The state-of-the-art theoretical description of magnetic materials relies on solving effective Heisenberg spin problems or their generalizations to relativistic or multi-spin-interaction cases that explicitly assume the presence of local magnetic moments in the system. We start with a general interacting fermionic model that is often obtained in \textit{ab initio} electronic structure calculations and show that the corresponding spin problem can be introduced even in the paramagnetic regime, which is characterized by a zero average value of the magnetization. Further, we derive a physical criterion for the formation of the local magnetic moment and confirm that the latter exists already at high temperatures well above the transition to the ordered magnetic state. The use of path-integral techniques allows us to disentangle spin and electronic degrees of freedom and to carefully separate rotational dynamics of the local magnetic moment from Higgs fluctuations of its absolute value. It also allows us to accurately derive the topological Berry phase and relate it to a physical bosonic variable that describes dynamics of the spin degrees of freedom. As the result, we demonstrate that the equation of motion for the derived spin problem takes a conventional Landau-Lifshitz form that explicitly accounts for the Gilbert damping due to itinerant nature of the original electronic model.

I. INTRODUCTION

The problem of magnetism of itinerant electrons seems to be one of the most challenging among all complicated many-body problems relevant for condensed matter. The key point is the duality between itinerant and localized (atomic-like) behavior of \textit{d}-electrons in magnetic transition metals and their alloys. To make the long story (described in the books cited above) short, direct measurements of Fermi surfaces and transport properties of iron-group metals clearly indicate itinerant properties of \textit{3d}-electrons whereas temperature dependence of the magnetic susceptibility (Curie-Weiss law) and neutron scattering data are reliable evidences of localized behavior of magnetic moments, both below and above the Curie temperatures. This itinerant-localized duality can be considered as a bright manifestation of generic particle-wave duality in quantum many-body systems and thus has a general physical interest.

The finite-temperature state with local magnetic moments cannot be described within Landau Fermi-liquid theory since it violates the main Landau postulate on one-to-one correspondence between the states of bare particles and quasiparticles. The combination of itinerant band theory based on a density functional with atomic-like effective impurity approach based on dynamical mean-field theory (DMFT) allows one to describe quantitatively this duality and the properties of the iron-group metals. However, this approach does not solve the problem completely, not least because the non-local correlation effects beyond DMFT seem to play a crucial role in elemental iron.

Describing the magnetic properties of itinerant systems with local magnetic moments from the point of view of a generic quantum many-body theory is quite problematic. For localized spins, the most convenient technique is based on the use of path integrals over spin coherent states. Evaluating the path integrals by the saddle-point method leads to the classical equation of the spin precession, the “kinetic” term with the first derivative in time originating from the topological (Berry) phase. For this construction, conservation of the length of the total spin on each site is crucially important. In itinerant-electron systems, the length of local magnetic moment is fluctuating which changes dramatically the mathematical structure of the theory.

In many contemporary works, the problem of fluctuating length of the local magnetic moment is described in terms of the “Higgs mode” borrowed from high-energy physics. Indeed, whereas magnons associated to the spin rotations are Goldstone modes originating from the broken rotational invariance in spin space, the fluctuating length of the spin is naturally associated to the massive Higgs mode. The magnetic Higgs mode has been observed in quantum dimer systems. Recent inelastic neutron scattering experiments have also revealed Higgs oscillations of the magnetization in \textit{Ca}_2\textit{RuO}_4 and \textit{C}_9\textit{H}_{18}\textit{N}_2\textit{CuBr}_4.

Theoretically, Higgs fluctuations that are seen in experiments are usually explained on a basis of spin or bosonic Hubbard models. However, for fermionic systems which we are interested in here, it was not possible to introduce a proper Higgs field that couples to electrons. Usually, this field was introduced via decoupling of the interaction term. The problem with this trick is that such field has no clear physical meaning whereas the free energy of the system is always plotted as a function of this field and not of the observed quantity, such as magnetization. The second problem is that this field is frequently treated in a mean-field approximation assuming that the magnetization (and the field) has a non-zero average. This approach is problematic (or even useless) in paramagnetic phase. In other words, it is not possi-
ble to prove that this field can be connected to a local magnetic moment, because the local magnetization does not necessarily point in the direction of the field.

Another problem is to derive the equation of motion for rotational dynamics of the itinerant-electron spin. It is not easy at all to generalize the formalism of spin-coherent states and related Berry phase for fermionic systems. Usually, one introduces rotation matrices for a quantization axis of fermions to get a Berry phase [33–36]. However, previously it was not possible to connect this Berry phase to a proper bosonic variable that describes the modulus of magnetization. In addition, in paramagnetic situation one cannot claim that the variation of magnetization angles are small, which is usually necessary for these calculations. The difficulty of introducing physical variables for describing the rotational dynamics of the local magnetization is directly related to the fact that spin degrees of freedom that can be associated with the local magnetic moment cannot be easily separated from electronic degrees of freedom that form this local moment. Therefore, the equation of motion in the presence of electrons was possible to derive (until now) only assuming the existence of a classical spin [37,38].

In this paper, we solve this problem based on a modification and development [39,42] of the dual boson formalism [43–47]. Our aim is twofold: to derive properly the Berry phase and development [39–42] of the dual boson formalism [43–47]. Our aim is to write a physical criterion for the formation of local magnetic moments, and to develop a physical criterion for the formation of local magnetic moments.

Our approach is applicable for both magnetically ordered and paramagnetic phases and does not assume the smallness of the rotation angles, the standard assumption in the theory of exchange interactions in magnetically ordered phases [48,52]. Thus, we provide a fully consistent framework to describe both equilibrium and dynamical magnetic properties of strongly interacting fermionic systems.

II. EFFECTIVE Bosonic ACTION FOR CHARGE AND SPIN DEGREES OF FREEDOM

In the current work we aim at deriving a quantum bosonic action that describes the behavior of the charge and spin degrees of freedom of an initially purely fermionic problem. We start with the lattice action of the extended Hubbard model written in the coordinate and imaginary time representation

$$S_{\text{latt}} = \int_0^\beta d\tau \left\{ - \sum_{ij\sigma\sigma'} c_{ij\sigma}^\dagger \left[ \delta_{ij} \delta_{\sigma\sigma'} (-\partial_\tau + \mu) - c_{ij\sigma'}^\sigma \right] c_{ij\sigma'} + \sum_{i\sigma\sigma'} U n_{i\sigma} n_{i\sigma'} + \frac{1}{2} \sum_{ij\sigma} \rho_{ij\sigma}^\dagger V_{ij\sigma} \rho_{ij\sigma}^\sigma \right\} \tag{1}$$

Fermionic Grassmann variables $c_{ij\sigma}^\sigma$ describe annihilation (creation) of an electron with the spin projection $\sigma = \uparrow, \downarrow$ at the site $i$ and imaginary time $\tau$. $\mu$ is the chemical potential, and $\epsilon_{ij}^\sigma$ is the hopping matrix that has the following form in the spin space: $\epsilon_{ij}^{\sigma\sigma'} = \epsilon_{ij} \delta_{\sigma\sigma'} + i \delta_{ij} \cdot \sigma_{i}^\sigma$. The spin component-diagonal part $\epsilon_{ij}$ of this matrix corresponds to the hopping amplitude of electrons between $i$ and $j$ lattice sites. The non-diagonal in spins part accounts for the spin-orbit coupling (SOC) $\delta_{ij}$ in the Rashba form [53,54], where $\sigma = \{\sigma^x, \sigma^y, \sigma^z\}$ is a vector of Pauli matrices. $U$ is the on-site Coulomb repulsion and $V_{ij\sigma}^\sigma$ describes the non-local ($V_{ij\sigma} = 0$) interaction between charge ($\sigma = c$) and spin ($\sigma = s = \{x, y, z\}$) densities $n_{ij}^\sigma = \sum\sigma\sigma' c_{ij\sigma}^\dagger \sigma^\sigma \rho_{ij\sigma}^\sigma$. For convenience we introduce the variables $\rho_{ij}^\sigma = n_{ij}^\sigma - \langle n^\sigma \rangle$ that describe fluctuations of the densities around their average value. We assume that the average densities can be obtained from a certain local reference system.

