0, \pm 1$. The larger values of $m_f$ can be efficiently generated by inducing transitions of higher multiplicity. This angular momentum transfer, together with a remarkable cross section, that is many orders of magnitude larger than that of the backward Compton scattering, makes the resonant photon scattering an effective tool for the production of twisted x– and even gamma–rays at the Gamma Factory facility.

I. INTRODUCTION

The resonant elastic photon scattering by an atom (or ion), which proceeds via formation and subsequent decay of a particular atomic state, has been in the focus of experimental and theoretical for many decades [1–5]. Recently, this process has attracted a particular attention also as a key element for the Gamma Factory project at the CERN facility [6–8]. In the Gamma Factory, the incident laser radiation with the frequency $\omega_i^{(\text{lab})}$ will be collided head–to–head with fast–moving partially striped ions and scattered predominantly backwards. Owing to the Lorentz transformation between the laboratory (collider) and ion–rest reference frames, the frequency of the scattered photons will be boosted to $\omega_f^{(\text{lab})} \approx 4\gamma^2 \omega_i^{(\text{lab})}$, where $\gamma$ is the ion’s Lorentz factor. Since ions with $\gamma = 10–2900$ can be stored in the LHC collider ring, the gamma–rays with the energies up to 30 MeV and the intensity up to $10^{17}$ photons per second can be generated from the incident laser radiation with an energy just about 1 eV, see Ref. [6–8] for further details.

Besides energy and emission pattern, further characteristics of the resonantly scattered photons are also of great interest for the Gamma Factory. For example, a number of theoretical works have been performed recently to investigate the polarization of outgoing radiation [3, 10]. Yet another degree of freedom, that also attracts particular attention, is the orbital angular momentum (OAM) of light. The generation of photon beams, carrying a non–zero OAM projection onto their propagation direction, is presently under discussion in the framework of the Gamma Factory project. Having an energy of up to tens of MeV, these so–called twisted beams can become a valuable tool for a wide range of studies in atomic, optical and nuclear physics [11–14].

The generation of twisted x– or even gamma–rays at the Gamma Factory may rely on the resonant scattering of incident twisted light by ultrarelativistic partially striped ions. However, in order to decide about the feasibility of this approach one has to investigate first how (and whether) the projection of the angular momentum is transferred between incident and outgoing photons in the scattering process. Until now, the theoretical analysis of such a “twistedness transfer” has been based on projecting the scattered light states onto plane–cylindrical– (twisted) or spherical–wave solutions [4–13]. The outcome of this projection can be understood as a probability to get a “click” in a detector, that is sensitive only to a particular state of light. In the present work, we propose an alternative and more general approach that allows one to perform a quantum tomography of the scattered ra-
diation without a need to introduce detector states. This approach makes use of the well-established S–matrix theory and provides the wave–function of the outgoing photon as it results from the scattering process itself.

In order to discuss how the “quantum tomography” method helps to analyze the state of a photon, produced in the resonant scattering of incident twisted radiation, we have to remind first how to describe such (twisted) solutions. In Sec. III therefore, we briefly review the Bessel electromagnetic waves, that are characterized by a well–defined projection of their total angular momentum (TAM) onto propagation direction, and can be written as a coherent superposition of standard plane–waves. The most general description of the scattering of Bessel photons is given in Sec. [III] within the framework of the S–matrix theory. In particular, it is shown that the evolved state of the outgoing light, obtained irrespectively of the detector setup, can be written as a sum of plane–waves, weighted by the scattering matrix elements. In Sec. [IV] we evaluate these matrix elements and, hence, the vector potential of the final (evolved) photon state for the electric dipole $ns_0 \rightarrow n'P_1 \rightarrow nS_0$ resonant transition, which is of special interest for the Gamma Factory program. Based on the performed analysis, we argue that the resonant E1 scattering of incident twisted light leads to the emission of secondary radiation in a superposition of Bessel states with TAM projections $m_f = 0, \pm 1$. The larger values of $m_f$ can be obtained by inducing quadrupole and even higher–order ionic transitions. Moreover, as shown in Sec. [V] the cross section of the resonant scattering is many orders of magnitude larger than the one of the Compton scattering by free electrons; the process which is discussed as an alternative source of high–energy twisted radiation [16, [17]. Together with our predictions for the TAM transfer this cross–section argument suggests that the resonant scattering by fast–moving partially stripped ions provides an efficient tool for generating x– and even gamma–ray twisted photon beams at the Gamma Factory facility. The summary of these important results is given finally in Sec. [VI].

Relativistic units ($\hbar = 1$, $c = 1$) are used throughout the paper.

II. PLANE–WAVE AND TWISTED STATES

Before starting the theoretical investigation of the resonant scattering process, we have to remind first how to describe the states of incident and outgoing photons. In this section we focus on two such states: (i) the “standard” plane–wave and (ii) cylindrical–wave Bessel solutions. Since both solutions and their relations are well discussed in the literature [12, [16, [18], here we restrict ourselves just to a brief compilation of basic formulas, needed for the further analysis.

A. Plane–wave photons

The vector potential of a freely propagating electromagnetic plane–wave reads as:

$$A_{k\lambda}(r) = \epsilon_{k\lambda} e^{ikr},$$

where $k$ is the wave–vector, that defines not only the direction of propagation, $\hat{k} = k/k = (\theta, \phi)$, but also the energy $\omega = |k|$ of light. In Eq. (1), moreover, $\epsilon_{k\lambda}$ is the circular polarization vector with $\lambda = \pm 1$ being the photon’s helicity, i.e. projection of its spin onto the $\hat{k}$–direction. Within the Coulomb gauge for the light–matter coupling, this polarization vector is orthogonal to the wave–vector, $\hat{k} \cdot \epsilon_{k\lambda} = 0$, and can be written as:

$$\epsilon_{k\lambda} = \sum_{\sigma = 0, \pm 1} e^{-i\sigma \phi} d^{1\lambda}_{\sigma}(\theta) \epsilon_{\sigma}.$$  (2)

Here, $d^{1\lambda}_{\sigma}(\theta)$ are the small Wigner functions:

$$d^{1\lambda}_{\lambda\lambda}(\theta) = \frac{1}{2} (1 + \lambda \lambda' \cos \theta),$$

$$d^{1\lambda}_{\lambda\sigma}(\theta) = -d^{1\lambda}_{\sigma\lambda}(\theta) = \frac{\lambda}{\sqrt{2}} \sin \theta,$$

$$d^{1\lambda}_{\sigma\sigma}(\theta) = \cos \theta,$$

and the spherical basis unit vectors:

$$\epsilon_0 = (0, 0, 1), \quad \text{and} \quad \epsilon_{\pm 1} = \frac{\mp \mathbf{1}}{\sqrt{2}} (1, \pm i, 0),$$

are the eigenvectors of the operator $\hat{S}_z$ of the spin projection onto $z$–axis:

$$\hat{S}_z \epsilon_\sigma = \sigma \epsilon_\sigma,$$

with the eigenvalues $\sigma = 0, \pm 1$.

B. Twisted Bessel photons

Beside the plane waves [11], we also briefly discuss the cylindrical–wave solutions of the free Maxwell equations as can be described, for example, by the so–called Bessel state. The Bessel beam, propagating along the quantization $z$–axis is characterized by its longitudinal momentum $k_z > 0$, an absolute value of the transverse momentum $k_\perp$, as well as by an energy $\omega = \sqrt{k_z^2 + k_\perp^2}$. The vector potential of this Bessel photon state can be written:

$$A_{k_\perp m k_z \lambda}(r) = i^{-m} \int_0^{2\pi} \epsilon_{k\lambda} e^{i(k r + i m \phi)} \frac{d \phi}{2\pi},$$

with $m$, and $m$.
as a coherent superposition of plane-wave with the helicity $\lambda$ and wave-vectors $k = (k_\perp \cos \varphi, k_\perp \sin \varphi, k_z)$. This expression implies, moreover, that the Bessel photon beam carries a well-defined $z$–projection

$$m = 0, \pm 1, \pm 2, \ldots$$

of its total angular momentum (TAM). This can be easily obtained from Eq. (2) and the fact that $e_{k\lambda} e^{im\varphi}$ is an eigenvector

$$\hat{J}_z e_{k\lambda} e^{im\varphi} = m e_{k\lambda} e^{im\varphi},$$

of the corresponding operator $\hat{J}_z$, which can be written as:

$$\hat{J}_z = -i \frac{\partial}{\partial \varphi} + \hat{S}_z,$$

where $\hat{S}_z e_{k\lambda} = -i e_{k\lambda} \times e_0$, and $e_0$ is given by Eq. (4).

One can further evaluate the vector potential by performing integration over the azimuthal angle:

$$A_{k_\perp m k_\lambda}(r) = e^{ik_z z} \sum_{\sigma = 0, \pm 1} [i^{-\sigma} d^{1/2}_{\sigma \lambda}(\theta)$$

$$\times J_{m-\sigma}(k_\perp r_\perp) e^{i(m-\sigma)\varphi} e_\sigma] \quad (10)$$

where $J_{m-\sigma}(k_\perp r_\perp)$ is the Bessel function. As seen from this expression, the potential $A_{k_\perp m k_\lambda}(r)$ depends on the opening angle:

$$\theta = \arctan(k_\perp/k_z), \quad (11)$$

which is usually employed to characterize the ratio of the transverse to longitudinal momenta of twisted light. In the present-day experiments this ratio and, hence, the opening angle, are usually rather small, $\theta \ll 1$, leading to the so-called paraxial regime. In this regime the sum in Eq. (10) is dominated by a single term $\sigma = \lambda$ and the vector potential of Bessel light can be written as:

$$A_{k_\perp m k_\lambda}(r) \approx i^{-\lambda} \cos^2(\theta/2) J_{m-\lambda}(k_\perp r_\perp)$$

$$\times e^{i(m-\lambda)\varphi} e_\lambda e^{ik_z z}. \quad (12)$$

It implies for a paraxial twisted beam, that the $z$–projection of the total angular momentum $m$ unambiguously splits into the (projections of) spin $\lambda$, and orbital $m - \lambda$ angular momenta. If, moreover, $m - \lambda \neq 0$, the energy density of the electromagnetic field vanishes in the center of such a beam, whereas the first maximum appears at the distance $r_\perp \approx |m - \lambda|/(k \sin \theta)$.