In this work the role of the reference system is played by an effective local impurity problem of the dynamical mean-field theory (DMFT) [7],

$$S_{\text{imp}} = - \int_0^\beta d\tau d\tau' \sum_{\sigma\sigma'} c_{\tau\sigma}^\dagger \left[ \delta_{\tau\sigma} \delta_{\sigma\sigma'} (-\partial_\tau + \mu) - \Delta_{\tau\sigma'} \right] c_{\tau\sigma'} + \int_0^\beta d\tau U n_{\tau\uparrow} n_{\tau\downarrow} \tag{2}$$

The advantage of considering this reference system is that it can be solved numerically exactly, e.g. by means of the continuous-time quantum Monte Carlo method [55,58]. Therefore, introducing such reference system makes investigation of local correlation effects more accessible. In particular, this will help us to address the problem of the local moment formation in the system. In order to isolate the impurity problem from the initial action (1), we add the fermionic hybridization function $\Delta_{\tau\sigma'} = \delta_{\tau\sigma'} (\tau - \tau')$ to the local part of the lattice problem. To be consistent, the same hybridization is subtracted from the remaining (non-local) part of the lattice problem $S_{\text{rem}} = S_{\text{latt}} - \sum_i S_{\text{imp}}$. This way of introducing the reference system gives some freedom in choosing the form of the hybridization function [59]. For instance, $\Delta_{\tau\sigma'}$ does not necessarily have to be obtained from the DMFT self-consistency condition, which equates the local part of the lattice Green’s function $G_{\tau\sigma'}$ to the exact local impurity Green’s function $g_{\tau\sigma'}$. In this work we stick to the paramagnetic case, which is the most challenging regime for describing the behavior of the local magnetic moment. Indeed, in the order stated the value of the magnetic moment is given by the average magnetization, which in many cases can be obtained from DFT in reasonable agreement with the experiment [60,61]. On the contrary, in the paramagnetic regime the average magnetization is equal to zero even if the magnetic moment has already been formed. In the latter case the zero average magnetization is a consequence of an uncorrelated precession of the magnetic moment, and distinguishing this situation from the case when the system does not possess any magnetic moment at all is a non-trivial task. As has been mentioned above, in the current work the average magnetization is given by the local reference system (2). For this reason, we consider a spin-independent hybridization function $\Delta_{\tau\sigma'} = \delta_{\tau\sigma'} \Delta_{\tau\sigma'}$, which ensures that the average local spin density is zero $\langle n^\sigma \rangle_{\text{imp}} = 0$, and therefore $\rho_{ij}^\sigma = n_{ij}^\sigma$. As a consequence, the Green’s function $g_{\tau\sigma'} = \delta_{\tau\sigma'} G_{\tau\sigma'}$ of such reference system is also diagonal in the spin space. At the same...
time, the lattice Green’s function can have non-diagonal spin components due to the presence of the SOC. For this reason, we determine the hybridization function from the following self-consistency condition for the diagonal part of the lattice Green’s function $\frac{1}{2} \sum_i G^{\sigma\sigma}_{i\tau\tau} = g^{\sigma\sigma}_{i\tau\tau}$.

We point out that $\rho^{\sigma\sigma}$ are not suitable variables for addressing the problem of charge and spin dynamics. Indeed, they are not true bosonic fields, because they are composed of two fermionic Grassmann variables. Proper bosonic variables that describe fluctuations of charge and spin densities can be introduced performing a set of Hubbard-Stratonovich transformations as has been shown in Refs. [39 and 40]. Following the idea of these works we first rewrite the non-local part of the lattice action in terms of new fermionic $f^{(s)}$ and truly bosonic $\phi^s$ fields instead of original fermionic $c^{(s)}$ and composite $\rho^s$ variables. This transformation is explicitly shown in Appendix A for a general multi-oriental case and results in the following lattice action

$$S = -\int_0^\beta [d\tau_i] \sum_{i,j,\sigma\sigma'} f_{i\tau\sigma} g_{i\tau\sigma}^{-1} \left[f_{i\tau\sigma}^{\sigma'} g_{i\tau\sigma}^{-1} f_{i\tau\sigma'} + \sum_i S_{imp} \right]$$

$$- \frac{1}{2} \int_0^\beta d\tau_i \sum_{i,j,s} \phi^s_{i\tau\sigma} \phi^s_{i\tau\sigma} - \sum_i S_{imp}$$

$$+ \int_0^\beta d\tau_i \sum_{i,j,s} \left( c^s_{i\tau\sigma} g_{i\tau\sigma}^{-1} f_{i\tau\sigma'} + f^s_{i\tau\sigma} g_{i\tau\sigma}^{-1} c_{i\tau\sigma'} \right)$$

(3)

where $\bar{\epsilon}_{ij\tau\tau'} = \delta_{ij} \epsilon_{ij\sigma\sigma'} - \delta_{ij} \delta_{\sigma\sigma'} \Delta_{ij\tau}$. In Eq. (3) we have introduced a source field $f^s$ for a composite $\rho^s$ variable. This source field will help us identify the correct variables for original charge and spin degrees of freedom after multiple transformations of the initial action.

Static properties of effective bosonic models for spin or charge degrees of freedom, namely the exchange interaction between spin or charge densities, have been studied in previous works [39, 40]. Description of the spin dynamics, which has not been performed in these works, is a non-trivial task that requires a careful separation of the precession of the vector spin field from the fluctuation of the absolute value of the local magnetic moment. To this effect, we deviate from the main route of these works and make a transformation to a rotating frame for original fermionic variables $c^s_{i\tau\sigma} \rightarrow c^s_{i\tau\sigma} R^s_{i\tau\sigma}$ and $c_{i\tau\sigma} \rightarrow R^s_{i\tau\sigma} c_{i\tau\sigma}$ introducing a unitary rotation matrix in the spin space [33, 36]

$$R^s_{i\tau\sigma} = \begin{pmatrix}
\cos(\theta_{i\tau\sigma}/2) & -e^{i\varphi_{i\tau\sigma}} \sin(\theta_{i\tau\sigma}/2) \\
e^{i\varphi_{i\tau\sigma}} \sin(\theta_{i\tau\sigma}/2) & \cos(\theta_{i\tau\sigma}/2)
\end{pmatrix}$$

(4)

where $c^s_{i\tau\sigma} = (c_{i\tau\sigma}, c^\dagger_{i\tau\sigma})^T$. Later on, polar angles $\theta_{i\tau\sigma}$ and $\varphi_{i\tau\sigma}$ will be associated with the direction of the local magnetic moment. Therefore, at each lattice site $i$ and imaginary time $\tau$ the rotation matrices are intended to adjust the coordinate system such that the local magnetic moment in new coordinates always points in $z$ direction. In this way the accounting for the rotation dynamics of the local magnetic moment is transferred from the corresponding bosonic field to a new time- and position-dependent coordinate system. Under this rotation the impurity problem transforms as

$$S_{imp} \rightarrow S_{imp} + \int_0^\beta d\tau_i \sum_{i,j} R^s_{i\tau\sigma} \phi^s_{i\tau\sigma}$$

(5)

where $R^s_{i\tau\sigma} = \partial_\tau R^s_{i\tau\sigma}$ and $\mathcal{A}^s_{i\tau}$ is an effective gauge field introduced as $R^s_{i\tau} \mathcal{A}^s_{i\tau} = \sum_i \mathcal{A}^s_{i\tau} \sigma^s$. The explicit form of the rotation matrix (4) implies that $\mathcal{A}^s_{i\tau} = 0$. Composite variables for charge and spin degrees of freedom become

$$\rho^s_{i\tau} \rightarrow \sum_{i} \mathcal{U}^s_{i\tau} \rho^s_{i\tau}$$

(6)

where $\mathcal{U}^s_{i\tau}$ satisfies

$$R^s_{i\tau} \sigma^s R^s_{i\tau} = \sum_{i} \mathcal{U}^s_{i\tau} \sigma^s$$

(7)

It can be shown that $\mathcal{U}^s_{i\tau}$ is a unitary matrix, i.e. $[\mathcal{U}^s_{i\tau}]^\dagger = [\mathcal{U}^s_{i\tau}]^T$, and that $\mathcal{U}^s_{i\tau} = 0$ and $\mathcal{U}^s_{i\tau} = 1$. The last equality originates from the fact that the charge density $n^s_{i\tau}$ is invariant under rotation in the spin space. Upon collecting all terms, the lattice action (3) transforms to

$$S = -\int_0^\beta [d\tau_i] \sum_{i,j,\sigma\sigma'} f_{i\tau\sigma} g_{i\tau\sigma}^{-1} \left[f_{i\tau\sigma}^{\sigma'} g_{i\tau\sigma}^{-1} f_{i\tau\sigma'} + \sum_i S_{imp} \right]$$

$$- \frac{1}{2} \int_0^\beta d\tau_i \sum_{i,j,s} \phi^s_{i\tau\sigma} \phi^s_{i\tau\sigma} - \sum_i S_{imp}$$

$$+ \int_0^\beta d\tau_i \sum_{i,j,s} \left( c^s_{i\tau\sigma} g_{i\tau\sigma}^{-1} f_{i\tau\sigma'} + f^s_{i\tau\sigma} g_{i\tau\sigma}^{-1} c_{i\tau\sigma'} \right)$$

$$+ \int_0^\beta d\tau_i \sum_{i,j,s} \left( \phi^s_{i\tau\sigma} + j^s_{i\tau\sigma} + \sum_{i} \mathcal{A}^s_{i\tau} \left( [\mathcal{U}^s_{i\tau}]^\dagger \right) \mathcal{U}^s_{i\tau} \rho^s_{i\tau} \right)$$

(8)

We find that the bosonic field $\phi^s_{i\tau}$ enters the lattice action (8) as an effective magnetic field. However, it is important to emphasise that the local magnetic moment at a given lattice site does not necessarily point in the same direction as the polarizing field applied to the same site. Therefore we prefer to keep this freedom and do not relate the polar angles $\theta_{i\tau\sigma}$ and $\varphi_{i\tau\sigma}$ with the direction of the field $\phi^s_{i\tau}$ as commonly used at similar transformations of the effective action (see e.g. [28, 32]). Instead, below we demonstrate an alternative way of introducing the bosonic field that describes Higgs fluctuations of the local magnetic moment rather than of its conjugated field.

After the rotational dynamics of the magnetic moment is explicitly isolated, original fermionic variables can be integrated out. This allows to account for local correlation effects exactly via the reference system (2), which is formulated solely in terms of original variables. It is important that upon all transformations of the lattice problem the source field $f^s$ and the effective gauge field $\mathcal{A}^s$ be taken into account exactly.
without any approximation. For this purpose we make the following shift of variables
\[ \phi^s_{\tau} \rightarrow \hat{\phi}^s_{\tau} = \phi^s_{\tau} - \sum_{s'} \mathcal{A}^s_{\tau}[U^s_{\tau}]^{-1} j^s_{\tau} \] (9)
that excludes \( j^s \) and \( \mathcal{A}^s \) fields from the integration of original fermionic degrees of freedom. When the latter are integrated out, we transform unphysical bosonic fields \( \hat{\phi}^s \) to physical variables \( \rho^s \) that describe fluctuations of charge and spin densities. For a general multi-orbital case all these steps are performed in details in Appendix [A] which results in the effective fermion-boson action

\[ S = -\int_0^\beta [dr^i \sum_{i,j,s'} f^s_{i,r^i} g^s_{r^i} f^s_{j,r^i} R^s_{i,r^i}] \int_0^\beta [dr^i \sum_{i,j,s'} f^s_{i,r^i} g^s_{r^i} f^s_{j,r^i} R^s_{i,r^i}]^{-1} g^s_{r^i} f^s_{j,r^i} - \frac{1}{2} \int_0^\beta \sum_{s,s'} \mathcal{A}^s_{\tau}[U^s_{\tau}]^{-1} \tilde{\rho}^s_{\tau} \int_0^\beta \sum_{s,s'} \mathcal{A}^s_{\tau}[U^s_{\tau}]^{-1} \tilde{\rho}^s_{\tau} \] (10)

Quantities \( g_{\tau^s, \chi^s_{\tau^s}} \), and \( \Lambda^s_{\tau^s, \bar{\tau}^s} \) are respectively the exact Green’s function, the susceptibility, and the three-point vertex function of the reference system [2]. They are explicitly defined in Appendix [A]. In analogy to \( s-d \) exchange model [2], \( \Lambda^s_{\tau^s, \bar{\tau}^s} \) can be seen as a renormalized local coupling between charge/spin densities \( \rho^s \) and fermions \( f^s \).

We find that the source field \( j^s \) enters the new lattice problem [10] only multiplied by the new bosonic field \( \tilde{\rho}^s_{\tau} \). This means that all correlation functions written in terms of original composite variables \( \rho^s_{\tau} \) identically coincide with the ones where the \( \tilde{\rho}^s_{\tau} \) variables are replaced by the corresponding bosonic fields \( \tilde{\rho}^s_{\tau} \). Therefore, the introduced fields \( \tilde{\rho}^s_{\tau} \) have the same physical meaning as the composite variables \( \rho^s_{\tau} \) that describe fluctuations of charge and spin densities. To emphasize this point hereafter we omit the bar over the \( \tilde{\rho}^s_{\tau} \) field. This fact allows us to associate polar angles \( \theta_{\tau} \) and \( \phi_{\tau} \) that define the direction of the local magnetic moment with the direction of the newly introduced vector field \( \rho^s_{\tau} \). It is convenient to rewrite the latter as \( \rho^s_{\tau} = M_{\tau} \epsilon^s_{\tau} \), where \( M_{\tau} \) is a scalar field that describes Higgs fluctuations of the absolute value of the local magnetic moment, and \( \epsilon_{\tau} \) is the unit vector field that points in the direction of the local moment on the lattice site \( i \) at the time \( \tau \).

Our constraint for the polar angles results in the following relation for the unit vector field \( R^s_{\tau} \), \( \tilde{\sigma} \) \( \epsilon_{\tau}^s \), \( R^s_{\tau} \): \( \sigma^s \). Using the relation [7], one also finds that \( \sum_{s'}[U^s_{\tau}]^{-1} \epsilon_{\tau}^s = \delta_{sz,s} \) which immediately yields the Berry phase term

\[ \sum_{s,s'} \mathcal{A}^s_{\tau}[U^s_{\tau}]^{-1} \rho^s_{\tau} = \sum_{s,s'} \mathcal{A}^s_{\tau}[U^s_{\tau}]^{-1} e^s_{\tau} M_{\tau} = \mathcal{A}^s_{\tau} M_{\tau} \] (11)

where \( \mathcal{A}^s_{\tau} = \frac{1}{2} \psi_{\tau}(1 - \cos \theta_{\tau}) \). Also, one straightforwardly gets that

\[ \sum_{s,s'} \rho^s_{\tau} [U^s_{\tau}]^{-1} \chi_{\tau^s}^{-1} [U^s_{\tau}]^{-1} \rho^s_{\tau} = M_{\tau} \chi_{\tau^s}^{-1} M_{\tau} \] (12)

Remaining rotation matrices can be excluded from the action [10] by assuming the adiabatic approximation that characteristic times for electronic degrees of freedom are much faster than for spin ones. In this framework \( g_{\tau^s} \) changes much faster than the rotation matrices \( R_{\tau^s} \). This approximation results in

\[ \int_0^\beta d\tau^s \sum_{i,j} f^s_{i,r^i} R^s_{i,r^i} g^s_{r^i} \approx \int_0^\beta d\tau^s \delta_{\tau^s} G_{\tau^s} \] (13)

because the local reference system [2] is non-polarized, and its exact Greens function \( g_{\tau^s} \) is diagonal in the spin space. A similar trick can be performed for the three-point vertex function, which leads to (see Appendix [A])

\[ \sum_{s,s'} \int_0^\beta d\tau^s \sum_{i,j} f^s_{i,r^i} R^s_{i,r^i} g^s_{r^i} \approx \sum_{s,s'} \int_0^\beta d\tau^s f^s_{i,r^i} \sum_{i,j} \Lambda^s_{\tau^s, \bar{\tau}^s} [U^s_{\tau}]^{-1} \rho^s_{\tau^s} \] (14)

The action [10] becomes

\[ S = -\int_0^\beta d\tau^s \sum_{i,j,s'} f^s_{i,r^i} \tilde{G}^{s,s'}_{i,j} \sum_{i,j,s'} f^s_{i,r^i} \tilde{G}^{s,s'}_{i,j} \] \( + \sum_{i,j,s'} f^s_{i,r^i} \sum_{i,j,s'} f^s_{i,r^i} \Lambda^s_{\tau^s, \bar{\tau}^s} \rho^s_{\tau^s} \]

\[ + \frac{1}{2} \int_0^\beta d\tau^s \sum_{i,j,s'} \rho^s_{\tau^s} V^s_{i,j} \rho^s_{\tau^s} + \int_0^\beta d\tau^s \sum_{i,j} \mathcal{A}_{\tau^s} M_{\tau} \]

\[ - \frac{1}{2} \int_0^\beta d\tau^s \sum_{i,j} \left( \chi_{\tau^s}^{-1} \rho^s_{\tau^s} M_{\tau} \chi_{\tau^s}^{-1} M_{\tau} \right) \] (15)

Source fields \( j^s \) have been introduced only to identify correct bosonic variables and were excluded from the action [15]. The bare Green’s function of the action [15] is given by the difference between the DMFT and the impurity Green’s functions [62] [63]

\[ \tilde{G}^{s,s'}_{i,j} = G^{s,s'}_{i,j} - \delta_{ij} \delta_{s,s'} g_{\tau^s} \] (16)

In the absence of SOC the local part of the bare dual Green’s function is identically zero due to DMFT self-consistency condition. Therefore, the performed set of transformations allows one to separate spatial electronic fluctuations described
by fields \( f^{(s)} \) from local correlation effects that are accounted for by the reference system (2).

To obtain an effective bosonic action we integrate out fermionic fields and get

\[
S = -\text{Tr} \ln \left[ \bar{G}_{ij,j'\tau'}^{\rho,\rho'} \right] - \delta_{ij} \int_0^\beta d\tau' \sum_\varsigma \sigma_\varsigma \Lambda_\varsigma^{\rho,\rho'} \rho^{\rho'}_{\tau \tau'}
+ \frac{1}{2} \int_0^\beta d\tau \int_{ij} \rho^{\rho'}_{ij} V^{\rho,\rho'}_{ij} \rho^{\rho'}_{\tau \tau'}
+ \int_0^\beta d\tau \sum_i \mathcal{A}^{\rho}_i M_{\tau \tau'}
- \frac{1}{2} \int_0^\beta d\tau d\tau' \sum_i \left\{ \rho^{\rho'}_{\tau \tau'} \chi^{-1}_{\tau} \rho^{\rho'}_{\tau \tau'} + M_{\tau \tau'} \chi^{-1}_{\tau} M_{\tau \tau'} \right\}
\]

(17)

The first line in this expression describes all possible (non-local) exchange interactions between charge and spin densities. These interactions can be obtained by expanding this part in terms of the \( \rho^{\rho'} \) variables. The first order contribution in this expansion is local and thus vanishes in the absence of the SOC due to non-locality of the bare Green’s function \( \tilde{G} \) (16).