In the limit of vanishing transverse momentum and opening angle, $k_\perp \to 0$ and $\theta \to 0$, the vector potential $A_{k_\perp m k_\lambda}(r)$ can be further simplified to:

$$A_{k_\perp m k_\lambda}(r)|_{0 \to 0} \approx \delta_{m\lambda} i^{-\lambda} e_\lambda e^{ik_z z}, \quad (13)$$

where we used the well-known asymptotic formulae for the Wigner, $d^{1/2}_m(0) = \delta_{m\lambda}$, and the Bessel, $J_{m-\lambda}(0) = \delta_{m\lambda}$, functions. One can see from this expression, that for $m = \lambda$ the vector potential of Bessel photons restores, up to insignificant phase factor $i^{-\lambda}$, the “standard” solution for a plane wave propagating along the $z$ axis.

Until now we have discussed the basic expressions to describe the twisted Bessel photons in the coordinate space. For the further analysis, however, it is useful to re-write the vector potential $A_{k_\perp m k_\lambda}$ also in momentum representation:

$$\hat{A}_{k_\perp m k_\lambda}(p) = \int A_{k_\perp m k_\lambda}(r) e^{-ipr} d^3 r$$

$$= i^{-m} e^{im\varphi} \frac{4\pi^2}{p_\perp} \epsilon_{p\lambda}$$

$$\times \delta(p_\perp - k_\perp) \delta(p_z - k_z). \quad (14)$$

This expression again suggests a “visualization” of a Bessel state as a superposition of plane waves, whose wave–vectors lay on the surface of a cone with the opening angle $\theta$, see also Eq. (6).

### III. S–MATRIX APPROACH

#### A. General formalism

Our further analysis is based on the standard S–matrix approach, that allows one to relate the states of a physical system long before and after the scattering. In the operator form, this relation can be written as:

$$|e\rangle = \hat{S}|i\rangle, \quad (15)$$

where the explicit form of the evolution operator $\hat{S}$ depends, of course, on a particular process. By defining such a process and by choosing the initial state $|i\rangle$ of a system, one can use Eq. (15) to obtain the so-called evolved state $|e\rangle$.

It is important to distinguish a detected state of the final photon $|f\rangle$, which is defined by the properties of a detector, and the evolved state $|e\rangle$ in which the photon goes as a result of the scattering, irrespectively of the post-selection process. In this paper, we concentrate on the properties of the final photon itself, without a reference to how this photon is detected, which allows us to explicitly retrieve the phase of the evolved state and show that the latter might have a phase vortex. In other words, we perform quantum tomography of the final photon state, while in order to judge whether the final photon is twisted or not it is usually enough to employ just two representations, the momentum and the coordinate one, corresponding to two marginal values of the quadrature operator
\[ \hat{X}_0 = \hat{r} \text{ and } \hat{X}_{\pi/2} = \hat{k}. \]  

(16)

Other intermediate values of the quadrature angle \(\alpha\) are not needed for our purposes.

It is usually practical to re-write Eq. (15) in terms of wave-functions, instead of state vectors. In order to achieve this one needs to agree first about the representation in which the wave-functions are written. For example, the initial- and final-state wave-functions of a system in the coordinate representation are related to each other as:

\[
\psi_e(r) = (r | e) = \langle r | \hat{S} | i \rangle = \sum_f \langle r | f \rangle \langle f | \hat{S} | i \rangle = \sum_f \psi_f(r) S_{fi}.
\]

(17)

Here, we introduced the notation \(S_{fi} = \langle f | \hat{S} | i \rangle\) for the S-matrix element and assumed that detected states \(|f\rangle\) form a complete basis set, so that \(\sum_f |f\rangle \langle f| = \hat{I}\) is the identity operator.