In addition, since the SOC enters the problem (1) as a non-local hopping \( \hat{\delta}_{ij} \cdot \hat{\sigma}_{\tau \tau'} \), the local part of \( \tilde{G}_{ij,j'\tau'} \) in the case of a small SOC is also negligibly small. Quadratic exchange can be obtained as the second order of the expansion, which gives

\[
S \approx \frac{1}{2} \int_0^\beta d\tau d\tau' \sum_{ij} \rho^{\rho'}_{ij} T^{\rho,\rho'}_{ij} \rho^{\rho'}_{\tau \tau'} + \int_0^\beta d\tau \sum_i \mathcal{A}^{\rho}_i M_{\tau \tau'}
- \frac{1}{2} \int_0^\beta d\tau d\tau' \sum_i \left\{ \rho^{\rho'}_{\tau \tau'} \chi^{-1}_{\tau} \rho^{\rho'}_{\tau \tau'} + M_{\tau \tau'} \chi^{-1}_{\tau} M_{\tau \tau'} \right\}
\]

(18)

The total non-local exchange interaction

\[
T^{\rho,\rho'}_{ij,j'\tau'} = \delta_{\tau \tau'} \delta_{\varsigma \varsigma} V^{\rho,\rho'}_{ij} + J^{\rho,\rho'}_{ij,j'\tau'}
\]

(19)

contains the bare (direct) interaction \( V^{\rho,\rho'}_{ij} \) of the initial action (1) and the RKKY-like (kinetic) interaction mediated by electrons

\[
J^{\rho,\rho'}_{ij,j'\tau'} = \sum_{\{\varsigma\}} \Lambda_\varsigma^{\rho,\rho'} \tilde{G}_{ij,j'\tau' \tau}^{\varsigma,\varsigma} \tilde{G}_{ij,j'\tau' \tau}^{\varsigma,\varsigma}
\]

(20)

Here, \( \tilde{G} \) is the full Green’s function of the problem (15), and the “transposed” three-point vertex \( \Lambda_\varsigma^{\rho,\rho'} \) is introduced to simplify notations. The diagonal part of the kinetic interaction is given by the Heisenberg exchange interaction \( J^{\rho,\rho'}_{ij} \) for spin (39) and the Ising interaction \( J^{\rho,\rho'}_{ij} \) for charge (40). The non-diagonal \( J^{\rho,\rho'}_{ij} (s \neq s') \) component gives rise to the antisymmetric anisotropic (Dzyaloshinskii-Moriya) and the symmetric anisotropic interactions (see, e.g., Ref. 54). More involved interaction terms, as for example the chiral three-spin (64-69) and the four-spin (70-72) exchange interactions can be obtained by a straightforward expansion the first term in Eq. (17) to higher orders in \( \rho \).

III. EQUATION OF MOTION

In this section we derive equation of motion for the precession of the local magnetic moment and thus exclude charge degrees of freedom from consideration. The last term in Eq. (15) describes the Higgs dynamics of the absolute value of the local magnetic moment \( M_{\tau \tau'} \). These fluctuations are fast and the corresponding contribution is strongly non-local in time. This fact is confirmed by a rapidly decaying behavior of the Fourier transform of the local spin susceptibility \( \chi^{\rho}_{\omega} \) to the Matsubara frequency space \( \omega \) shown in Fig. 1. On the contrary, the precession of the local magnetic moment is slow in time and can be described by the Landau-Lifshitz-Gilbert equation of motion (73, 74). To derive this equation we assume that the local magnetic moment has already been formed in the system. The criterion for the formation of the magnetic moment is discussed in details in the Section IV. At this point we average over fast Higgs fluctuations and replace the scalar field \( M_{\tau \tau'} \) by its constant non-zero average value \( \langle M_{\tau \tau'} \rangle = 2S \). In this case the Higgs term can be neglected in the action, because now it only gives a constant contribution to the energy. The bosonic action (15) reduces to an effective spin problem

\[
S_{\text{spin}} = \int_0^\beta d\tau \sum_j \left( i\dot{\phi}_{jr} (1 - \cos \theta_{jr}) S - \tilde{S}_{\tau} \cdot \tilde{h}_{jr} \right)
\]

(21)

where \( \tilde{S}_{\tau} = S \tilde{e}_{\tau} \), and components of an effective magnetic field \( \tilde{h}_{jr} \) are following

\[
\tilde{h}_{jr}^s = -4 \int_0^\beta d\tau' \sum_{i,j} I_{ji,jr}^{s,s'} \tilde{S}_{\tau}^s
\]

(22)

In the general case the equation of motion for the spins is a set of integro-differential equations. To simplify the problem, we make use of the fact that the interaction between spins is determined by the super-exchange processes due to electrons (20) and thus decays fast on the time scales of inverse band width, while the time-dependence of the angle variables \( \phi_{jr} \) and \( \theta_{jr} \) is slow. For this reason, we can expand the time-dependence of the spin variable \( \tilde{S}_{\tau}^s \) in Eq. (22) up to the first
order in powers of $\tau - \tau'$. In the zeroth order the $\tau'$ time argument of $S^\perp_{\tau'}$ is simply replaced by $\tau$. Then, the $\tau'$ integration of $I^s_{ji}(\tau - \tau')$ leads to the zero Matsubara frequency Fourier component of the spin-spin interaction $I^s_{ij}(\omega = 0)$, and the zeroth-order contribution to the effective magnetic field (22) becomes

$$\tilde{H}^{\text{eff}}_{ij} = -4 \sum_{\nu} I^s_{\nu,ij}(\omega = 0) S^\nu_{ji}$$

We note that the local three-point vertex function that enters the expression for the kinetic interaction $J^s_{j\omega = 0}$ (20) can be obtained from the self-energy of the impurity problem as

$$\Lambda^s_{\nu \omega = 0} = \frac{\partial \omega_{\text{imp}}}{\partial M} + \chi^s_{\omega = 0}$$

where $\nu$ is the fermionic Matsubara frequency. If the inverse of the local susceptibility is neglected, the equal-time kinetic interaction reduces to well-known expression

$$J^s_{j\omega = 0} = \sum_{\nu [\sigma]} (\partial M^s_{\nu j}) \tilde{G}_{ij,\nu}^{\sigma,\sigma,\sigma} (\partial M^s_{\nu j}) \tilde{G}_{ji,\nu}^{\sigma,\sigma,\sigma}$$

that has been derived in Refs. [48-51] for the exchange interaction in a magnetically ordered state based on magnetic force theorem. For a paramagnetic case this form for the exchange interaction has been obtained in Ref. [75] using Hubbard-I approximation. Within this approximation the local reference system (2) is considered in the atomic limit that corresponds to a zero fermionic hybridization function $\Delta = 0$. In the presence of the SOC the simplified form (25) of the effective exchange (20) gives a result for the Dzyaloshinskii-Moriya and the symmetric anisotropic interactions similar to the ones derived in Refs. [51] and [76] using the magnetic force theorem.

The first order expansion of $S^\perp_{\tau'}$ in $\tau - \tau'$ in Eq. (22) would lead to a term proportional to the time derivative of the spin in the effective field (22), which would be the Gilbert damping. But this term vanishes in the imaginary time due to the exchange $I^s_{\nu j}(\tau - \tau')$ being an even function of time. On the other hand, if at this point we perform analytical continuation to real times $t$, the exchange transforms to a retarded function $R^s_{\nu j}(t - t')$, and the contribution with the first order time derivative of the spin in Eq. (22) does not vanish. Up to this order we can write

$$\tilde{h}_{\nu j}(t) = \tilde{h}_{\nu j}(t) - 4 \sum_{\nu \nu'} \left[ \partial M^s_{\nu j} \right]_{\nu \nu'} \tilde{S}^\nu_{ji}(t)$$

where the second term describes the Gilbert damping for which we keep only the leading diagonal ($s = s'$) component of the exchange interaction. $R^s_{\mu j}(t - t')$ is a Fourier transform of the retarded exchange interaction $I^s_{\nu j}(t - t')$ to real frequency $\Omega$. We note that a similar expression for the Gilbert damping has been derived in Refs. [37] and [38] for the case of a classical spin coupled to the system of conduction electrons.

The derived effective magnetic field (26) allows to obtain the equation of motion for the spin precession in the conventional Landau-Lifshitz-Gilbert form directly varying the action (21)

$$\dot{S}_{ij}(t) = -\tilde{h}_{ij}(t) \times \tilde{S}_{ij}(t)$$

A more general expression for the equation of motion that accounts for all components of the exchange interaction can be found in Appendix C.

At this point we should emphasize again that our aim was a mapping of the initial interacting fermionic problem onto the effective dynamics of spin degrees of freedom which is supposed to be much slower than the electron hopping and other fast electron processes, in particular, related to the Hubbard $U$ energy scale. Within this approach, we should take into account only low-frequency part of the exchange term (20). Actually, it has a complicated frequency dependence, in fact it diverges for high frequencies, but taking into account such non-adiabatic effects is not allowed in our theory. In the high frequency region the separation of spin and electron dynamics is, generally speaking, impossible.

## IV. LOCAL MAGNETIC MOMENT FORMATION

The introduced equation of motion (27) is valid only when the local magnetic moment exists. Otherwise there is no way to discuss a specific spin dynamics separated from general dynamics of electron-hole excitations. In this section we derive the corresponding condition for the formation of the local magnetic moment in the system.

According to Landau phenomenology [77], a transition from a paramagnetic to a magnetically ordered state occurs due to a spontaneous symmetry breaking. The latter results in the change of the free energy $F[m]$ from a paraboloid-like form with a minimum at $m = 0$ to a Mexican-hat potential characterized by a continuous set of minima at $m \neq 0$. This change in the free energy can be seen in the sign change of the second variation of the free energy $\frac{\partial^2 F[m]}{\partial m^2}$ with respect to the corresponding order parameter $m$ (see e.g. Ref. [78]). As an example, let us consider a half-filled Hubbard model on a three-dimensional (3D) cubic lattice, where the spontaneous symmetry breaking is associated with the formation of the antiferromagnetic (AFM) ordering with the wave vector $\vec{Q} = \{\pi, \pi, \pi\}$. The free energy of our problem is given by the action derived above (17) that is written in terms of the physical bosonic variables $\rho^s$ describing fluctuations of charge and spin densities. Thus, the second variation of the free energy with respect to the AFM order parameter $\rho^s_{\vec{Q},\omega = 0}$ results in the inverse of the AFM susceptibility $X^s_{\vec{Q},\omega = 0}$ that becomes zero at the transition point

$$-\frac{\partial^2 S[\rho^s]}{\partial \rho^s_{\vec{Q},\omega = 0} \partial \rho^s_{-\vec{Q},\omega = 0}} = X^{-1}_{\vec{Q},\omega = 0} = \chi^{-1}_{\omega = 0} - I^s_{\vec{Q},\omega = 0} = 0$$

Above the AFM phase boundary fluctuations of magnetic moments are uncorrelated at large distances, which means that the moments on different lattice sites fluctuate independently on each other, assuming that the distance between sites is larger than the magnetic correlation length. It can be expected that the formation of the local magnetic moment can be captured in the same way as the formation of the AFM ordering but looking at the corresponding local free energy. Importantly, this local free energy is different from the one...
of the local reference system (2). Indeed, the impurity problem $S_{\text{imp}}$ describes local correlation effects of both, itinerant electrons and local magnetic moments. In order to isolate the energy related to the magnetic moment only, one has to find a way to subtract the contribution of itinerant electrons from the local free energy of the reference system (2). As we argue in Appendix [B] this procedure can be done by excluding non-local terms from Eq. (10) and integrating out fermionic factors. At the same time, as was already stressed, local magnetic moment exists at relatively long times in comparison with the inverse of the hopping amplitude, or $1/U$.

As the result we get the local problem written in terms of only physical bosonic variables $\rho$

$$S_{\text{loc}} = - Tr \ln \left[ g_{\sigma\tau}^{-1} \delta_{\sigma\tau} + \int_0^\beta d\tau \sum_{\omega_n} \sigma_{\sigma\tau}^{\omega_n} \Lambda_{\sigma\tau}^{\omega_n} \rho_{\sigma\tau}^{\omega_n} \right]$$

$$- \frac{1}{2} \int_0^\beta d\tau d\tau' \left( \rho_{\sigma\tau}^{\omega_n} \rho_{\sigma\tau}^{-\omega_n} + M_{\tau} \chi_{\sigma\tau}^{\omega_n} \right) + \int_0^\beta d\tau A_{\tau} M_{\tau}$$

(29)

In analogy to the formation to the AFM state the formation of the local magnetic moment in the system can be seen in the sign change of the second variation of the local action (29) with respect to the local magnetic moment

$$- \frac{\partial^2 S_{\text{loc}}[M]}{\partial M_{\tau} \partial M_{\tau'}} = \chi_{\tau\tau}^{\omega_n} - f_{\text{loc}}^{\omega_n}$$

(30)

Importantly, and contrary to the case of the true phase transitions for the infinite system, we keep times $\tau$ and $\tau'$ different since in the static limit local magnetic moment does not exist, it is screened by Kondo effect, or by intersite exchange-induces spin flips (in paramagnetic phase), or by both these factors. At the same time, as was already stressed, local magnetic moment exists at relatively long times in comparison with basic electron processes. In this sense, its existence means symmetry breaking at intermediate time scales.

The expression (30) corresponds to a “slow” exchange coupling of the local moment to itself at a different time point that can be obtained by subtracting the contribution of itinerant electrons given by a local analog of the exchange interaction (20)

$$f_{\text{loc}}^{\omega_n} = \int_0^\beta \langle dt_i \rangle \sum_{\sigma} \Lambda_{\tau\tau t_2}^{\omega_n} g_{\tau\tau t_1}^{\sigma} g_{\tau\tau t_2}^{\sigma} \rho_{\sigma\tau}^{\omega_n}$$

(31)

from the total exchange interaction $\chi_{\tau\tau}^{\omega_n}$ of the local reference system (2). The moment when this self-exchange becomes diamagnetic clearly marks the instability of the truly paramagnetic phase without a developed local moment. Remarkably, by direct numerical calculations we find that the self-interaction of the local moment (30) evaluated at equal times $\tau = \tau'$ never changes sign, at least for the considered model. This fact suggests that the formation of the local magnetic moment is not a real physical transition and should rather be seen as a crossover. In other words, although the electronic response is fast in time, electrons cannot react immediately to the polarization created by themselves. In confirmation of that we find that at the critical temperature the second variation of the local free energy (30) changes sign at any times except $\tau = \tau'$. In this sense the formation of the local moment drastically differs from the formation of the AFM ordering on a lattice that fulfills an equal-time criterion (28). To illustrate this point, let us separate the static contribution in Eq. (30) that is contained in the inverse of the local susceptibility $\chi_{\tau\tau}^{\omega_n} = (\Pi_{\tau\tau}^{\text{imp}})^{-1} - \delta_{\tau\tau} U^z$. In this expression $\Pi_{\tau\tau}^{\text{imp}}$ is the polarization operator of the impurity problem (2) and $U^z = -U/2$ is the bare interaction in the spin channel. Then, the Eq. (30) becomes

$$- \frac{\partial^2 S_{\text{loc}}[M]}{\partial M_{\tau} \partial M_{\tau'}} = C_{\tau\tau'} - \delta_{\tau\tau'} U^z$$

(32)

where $C_{\tau\tau'} = (\Pi_{\tau\tau}^{\text{imp}})^{-1} - f_{\text{loc}}^{\omega_n}$ is an effective dynamical self-exchange coupling of the local magnetic moment. The Fourier transform of $C_{\tau\tau'}(\tau - \tau')$ to Matsubara frequency $\omega$ space is shown in Fig. 2. This quantity has a delta-functional behavior for all considered temperatures, which means that the second variation of the local action (32) is nearly constant in time except a delta-function peak at $\tau = \tau'$ due to $\delta_{\tau\tau'} U^z$ term. Therefore, the criterion for the local moment formation can be obtained by excluding this static contribution $\delta_{\tau\tau'} U^z$ from Eq. (32), which results in the following condition

$$C_{\omega = 0} = 0$$

(33)

that is more convenient to write in the frequency space. As we show in Appendix [D] the sign change of the self-exchange coupling $C_{\omega}$ can be related to the sign change of the first variation of the local electronic self-energy with respect to the magnetization. The negative value of the variation indicates that the formation of the local magnetic moment is energetically favorable, because it minimizes the energy of electrons.
This condition can then serve as an approximate criterion for the formation of the local magnetic moment in the system.

V. APPLICATION TO 3D HUBBARD MODEL

In this section we explore the formation of the local magnetic moment in the context of the 3D Hubbard model. For simplicity, we consider only the nearest-neighbor hopping amplitude $t_{ij} = 1$ which defines the energy unit of the system. The SOC $\kappa_{ij}$ and the non-local interaction $V_{ij}$ are set to zero. Numerical results are obtained on the basis of the converged DMFT solution of the lattice problem [1]. In this case the local reference system is given by the impurity problem of DMFT [2]. Fig. 3 shows the phase diagram for the considered model in the temperature ($T$) vs local Coulomb interaction ($U$) space. The red line corresponds to the condition (33) that defines the temperature at which the local magnetic moment is formed in the system. For illustrative purposes we also show the AFM phase boundary of DMFT (green line) that was obtained in Ref. [82] using the criterion on the inverse of the AFM susceptibility (28). Remarkably, we find that the local magnetic moment appears already at high temperatures well above the Néel phase transition to the AFM state. This observation is consistent with the fact that in some cases paramagnetic phase can be well described by a classical Heisenberg model that explicitly assumes the existence of the magnetic moment. At the same time, the obtained result suggests that the local magnetic moment exists only above a relatively large critical value of the local Coulomb interaction $U^* \approx 6.5$, which is comparable to the half of the bandwidth $D/2 = 6$. More interestingly, the red line in Fig. 3 crosses the AFM phase bound-
regime of valence fluctuations [84].

The average value of the local moment can also be compared to the magnetization \( \langle M' \rangle \) estimated from the equal-time local spin susceptibility (see e.g. Refs. [85] and [86])

\[
3 \chi^z_{\tau \tau} = \langle M'^2 \rangle \approx \langle M' \rangle \left( \langle M' \rangle + 2 \right) \tag{34}
\]

This expression gives nearly constant value \( \langle M' \rangle = 0.85 \pm 0.03 \) for all considered temperatures. Therefore, we find that the magnetization calculated from the susceptibility strongly overestimates the average value of the local moment \( \langle M \rangle \) and is non-zero even when the system possesses no local moment at all. This result is a direct consequence of the fact that the spin susceptibility of the local reference system cannot distinguish the fluctuations of the local magnetic moment from the spin fluctuations of the itinerant electrons that also contribute to the susceptibility, especially in the paramagnetic regime. In particular, this explains the large value of \( \langle M' \rangle \) obtained at \( T = 0.3 \) that lies in the Kondo (or valence fluctuation) regime, where the local magnetic moment is screened by the electrons.

Importantly, the presence of the local magnetic moment in the system can influence different physical quantities not necessarily related to magnetism. Recently, it has been argued that the appearance of the “onion-like” fermionic Matsubara frequency structure of the generalized charge susceptibility can be seen as a fingerprint of the formation of the local magnetic moment [81]. The main argument of the authors in favor of that was the fact that in the low temperature and large \( U \) regime this change in the frequency structure occurs exactly at Kondo temperature. For comparison we plot the “finger-print” temperature (blue line in Fig. 3) that was deduced from the local generalized charge susceptibility of the DMFT impurity problem [2] applying the criterion proposed in Ref. [81].