### B. Evolved photonic states

Having briefly discussed the general formulas of the S-matrix approach, we are ready to apply them to the photon scattering process. As seen from Eqs. (15) and (17), this would require a definition of an initial photon state. By assuming, for example, the incident plane-wave with the wave-vector \(k_i\) and helicity \(\lambda_i\), one can derive:

\[
A^{(pl)}_e(r) = \sum_f \langle r | f \rangle S^{(pl)}_{fi} = \sum_{\lambda_f = \pm 1} \int \epsilon_{k_f \lambda_f} e^{i k_f r} S^{(pl)}_{f i} \frac{d^3 k_f}{(2\pi)^3}
\]

(18)

the vector potential of the evolved state of a scattered photon in the coordinate representation. The second line of this expression is obtained in the lowest order of the perturbation theory and by using complete basis set of plane-wave solutions, \(\langle r | f \rangle = \epsilon_{k_f \lambda_f} e^{i k_f r}\). In Eq. (18), moreover, the plane-wave scattering matrix element is given by:

\[
S^{(pl)}_{f i} = \langle k_f \lambda_f | \hat{S} | k_i \lambda_i \rangle = i N 8\pi^2 \delta(\omega_i - \omega_f) \mathcal{M}^{(pl)}_{f i},
\]

(19)

where the normalization \(N = 1/\sqrt{(2\omega_i V)(2\omega_f V)}\) corresponds to a single photon in a volume \(V\), and \(\mathcal{M}^{(pl)}_{f i}\) is a transition amplitude. This amplitude depends, of course, on a specific resonant transition in a “target” ion and is directly related to the differential cross-section of the resonant scattering:

\[
\frac{d\sigma^{(pl)}_{fi}}{d\Omega_f} = |\mathcal{M}^{(pl)}_{fi}|^2.
\]

(20)

While the explicit form of the plane-wave scattering amplitude \(\mathcal{M}^{(pl)}_{fi}\) will be discussed in the next Section, here we will discuss the scattering of incident Bessel light.

Owing to the complex internal structure of twisted light, its scattering demands more attention, comparing to the plane-wave case. One has to agree first about the geometry of the scattering process. In the present work, we will consider scenario of the head–to–head collisions of incident Bessel and ion beams, that is planned to be realized at the Gamma Factory. In this scenario, the twisted light counter–propagates the quantization \(z\)-axis, chosen along ion beam direction, and is described by the vector potential:

\[
A_{k_{\perp} m k_{\perp} \lambda}(r) = i m \int_0^{2\pi} \epsilon_{k_{\perp} \lambda} e^{i k_{\perp} r - i m \sigma \phi} \frac{d\sigma}{2\pi} = (-1)^m e^{i k_z z} \sum_{\sigma = 0, \pm 1} \left[ i^\sigma d_{\sigma \lambda}^1(\theta) \times J_{m+\sigma}(k_{\perp} r_{\perp}) e^{-i(m+\sigma)\varphi_r} \epsilon_{\sigma} \right],
\]

(21)

where the longitudinal momentum is negative, \(k_z < 0\), and the opening angle lies in the interval \(\pi/2 < \theta < \pi\). One can note that this expression is trivially obtained from Eqs. (3) and (10) by changing the sign of \(m\).

With the help of Eq. (21) one can derive the vector potential of scattered photon for the incident Bessel light. Indeed, by applying the S-matrix approach we easily find it in the coordinate representation:

\[
A^{(tw)}_e(r) = \sum_f \langle r | f \rangle S^{(tw)}_{f i} \]

(22)

\[
= \sum_{\lambda_f = \pm 1} \int \epsilon_{k_f \lambda_f} e^{i k_f r} S^{(tw)}_{f i} \frac{d^3 k_f}{(2\pi)^3}
\]

where we again perform “summation” over the complete set of plane-wave solutions \(\langle r | f \rangle = \epsilon_{k_f \lambda_f} e^{i k_f r}\) in the first line, and use the lowest order perturbation theory in the second line. Moreover, the vector potential in the momentum representation:

\[
\tilde{A}^{(tw)}_e(k_e) = \int A^{(tw)}_e(r) e^{-i p r} d^3r = \sum_{\lambda_f = \pm 1} \epsilon_{k_f \lambda_f} S^{(tw)}_{f i} \bigg|_{k_f = k_e},
\]

(23)
immediately follows from Eq. (22), and has even simpler form.

As seen from Eqs. (22) and (23), the analysis of the scattering of initially Bessel radiation is traced back to the S–matrix element:

\[ S_{fi}^{(tw)} = \left( k_f \lambda_f \left| \hat{S} \right| k_{\perp,i} m_i k_{z,i} \lambda_i \right), \]  

(24)

which describes “transition” between twisted \(|k_{\perp,i} m_i k_{z,i} \lambda_i\rangle\) and plane–wave \(|k_f \lambda_f\rangle\) photon states. This matrix element can be again expressed in terms of transition amplitude:

\[ S_{fi}^{(tw)} = i N^{(tw)} 8\pi^2 \delta(\omega_i - \omega_f) M_{fi}^{(tw)}(b), \]  

(25)

which, in turn, is directly related to its plane–wave counterpart:

\[ M_{fi}^{(tw)}(b) = \int_0^{2\pi} \frac{d\varphi}{2\pi} m_i e^{-im_i \varphi_i + ik_{\perp,i} \cdot b} M_{fi}^{(pl)}(\varphi_i). \]  

(26)

Here, we introduced the impact parameter \(b = b(\cos \varphi_b, \sin \varphi_b, 0)\) to describe the displacement of the axis of incident Bessel beam from a “target” ion. In Eq. (25), moreover, the normalization factor \(N^{(tw)} = \sqrt{k_{\perp}/4\omega R L_z} 2\omega J\) corresponds to a single photon in the cylindrical volume \(V = \pi R^2 L_z\).

We conclude from the analysis above that the analysis of the final photon state, following the scattering of both, incident plane–wave and twisted radiation, requires the knowledge about the (plane–wave) amplitude \(M_{fi}^{(pl)}\). The explicit form of this amplitude depends, of course, on details of electronic structure of a “target” ion as well as on a particular resonant transition. In the next Section, for example, we will discuss the electric dipole (E1) scattering channel \(nS_0 \rightarrow n^pP_1 \rightarrow nS_0\), for which the amplitude \(M_{fi}^{(pl)}\) has a simple analytic form.

\[ A_e^{(pl)}(r) = i N \frac{8\pi^2 R(\omega_i)}{} \times \int \chi_{\lambda_i}(k_f) e^{ik_f \cdot r} \delta(\omega_i - \omega_e) \frac{d^3 k_f}{(2\pi)^3}. \]  

(29)

Here we used the fact that for the head–on collisions \(e_{k_f \lambda_f} = e_{-\lambda_i}\), as follows from Eq. (24) for \(\theta_i = \pi\) and \(\varphi_i = 0\), and introduced the vector:

\[ \chi_{\lambda_i}(k_f) = \sum_{\lambda_f} e_{k_f \lambda_f} \left( e_{k_f \lambda_f} \cdot e_{k_i \lambda_i} \right) \]  

(31)

with \(\sigma = 0, \pm 1\) and \(\lambda_f = \pm 1\).

By making use of Eq. (29) one can easily derive the vector potential in the momentum representation:

\[ \check{A}_e^{(pl)}(k_e) = 2\pi N i \delta(\omega_i - \omega_e) R(\omega_i) \chi_{\lambda_i}(k_e). \]  

(31)

Apart of its simple analytical form, this expression allows one to analyze the properties of the scattered photon. Indeed, by employing the definition (30) and Eqs. (29) we trivially obtain:

\[ k_e \cdot \check{A}_e^{(pl)}(k_e) = 0, \]  

(32a)

\[ \check{j}_e \check{A}_e^{(pl)}(k_e) = -\lambda \check{A}_e^{(pl)}(k_e), \]  

(32b)

\[ \check{j}_e^2 \check{A}_e^{(pl)}(k_e) = 2 \check{A}_e^{(pl)}(k_e), \]  

(32c)
which implies that the vector potential $\tilde{A}_{k_t}^{(pl)}(k_c)$ represents a spherical wave with the energy $\omega_e = \omega_i$ and a definite value of the total angular momentum, $J_f = 1$. This dipole wave possesses, moreover, a well-defined projection $J_z$ onto the quantization axis:

$$m_e = -\lambda_i, \quad (33)$$

as can be expected from the angular momentum conservation rule.

Finally, by projecting the vector potential $\tilde{A}_{k_t}^{(pl)}$ onto the plane–wave solution and using Eq. (30), one can again restore the well–known angular distribution:

$$W(\theta_f, \varphi_f) = \left| \left\langle \tilde{A}_{k_t}^{(pl)}(\lambda_i) | \tilde{A}_e^{(pl)}(\sigma) \right\rangle \right|^2 \propto \left| \langle \epsilon_{k_t, \lambda_f} \cdot \epsilon_{k_i, \lambda_i} \rangle \right|^2, \quad (34)$$

of the photons, emitted in the $nS_0 \to nP_1 \to nS_0$ resonant transition, see Ref. [9].

### B. Scattering of twisted photons

As the second example, we investigate the vector potential of light, emitted in the $nS_0 \to n'P_1 \to nS_0$ resonant transition for the incident Bessel photons. As mentioned above, a special attention has to be paid for this case to the geometry of the process and, in particular, to the choice of the quantization ($z$–) axis. Below we consider two particular choices of $z$–axis, which can be employed for the theoretical description of the same evolved photon state. First, we will study the resonant scattering for the geometry in which a “target” ion is located on the quantization $z$–axis, while axis of the incident twisted beam is anti–parallel to $z$ and is shifted from it by the impact parameter $b$. In the second scenario, we choose the $z$–axis to pass through the center of Bessel beam in the direction opposite to its propagation, and displace instead the ion by $b$. Of course, both choices coincide for the vanishing impact parameter $b = 0$, and this special case will be discussed in Sec. [IV B 3]. Finally, a scenario of collision of finite–size Bessel photon and ion beams is recalled briefly in the end of this Section.