We find that in the large interaction regime \( U \geq 11 \) the lower branches of both red and blue curves lie on top of each other and thus reproduce the Kondo temperature. However, upon decreasing the interaction strength the blue line rapidly shifts downwards to lower temperatures from the red one. This trend is preserved and significantly increased upon going to the high-temperature branches. Therefore, we observe that the phenomenological criterion proposed in Ref. [81] seems to correlate with the formation of the local moment but can be directly attributed to it only in the well-developed Kondo regime.

VI. CONCLUSIONS

To conclude, in this work we have shown that the extended Hubbard model that describes the behavior of electrons on a lattice can be turned into an effective bosonic action describing spin dynamics of itinerant-electron systems. We have proved that the special set of transformations allows one to write the resulting action in terms of physical variables that can be associated with fluctuations of the local magnetic moment. In particular, the use of these transformations makes possible a careful separation of electronic and spin degrees of freedom. We have shown that the derived effective spin problem takes into account all possible spin exchange interactions including the isotropic, the antisymmetric anisotropic, and the symmetric anisotropic interactions. Importantly, the obtained two-spin interactions can be reduced to a well-known expression [48, 50, 51] that is intensively used for realistic calculations of magnetic materials. Another important step in these transformations is a precise separation of the rotational dynamics of the local magnetic moment from the Higgs fluctuations of its modulus. This allowed us to obtain a correct Berry phase term, which is written in terms of rotation angles and of the scalar field that describes the behavior of the modulus of the magnetic moment. As a consequence, the equation of motion for the introduced spin problem takes the Landau-Lifshitz-Gilbert form, which, in addition to the uniform spin precession, accounts for the Gilbert damping.

The derived equation of motion assumes the presence of the local magnetic moment in the system. To capture the formation of the magnetic moment we have investigated the local free energy of the system. We have found that, according to Landau phenomenology, the energy as a function of the local magnetic moment transforms from the parabolic-like to a Mexican-hat potential form. The transition point between two cases can be captured by a sign change of the second variation of the local free energy, which allowed us to introduce a criterion for the formation of the local magnetic moment. This criterion can be interpreted as the appearance of a diamagnetic exchange coupling of the local magnetic to itself. According to the derived criterion this self-exchange coupling can be obtained by excluding the itinerant contribution from the total local exchange. In particular, this result explains the fact that the value of the local magnetic moment cannot be estimated from the local magnetic susceptibility, which also contains the contribution of itinerant electrons. Instead, we have argued that the value of the local magnetic moment can be found from the minima of the local free energy. As the result, we have observed that the local moment appears in the system well above the transition temperature to the ordered magnetic state and exists only above a critical value of the Coulomb interaction.

In this section we explicitly derive a spin problem for a multi-orbital electronic system. We start with the lattice action of the extended Hubbard model written in the coordinate and imaginary time space

\[ S = \int_0^\beta d\tau \left\{ -\sum_{ij,\sigma\sigma'} C_{i\sigma}^* \left[ \delta_{ij} \delta_{\sigma\sigma'} \delta_{\tau\tau} (-\partial_\tau + \mu) - \xi_{ij}^{\sigma\sigma'} c_{j\sigma'} \right] c_{j\sigma'} + \frac{1}{2} \sum_{i,\sigma,\sigma',l} U_{i,\sigma,l} c_{i\sigma}^* c_{i\sigma'}^* c_{i\sigma'} c_{i\sigma} + \frac{1}{2} \sum_{i,j,\sigma,l} \rho_{i\sigma,l}^l V_{l,j\sigma,l}^l \rho_{j\sigma,l}^l \right\} \]

(A1)

In this expression we introduced composite variables \( \rho_{i\sigma,l}^l = n_{i\sigma,l}^l - \langle n_{i\sigma,l}^l \rangle \) that describe fluctuations of the charge (\( \xi = c \)) and spin (\( \xi = s = \{x, y, z\} \)) densities \( n_{i\sigma,l}^l = \sum_{\sigma'} c_{i\sigma l}^* \sigma_{\sigma\sigma'} c_{i\sigma l} \) around their average values. The latter are provided by an effective impurity problem

\[ S_{\text{imp}} = -\int_0^\beta d\tau' \sum_{ij,\sigma\sigma'} C_{i\sigma}^* \left[ \delta_{ij} \delta_{\sigma\sigma'} \delta_{\tau\tau} (-\partial_\tau + \mu) - \Delta_{\tau\tau}^{\nu} \right] c_{j\sigma'} + \frac{1}{2} \int_0^\beta d\tau \sum_{i,j,\sigma,l} U_{i,\sigma,l} c_{i\sigma}^* c_{i\sigma'}^* c_{i\sigma'} c_{i\sigma} \]

(A2)

The impurity problem is considered in a non-polarized form so that \( \langle n_{l\sigma,l}^l \rangle = 0 \). Consequently, the corresponding retarded fermionic hybridization function is spin independent and reads \( \Delta_{\tau\tau}^{\nu} = \Delta^{\nu} (\tau - \tau') \). The remainder part of the action \( S_{\text{rem}} = S_{\text{lat}} - \sum_i S_{\text{imp}} \) is following

\[ S_{\text{rem}} = \int_0^\beta d\tau' \sum_{ij,\sigma\sigma'} C_{i\sigma}^* \left[ \delta_{ij} \delta_{\sigma\sigma'} \delta_{\tau\tau} (-\partial_\tau + \mu) - \Delta_{\tau\tau}^{\nu} \right] c_{j\sigma'} + \frac{1}{2} \int_0^\beta d\tau \sum_{i,j,\sigma,l} \rho_{i\sigma,l}^l V_{l,j\sigma,l}^l \rho_{j\sigma,l}^l \]

(A3)

where \( \tilde{\Delta}_{\tau\tau}^{\nu} = \delta_{ij} \delta_{\tau\tau}^{\nu} - \Delta^{\nu} \delta_{\tau\tau} \). In order to integrate out the local reference system (A2) that is soled numerically exactly we perform Hubbard-Stratonovich transformations over the remainder part of the lattice action (A3) as

\[ \exp \left\{ -\int_0^\beta d\tau d\tau' \sum_{ij,\sigma\sigma'} C_{i\sigma}^* \tilde{\Delta}_{\tau\tau}^{\nu} c_{j\sigma'} \right\} = \mathcal{D}_f \int D[f, \phi] \exp \left\{ \sum_{ij,\sigma\sigma'} \int_0^\beta d\tau \left[ f_{i\sigma,l}^l \left[ 1 - \frac{1}{\beta} \frac{\partial}{\partial \phi_{i\sigma,l}^l} \right] + \phi_{i\sigma,l}^l \right] - \sum_{ij,\sigma\sigma'} \int_0^\beta d\tau \left[ f_{i\sigma,l}^l \left[ 1 - \frac{1}{\beta} \frac{\partial}{\partial \phi_{i\sigma,l}^l} \right] + \phi_{i\sigma,l}^l \right] \right\} \]

(A4)

where determinants \( \mathcal{D}_f = \det \left[ g(\Delta - \epsilon) g \right] \) and \( g^{-1} = -\sqrt{\det \mathcal{V}} \) can be neglected when calculating expectation values. After that the lattice action becomes

\[ S = -\int_0^\beta \left[ \sum_{ij,\sigma\sigma'} f_{i\sigma,l}^l \left[ 1 - \frac{1}{\beta} \frac{\partial}{\partial \phi_{i\sigma,l}^l} \right] + \phi_{i\sigma,l}^l \right] - \sum_{ij,\sigma\sigma'} \int_0^\beta d\tau \left[ f_{i\sigma,l}^l \left[ 1 - \frac{1}{\beta} \frac{\partial}{\partial \phi_{i\sigma,l}^l} \right] + \phi_{i\sigma,l}^l \right] + \int_0^\beta d\tau \sum_{i,j,\sigma,l} \left( c_{i\sigma}^* \left[ 1 - \frac{1}{\beta} \frac{\partial}{\partial \phi_{i\sigma,l}^l} \right] + f_{i\sigma,l}^l \right) \]

(A5)

In the last equation we have introduced source field \( j^{\xi} \) for the composite \( \rho^{\xi} \) variable. Now we perform a transformation of fermionic variables to a rotation frame as discussed in the main text. This transformation can be written in terms of the unitary orbital-independent rotation matrix

\[ R_{\tau} = \begin{pmatrix} \cos(\theta_{\tau}/2) & -e^{-i\phi_{\tau}} \sin(\theta_{\tau}/2) \\ e^{i\phi_{\tau}} \sin(\theta_{\tau}/2) & \cos(\theta_{\tau}/2) \end{pmatrix} \]
where polar angles $\theta_{ir}$ and $\varphi_{ir}$ will be defined later. Fermionic variables are transformed as follows $c_{ir} \rightarrow R_{ir}c_{ir}$, where $c_{iri} = (c_{ir\uparrow}, c_{ir\downarrow})^T$. The action becomes

$$S = -\int_0^\beta [d\tau_t] \sum_{i,j,\sigma,\sigma'} f_{ir\sigma',l} \left(\frac{d}{d\tau_t}\right)^{-1} \left[\frac{d}{d\tau_t}\right]^{-1} f_{jr\sigma',l} + \frac{1}{\beta} \int d\tau d\tau' Tr_s \sum_{i,j,l} \left\{ c_{ir\sigma'}^R \left[\frac{d}{d\tau_t}\right]^{-1} f_{ir\sigma'} + f_{ir\sigma'}' \left[\frac{d}{d\tau_t}\right]^{-1} R_{ir\sigma'} c_{ir\sigma'} \right\}$$

$$- \frac{1}{2} \int_0^\beta d\tau d\tau' \sum_{i,j,l} \phi_{ir\sigma'}^c \left[\frac{d}{d\tau_t}\right]^{-1} \phi_{jr\sigma'}^c + \frac{1}{\beta} \int d\tau d\tau' Tr_s \sum_{i,j,l} \left\{ \phi_{ir\sigma'}^c + f_{ir\sigma'}' \right\} c_{ir\sigma'}^R \left[\frac{d}{d\tau_t}\right]^{-1} R_{ir\sigma'} c_{ir\sigma'} + \int d\tau Tr_s \sum_{i,l} c_{ir\sigma'}^R \tilde{R}_{ir\sigma'} + \sum_i S_{imp} \quad (A7)$$

The term that contains the derivative of the rotation matrix can be rewritten as an effective gauge field $R_{ir}^\dagger \tilde{R}_{ir} = \sum_s A_{ir}^s \sigma^s$. We also rewrite the coupling of an effective magnetic field to electronic degrees of freedom as $R_{ir}^\dagger \sigma^s R_{ir} = \sum_s U_{ir}^{\sigma^s} \sigma^s$, where $[U_{ir}^{\sigma^s}]^{-1} = [U_{ir}^{\sigma^s}]^\dagger$, $U_{ir}^{\sigma^s} = 0$, and $U_{ir}^{\sigma_s} = 1$. Using these notations the action can be rewritten as

$$S = -\int_0^\beta [d\tau_t] \sum_{i,j,\sigma,\sigma'} f_{ir\sigma',l} \left(\frac{d}{d\tau_t}\right)^{-1} \left[\frac{d}{d\tau_t}\right]^{-1} f_{jr\sigma',l} + \frac{1}{\beta} \int d\tau d\tau' Tr_s \sum_{i,j,l} \left\{ c_{ir\sigma'}^R \left[\frac{d}{d\tau_t}\right]^{-1} f_{ir\sigma'} + f_{ir\sigma'}' \left[\frac{d}{d\tau_t}\right]^{-1} R_{ir\sigma'} c_{ir\sigma'} \right\}$$

$$- \frac{1}{2} \int_0^\beta d\tau d\tau' \sum_{i,j,l} \phi_{ir\sigma'}^c \left[\frac{d}{d\tau_t}\right]^{-1} \phi_{jr\sigma'}^c + \frac{1}{\beta} \int d\tau d\tau' Tr_s \sum_{i,j,l} \left\{ \phi_{ir\sigma'}^c + f_{ir\sigma'}' \right\} c_{ir\sigma'}^R \left[\frac{d}{d\tau_t}\right]^{-1} R_{ir\sigma'} c_{ir\sigma'} + \int d\tau Tr_s \sum_{i,l} c_{ir\sigma'}^R \tilde{R}_{ir\sigma'} + \sum_i S_{imp} \quad (A8)$$

Now we make a shift of bosonic variables $\phi_{ir\sigma'}^c \rightarrow \phi_{ir\sigma'}^c = \phi_{ir\sigma'}^c - f_{ir\sigma'}' - \sum_{\sigma} A_{ir}^\sigma \left[\frac{d}{d\tau_t}\right]^{-1} \delta_{ir\sigma'}$ that leads to

$$S = -\int_0^\beta [d\tau_t] \sum_{i,j,\sigma,\sigma'} f_{ir\sigma',l} \left(\frac{d}{d\tau_t}\right)^{-1} \left[\frac{d}{d\tau_t}\right]^{-1} f_{jr\sigma',l} + \frac{1}{\beta} \int d\tau d\tau' Tr_s \sum_{i,j,l} \left\{ c_{ir\sigma'}^R \left[\frac{d}{d\tau_t}\right]^{-1} f_{ir\sigma'} + f_{ir\sigma'}' \left[\frac{d}{d\tau_t}\right]^{-1} R_{ir\sigma'} c_{ir\sigma'} \right\}$$

$$- \frac{1}{2} \int_0^\beta d\tau d\tau' \sum_{i,j,l} \phi_{ir\sigma'}^c \left[\frac{d}{d\tau_t}\right]^{-1} \phi_{jr\sigma'}^c + \frac{1}{\beta} \int d\tau d\tau' Tr_s \sum_{i,j,l} \left\{ \phi_{ir\sigma'}^c + f_{ir\sigma'}' \right\} c_{ir\sigma'}^R \left[\frac{d}{d\tau_t}\right]^{-1} R_{ir\sigma'} c_{ir\sigma'} + \int d\tau Tr_s \sum_{i,l} c_{ir\sigma'}^R \tilde{R}_{ir\sigma'} + \sum_i S_{imp} \quad (A9)$$

After shifting bosonic variables the gauge $A$ and the source $j$ fields are no longer coupled to original fermionic $e^{(\nu)}$ degrees of freedom and thus will not be affected by the integration of original fermionic degrees of freedom. The latter is performed as

$$\int D[c^*, c] \exp\left\{-\sum_i S_{imp} - \int_0^\beta d\tau d\tau' Tr_s \sum_{i,j,l} \left\{ c_{ir\sigma'}^R \left[\frac{d}{d\tau_t}\right]^{-1} f_{ir\sigma'} + f_{ir\sigma'}' \left[\frac{d}{d\tau_t}\right]^{-1} R_{ir\sigma'} c_{ir\sigma'} \right\} - \int_0^\beta d\tau Tr_s \sum_{i,l} \phi_{ir\sigma'}^c \left[\frac{d}{d\tau_t}\right]^{-1} R_{ir\sigma'} c_{ir\sigma'} \right\}$$

$$\mathcal{Z}_{imp} \times \exp\left\{-\int_0^\beta [d\tau_t] \sum_{i,l} \left\{ Tr_s f_{ir\sigma'} R_{ir\sigma'} \left[\frac{d}{d\tau_t}\right]^{-1} R_{ir\sigma'} f_{ir\sigma'} + \frac{1}{2} \sum_{\sigma} \phi_{ir\sigma'}^c \left[\frac{d}{d\tau_t}\right]^{-1} \phi_{ir\sigma'}^c \right\} - \tilde{F}[f, \phi] \right\} \quad (A10)$$

where $\mathcal{Z}_{imp}$, $\phi_{ir\sigma'}^c = -\langle c_{ir\uparrow} c_{ir\downarrow}^* \rangle_t$, and $\chi_{ir\sigma'}^{\tau\tau'} = -\langle c_{ir\sigma'} c_{ir\sigma'}^* \rangle_t$ are the partition function, the Green’s function, and the susceptibility of the local impurity problem, respectively. The interaction $\tilde{F}[f, \phi]$ that appears as the result of the integration of $e^{(\nu)}$ variables contains all possible exact fermion-fermion, fermion-boson, and boson-boson vertex functions of the local reference system. However, in actual calculations it is usually truncated at the two particle level, which is a standard approximation that is widely used in the dual fermion [62], the dual boson [43, 47], and the dual TRILEX [41, 42, 88] methods including their diagrammatic Monte Carlo realizations [89, 91]. Thus, the truncated interaction contains only the exact local three-point $\chi_{ir\sigma'}^{\tau\tau'}$ and four-point $\Gamma_{ir\sigma'}^{\tau\tau'}$ vertex functions of the reference system

$$\tilde{F}[f, \phi] \approx \int_0^\beta [d\tau_t] Tr_s \sum_{i,l} \left\{ \sum_{\nu\nu'} \sum_{\sigma\sigma'} f_{ir\sigma'} R_{ir\sigma'} f_{ir\sigma'} \chi_{ir\sigma'}^{\tau\tau'} \left[\frac{d}{d\tau_t}\right]^{-1} \phi_{ir\sigma'}^c \right\} + \frac{1}{4} \Gamma_{ir\sigma'}^{\tau\tau'} f_{ir\sigma'} R_{ir\sigma'} f_{ir\sigma'} R_{ir\sigma'} f_{ir\sigma'} f_{ir\sigma'} \quad (A11)$$
where

\[
\Lambda_{\tau\tau'}^{\varsigma_1\tau_2\tau_3\varsigma_3} = \int_0^\beta \langle d\tau' \rangle \sum_{l'j'c'} \langle \epsilon_{\epsilon_{l'}\epsilon_{j'}\epsilon_{c'}} \epsilon_{\epsilon_{l'}\epsilon_{j'}\epsilon_{c'}} \rho_{\epsilon_{l'}\epsilon_{j'}\epsilon_{c'}} \rangle [g_{\tau_1\tau_2}^{-1} g_{\tau_2\tau_3}^{-1} g_{\tau_3\tau_1}^{-1} g_{\varsigma_1\tau_3}^{-1}]
\]

(A12)

\[
\Gamma_{\tau\tau'\tau_2\tau_3}^{\varsigma_1\tau_2\tau_3\varsigma_3} = \int_0^\beta \langle d\tau' \rangle \sum_{l'j'c'} \langle \epsilon_{\epsilon_{l'}\epsilon_{j'}\epsilon_{c'}} \epsilon_{\epsilon_{l'}\epsilon_{j'}\epsilon_{c'}} \epsilon_{\epsilon_{l'}\epsilon_{j'}\epsilon_{c'}} \epsilon_{\epsilon_{l'}\epsilon_{j'}\epsilon_{c'}} \rangle [g_{\tau_1\tau_2}^{-1} g_{\tau_2\tau_3}^{-1} g_{\tau_3\tau_1}^{-1} g_{\varsigma_1\tau_3}^{-1} g_{\varsigma_1\tau_2}^{-1} g_{\varsigma_1\tau_3}^{-1}]
\]