#### 1. Ion is located on the $z$–axis

We start our analysis from the transition amplitude:

$$\mathcal{M}_{fi}^{(tw)}(b) = R(\omega_i) \int_0^{2\pi} \frac{d\varphi_i}{2\pi} \left\{ i^{m_f} e^{-im_f\varphi_f + ik_{z,i}b} \right\} \times \left( \epsilon_{k_f, \lambda_f}^* \cdot \epsilon_{k_i, \lambda_i} \right), \quad (35)$$

which is obtained from Eq. (20) and the plane–wave counterpart (27). By expanding the scalar product of polarization vectors in terms of small Wigner functions,

$$\left( \epsilon_{k_f, \lambda_f}^* \cdot \epsilon_{k_i, \lambda_i} \right) = \sum_{\sigma=0; \pm 1} e^{i\sigma(\varphi_f - \varphi_i)} d_{\sigma\lambda_i}^{\dag}(\theta_i) d_{\sigma\lambda_f}(\theta_f), \quad (36)$$

and by performing integration over $\varphi_i$ we can further evaluate this amplitude as:

$$\mathcal{M}_{fi}^{(tw)}(b) = R(\omega_i) (-1)^{m_i} e^{-im_i\varphi_b} \sum_{\sigma} \left[ e^{i\sigma(\varphi_f - \varphi_b)} \times \sum_{m_f=0; \pm 1} \sum_{\lambda_f=\pm 1} \sum_{m_f=0; \pm 1} \int_0^\pi C_{\lambda_f, m_f}(b) A_{k_{z,i} k_{z,f} \lambda_f, \lambda_f}(r) \times \sin\theta_f d\theta_f \right]. \quad (37)$$

Here, $\varphi_f$ and $\varphi_b$ are azimuthal angles of the photon momentum $k_f$ and of the impact parameter vector $b$, respectively.

With the help of the matrix element (37) and Eq. (22) we obtain, after simple algebra, the vector potential of the evolved photon state:

$$\mathbf{A}_e^{(tw)}(r; m_i) = (-1)^{m_i} \frac{i}{2\pi} R(\omega_i) e^{-im_i\varphi_b} \sum_{m_f=0; \pm 1} \sum_{\lambda_f=\pm 1} \sum_{m_f=0; \pm 1} \int_0^\pi C_{\lambda_f, m_f}(b) A_{k_{z,i} k_{z,f} \lambda_f, \lambda_f}(r) \times d_{\lambda_f m_{\pm 1} \lambda_f}(\theta_i) d_{\lambda_f m_{\pm 1} \lambda_f}(\theta_f). \quad (38)$$

where the potential $A_{k_{z,i} k_{z,f} \lambda_f, \lambda_f}(r)$ is defined in Eq. (6) and the coefficient $C_{\lambda_f m_f}$ reads as:

$$C_{\lambda_f m_f}(b) = (-1)^{m_f} e^{-im_f\varphi_b} J_{m_f+m_f}(k_{z,i} b) \times d_{m_f \lambda_i}(\theta_i) d_{m_f \lambda_f}(\theta_f). \quad (39)$$

Similar to the plane–wave case, the vector potential can be also derived in the momentum space:

$$\mathbf{A}_e^{(tw)}(k_c; m_i) = 2\pi i (-1)^{m_i} N^{(tw)}(\omega_i - \omega_e) R(\omega_i) \times e^{-im_i\varphi_b} \sum_{m_f=0; \pm 1} \left[ e^{i\lambda_f m_f} \chi_{m_f}(k_c) \right] \times d_{m_f \lambda_i}(\theta_i) J_{m_f+m_f}(k_{z,i} b) e^{-im_f\varphi_b}, \quad (40)$$

with the vector $\chi_{m_f}$ as defined in Eq. (30).

Eqs. (35) and (41) allow one to analyze the properties of the scattered photons without a need for projecting of evolved–state–photon wave function onto any detector state. For example, we conclude that the outgoing radiation can be seen as a coherent superposition of Bessel states with the TAM projections:

$$m_f = 0; \pm 1 \quad (41)$$

for any initial $m_i$. 

2. Ion is displaced from the z-axis

For the analysis of the scattering process under realistic experimental conditions it might be more convenient to choose the coordinate system in a different way than it is done in Subsection 3. For this choice of the quantization axis, one can still apply Eq. (38), in the right-hand side of which we have to expand the basis wave vectors $A_{k_{\perp},f}^{(b)} m_{f} k_{z,f} \lambda_{f}(r)$ in terms of their “on-axis” counterparts:

$$A_{k_{\perp},f}^{(b)} m_{f} k_{z,f} \lambda_{f}(r) = \sum_{m'_{f}} \left[ e^{-i(m'_{f}-m_{f})b} J_{m'_{f}-m_{f}}(k_{\perp,i} b) \right] \times A_{k_{\perp},f}^{(b)} m'_{f} k_{z,f} \lambda_{f}(r).$$

(42)

see Appendix C in Ref. [19] for further details. We note that this expansion can be obtained by multiplying the vector potential in the momentum representation $|k_{\perp},f\rangle$ by a “translation” factor $exp(i\lambda_{f}b)$ and expanding the exponent into series over the Bessel functions. It should be stressed that for the small values of $b < 1/k_{\perp,i}$ the distribution over $m'_{f}$ is concentrated near values $m_{f}$.

3. Zero impact parameter, $b = 0$

Of course, for $b = 0$ both coordinate systems coincide with each other and the final wave function is simplified. Indeed, in this case $J_{m_{f}+m_{i}}(0) = \delta_{m_{f},-m_{i}}$ and $J_{m_{f}'-m_{i}}(0) = \delta_{m_{f}',m_{i}'}$ and the initial- and final-state TAM projections are related to each other as:

$$m_{f} = -m_{i},$$

(43)

as can be expected from the conservation rules. This relation, together with Eq. (14), suggests that only incident Bessel photons with $m_{i} = 0, \pm 1$ can induce $nS_{0} \rightarrow n'P_{1}$ (E1) excitation of an ion, placed at $b = 0$. Again, it fully meets our expectations based on the electric–dipole selection rules.

Despite the fact that for $b = 0$ the scattered photon wave carries a well–defined projection of the total angular momentum onto $z$–axis, see Eq. (43), it can not be described by a single pure Bessel state. This immediately follows from Eq. (38) that simplifies, for the vanishing impact parameter, to:

$$A^{(tw)}(r; m_{i}) = \frac{i}{2\pi} \omega_{i}^{2} \chi^{(tw)} R^{1/2}_{m_{i},\lambda_{i}}(\theta_{i}) \times \sum_{\lambda_{f}} \int_{0}^{\pi} d\theta_{f} \left\{ A_{k_{\perp},f}^{-m_{i} k_{z},f} \lambda_{f}(r) \times d^{1/2}_{-m_{i},\lambda_{i}}(\theta_{f}) \sin \theta_{f} \right\},$$

(44)

and suggests that outgoing photons acquire some momentum distribution. One may note that similar momentum distribution can be expected also for the scattering of Laguerre–Gaussian beams or normalized wave–packets, similar to those, discussed in Ref. [20].

Beside the limit of the vanishing impact parameter $b$ we shall also briefly recall the case $\theta_{b} \rightarrow \pi$ and, hence, $k_{\perp,i} \rightarrow 0$. Most easily, this case can be analyzed in the momentum space, where

$$d^{1/2}_{m_{i} \lambda_{i}}(\theta_{i}) J_{m_{i}+m_{f}}(k_{\perp,b}) \approx \delta_{m_{i},\lambda_{i}} \delta_{m_{f},m_{f}'},$$

(45)

and the vector potential of scattered photons $A^{(b)}_{k_{\perp},m_{f}} k_{z,f} \lambda_{f}(r)$ coincides with the standard plane-wave result up to an inessential factor $i^{\lambda_{i}}$.

4. Collisions of beams of final width

Until now, we have discussed the resonant scattering of twisted light by a well–localized single atom. However, the derived expressions can be extended to analyze collisions of Bessel photon and ion beams, having finite cross sectional areas of $1/k_{\perp,i}$ and $\sigma_{\text{ion}}$, respectively. Of special interest here is, again, the TAM projections of outgoing photons. Owing to the finite (transverse) size of an ion beam, some of its ions will be displaced from the center of the Bessel beam, $b \neq 0$, thus resulting in a breakdown of relation (14) and, hence, in a distribution of TAM values. Of course, the shape and width of this distribution will depend on particular experimental setup. If, for example, the transverse size of an ion beam $\sigma_{\text{ion}}$ is smaller than the transverse coherence length $1/k_{\perp,i}$ of the incident Bessel light, and the centres of colliding beams (almost) coincide, the TAM distribution of scattered photons will be peaked around $m_{f} = -m_{i}$ with the width:

$$\delta m_{f} = \sqrt{\left\langle J_{z}^{2} \right\rangle_{e} - \left( J_{z} \right)_{e}^{2}}$$

$$\sim \sigma_{\text{ion}} k_{\perp,i} = \sigma_{\text{ion}} k_{z,i} \tan \theta_{b}.$$ 

(46)

This estimate follows from the fact that the wave function $\chi^{(b)}$ is proportional to $J_{m_{i}+m_{f}}(k_{\perp,b})$, where for a beam, treated as an incoherent mixture of ions, the maximum value of the impact parameter is of the order of the beam...
width, \( b \sim \sigma_{\text{ion}} \). For the Gamma Factory project, if the width of the ion beam \( \sigma_{\text{ion}} \) is much smaller than the transverse coherence length of the incoming photons then the width \( \delta m_\gamma \) is vanishing. Say, for Pb ions it is \( \sigma_{\text{ion}} \approx 16 \mu \text{m} ^2 \) and a paraxial optical photon beam satisfies this condition.

V. COMPTON SCATTERING

It follows from the analysis above that the resonant light scattering by fast–moving partially stripped ions may lead to the emission of high–energy twisted photon beams in the laboratory (collider) frame. Yet another possibility for the production of such beams was discussed recently in the literature, Refs. [16, 17], and relies on the inverse Compton scattering off free electrons:

\[
\gamma (k_i) + e (p_i) \rightarrow \gamma (k_f) + e (p_f).
\]

If the energy of the incident photon is much smaller than the electron rest mass, the “plane–wave” matrix element of this process:

\[
\mathcal{M}^{(C)}_{f_i} = r_e \left( \mathcal{E}_{k_i, \lambda_i} \cdot \mathcal{E}_{k_f} \right),
\]

has the same structure as the resonant–scattering one \([27]\), and where \( r_e \) is the classical electron radius. By making use of this matrix element one can investigate the properties of the Compton–scattered photons for the case when incident light is prepared in the Bessel states, see Refs. [16, 17] for further details. It was shown, in particular, that almost complete “TAM transfer” between incoming and outgoing photons, \( m_f \approx -m_i \), can be observed for small scattering angles, typical for ultra–relativistic electrons. Moreover, in contrast to the resonant photon scattering, there is no selection rule similar to \([11]\) for the Compton case, which implies that high–energy photons with any TAM projection can potentially be generated in the process \([15]\). A great advantage of the resonant scattering by partially stripped ions, however, is that its cross section is about 6 – 12 orders of magnitude larger than the one of the Compton scattering \([3]\). This can be easily seen from Eqs. \([27]\) and \([15]\), and from the fact that the cross sections of the scattered processes are determined by the squares of their transition amplitudes. Indeed, while the Compton cross section is proportional to the square of the classical electron radius, \( \sigma^{(C)} \propto r_e^2 \approx 7.8 \times 10^{-26} \text{ cm}^2 \), its resonant scattering counterpart is \( \sigma^{(\text{res})} \propto |R(\omega_i)|^2 \), with the radial function \( R(\omega_i) \) given by Eq. \([28]\). For vanishing detuning, \( E_{\nu_i} - \omega_i = 0 \), this function is maximal and gives:

\[
|R(\omega_i = E_{\nu_i})|^2 = \frac{9}{4 \omega_i^6} = \frac{9}{16 \pi^2} \lambda_i^2
\]

\[
\approx \left( 8.6 \times 10^{-20} / 1.6 \times 10^{-14} \right) \text{ cm}^2, \quad (49)
\]

where \( \lambda_i = 2\pi / \omega \) is the wave–length of incident light and the values in the second line are obtained for the typical experimental scenarios of the future Gamma Factory, see Ref. [4] for details. We can conclude, therefore, that the resonant scattering might become a powerful tool for the production of high–intensity (twisted) gamma beams with moderate values of the TAM projection.

VI. SUMMARY

In summary, we carried out a theoretical investigation of the resonant photon scattering by partially stripped ions. The special attention in our work was paid to the question of whether outgoing (scattered) photons are twisted if the incident radiation is twisted itself. In order to analyze this “twistiness transfer” we applied the well–established \( S \)–matrix theory that allows one to find the vector potential of scattered radiation \( \text{without} \) projecting it onto detector states. The expressions for this so–called evolved state of outgoing light are derived for both, incident plane–wave and twisted Bessel radiation. While the obtained expressions are general and can be used to any resonant transition, we illustrated their application for the simplest case of the electric dipole \( nS_0 \rightarrow n'P_1 \rightarrow nS_0 \) channel. It was shown, in particular, that the photons are scattered in the superposition of Bessel states with the TAM projections \( m_f = 0, \pm 1 \), if incident radiation is twisted. Moreover, this \( m_f \)–distribution can be controlled by varying the position of a “target” ion with respect to the incoming light beam, or by reducing the cross sectional area of ion bunches in realistic “beam–to–beam” collision scenarios.

Our theoretical analysis of the resonant scattering was performed within the ion rest frame, where the energies of incident and outgoing photons are the same, \( \omega_i = \omega_f \). However, in the laboratory frame, in which ions move with a high Lorentz factor \( \gamma \gg 1 \) and for the head–on collision scenario, the scattered photons will be emitted predominantly along the ion beam axis with the Doppler–boosted energy \( \omega_f^{(\text{lab})} \approx 4 \gamma^2 \omega_i^{(\text{lab})} \). Along with the results, reported in the present work, it implies that the resonant photon scattering by fast–moving ions can provide an effective tool for the generation of hard x– and even gamma–rays, carrying orbital angular momentum. Such experiments are planned, for example, at the Gamma Factory in CERN.

ACKNOWLEDGEMENTS

The theoretical investigations, reported in Sections 2 and 3, are supported by the Government of
the Russian Federation through the ITMO Fellowship and Professorship Program. The calculations of the resonant scattering in Section 4 are supported by the Russian Science Foundation (Project No. 21-42-04412) and by the Deutsche Forschungsgemeinschaft (Project No. SU 658/5–1).