(A13)

Here, \langle \ldots \rangle stands for the average with respect to the partition function of the local impurity problem (A2). After integrating out original fermionic variables, we perform a transformation from unphysical bosonic fields \(\tilde{\phi}_\rho\) to physical variables \(\tilde{\rho}_\rho\) that describe fluctuations of charge and spin densities. To this aim we make a Hubbard-Stratonovich transformation for the quadratic term that enters the second line of Eq. (A29), which is the only term in the action that contains bosonic source fields \(\tilde{f}^\varsigma\)

\[
\exp \left\{ \frac{1}{2} \int_0^\beta \langle d\tau \rangle \sum_{i,j,c,l} \tilde{\phi}_{\tau i l i}^c \left[ \delta_{\tau i l j} \right] \left[ g_{\tau i l j}^{-1} \right] \left[ g_{\tau j i c}^{-1} \right] \left[ \delta_{\tau j i c} \right] \left[ g_{\tau j i c}^{-1} \right] \right\}
\]

\[
\left[ \langle d\tau \rangle \int \left( \frac{1}{2} \sum_{i,j,c,l} \tilde{\phi}_{\tau i l i}^c \left[ \delta_{\tau i l j} \right] \left[ g_{\tau i l j}^{-1} \right] \left[ g_{\tau j i c}^{-1} \right] \left[ \delta_{\tau j i c} \right] \left[ g_{\tau j i c}^{-1} \right] \right) \right]
\]

After that the action takes the following form

\[
S = -\int_0^\beta \langle d\tau \rangle \sum_{i,j,c,l} \langle \epsilon_{\epsilon_{i j c} \epsilon_{l c}} \rangle \left[ g_{\tau i l j}^{-1} \right] \left[ g_{\tau j i c}^{-1} \right] \left[ \delta_{\tau j i c} \right] \left[ g_{\tau j i c}^{-1} \right] f_{\tau i l i}
\]

\[
+ \frac{1}{2} \int_0^\beta \langle d\tau \rangle \sum_{i,j,c,l} \langle \epsilon_{\epsilon_{i j c} \epsilon_{l c}} \rangle \left[ g_{\tau i l j}^{-1} \right] \left[ g_{\tau j i c}^{-1} \right] \left[ \delta_{\tau j i c} \right] \left[ g_{\tau j i c}^{-1} \right] f_{\tau i l i}
\]

(A15)

We find that the source field \(\tilde{f}^\varsigma\) enters the problem only as a multiplier of the new field \(\tilde{\rho}^\varsigma\). This means that the introduced field \(\tilde{\rho}^\varsigma\) is a correct variable that describes fluctuations of charge and spin densities as discussed in the main text. Further we omit bosonic sources \(\tilde{f}^\varsigma\) and bars over the bosonic field \(\tilde{\rho}^\varsigma\). Finally, bosonic fields \(\tilde{\phi}^\varsigma\) can be integrated out as

\[
\int D[\phi^\varsigma] \exp \left\{ -\frac{1}{2} \int_0^\beta \langle d\tau \rangle \sum_{i,j,c,l} \langle \epsilon_{\epsilon_{i j c} \epsilon_{l c}} \rangle \left[ g_{\tau i l j}^{-1} \right] \left[ g_{\tau j i c}^{-1} \right] \left[ \delta_{\tau j i c} \right] \left[ g_{\tau j i c}^{-1} \right] \right\}
\]

\[
\sum_{i,j,c,l} \left[ g_{\tau i l j}^{-1} \right] \left[ g_{\tau j i c}^{-1} \right] \left[ \delta_{\tau j i c} \right] \left[ g_{\tau j i c}^{-1} \right] f_{\tau i l i}
\]

(A16)

where \(\Lambda_\phi\) is a partition function of the Gaussian part of this bosonic integral. The four-point interaction that appears in the last line of this expression approximately cancels the exact four-point vertex function \(\Gamma\) (second term in Eq. (A11)) as discussed in Ref. [39]. As the result we get

\[
S = \int_0^\beta \langle d\tau \rangle \sum_{i,j,c,l} \langle \epsilon_{\epsilon_{i j c} \epsilon_{l c}} \rangle \left[ g_{\tau i l j}^{-1} \right] \left[ g_{\tau j i c}^{-1} \right] \left[ \delta_{\tau j i c} \right] \left[ g_{\tau j i c}^{-1} \right] f_{\tau i l i}
\]

\[
+ \frac{1}{2} \int_0^\beta \langle d\tau \rangle \sum_{i,j,c,l} \langle \epsilon_{\epsilon_{i j c} \epsilon_{l c}} \rangle \left[ g_{\tau i l j}^{-1} \right] \left[ g_{\tau j i c}^{-1} \right] \left[ \delta_{\tau j i c} \right] \left[ g_{\tau j i c}^{-1} \right] f_{\tau i l i}
\]

(A17)
At this step one can demand that polar angles of rotation matrices \( A_6 \) correspond to the direction of the local magnetic moment. We assume that the multi-orbital system that exhibits a well-developed magnetic moment is characterised by a strong Hund’s exchange coupling that orders spins of electrons at each orbital in the same direction. This allows one to decouple the orbital and spin degrees of freedom rewriting the vector spin field as \( \rho_{i\alpha\sigma} = M_{i\alpha\sigma} e_{i\alpha} \). Here, \( M_{i\alpha} \) is a scalar field that can be associated with the orbitally-resolved value of the local magnetic moment. In its turn, \( e_{i\alpha} \) is the unit vector that points in the direction of the local moment on the lattice site \( i \) at the time \( \tau \). Then, using the definition of \( \mathcal{U}^{s'} \) we get

\[
\sum_x \rho_{i\alpha\sigma}^{s'} \mathcal{U}_{i\alpha}^{s'} = \sum_x M_{i\alpha\sigma} e_{i\alpha} \mathcal{U}_{i\alpha}^{s'} = M_{i\alpha} \delta_{i\alpha} \delta_{s,s'}
\]

(A18)

In addition, we use that the difference between local fermionic times is small and that the local Green’s function is diagonal in the spin space. This allows one to write that

\[
\int_0^\beta dt \int_0^\beta d\tau \mathcal{T}_{\sigma} \sum_{l,l_1} f_{\mathcal{T}_{\sigma}}^{s^l} \left[ g_{l_1l}^{s^l} \right]^{-1} R_{l_1l_1} \left[ g_{l_1l}^{s^l} \right]^{-1} f_{\mathcal{T}_{\sigma}}^{s_l} \simeq \int_0^\beta dt \int_0^\beta d\tau \sum_{l} \delta_{l_1l} \delta_{l_1l} f_{\mathcal{T}_{\sigma}}^{s_l} R_{l_1l_1} \left[ g_{l_1l}^{s^l} \right]^{-1} f_{\mathcal{T}_{\sigma}}^{s_l}
\]

(A19)

Using the same argument, the three-point vertex can be transformed as

\[
\mathcal{T}_{\sigma} \sum_{x,l} f_{\mathcal{T}_{\sigma}}^{s^l} \sigma f_{\mathcal{T}_{\sigma}}^{s_{l_2l_3}} M_{\mathcal{T}_{\sigma}}^{s_{l_2l_3}} \simeq \mathcal{T}_{\sigma} \sum_{x,l} f_{\mathcal{T}_{\sigma}}^{s^l} \sigma f_{\mathcal{T}_{\sigma}}^{s_{l_2l_3}} M_{\mathcal{T}_{\sigma}}^{s_{l_2l_3}}
\]

(A20)

The action becomes

\[
S = -\int_0^\beta dt d\tau' \sum_{ij,l} f_{ij,l}^{s'} \left[ \tilde{G}_{ij,\sigma}^{s'} \right]^{-1} f_{ij,\sigma} + \int_0^\beta dt \sum_{ij,l} f_{ij,l}^{s'} \sigma f_{ij,l}^{s_{l_2l_3}} M_{ij,l}^{s_{l_2l_3}} + \frac{1}{2} \int_0^\beta dt \sum_{ij,l} \rho_{ij,l}^{s'} \rho_{ij,l}^{s_{l_2l_3}}
\]

(A21)

where \( \mathcal{A}_{\tau} = \frac{1}{2} i \phi (1 - \cos \theta) \) is the Berry phase, \( M_{\tau} = \sum_{l} M_{i\tau l} \) is the modulus of the total local magnetic moment, and \( \tilde{G} \) is the non-local part of the DMFT Green’s function

\[
\tilde{G}_{ij,\sigma}^{s'} = G_{ij,\sigma}^{s'} - \delta_{i,j} \delta_{\sigma,s'} \delta_{s,s'}
\]

(A22)

Appendix B: Local free energy

In this section we derive the local free energy related to the local magnetic moment. The total local free energy of the system is given by the reference system \( A_3 \), however, as pointed out in the main text, this local problem describes all local correlations including the effect of itinerant electrons. In order to isolate the part of the energy related to the local magnetic moment the electronic contribution should be subtracted from the total local energy. To this effect we start with the action \( A_5 \), that is reminiscent of the \( s-d \) model, since it describes a set of localized impurities \( A_2 \) that are coupled to each other via itinerant electrons \( f^{(s)} \). If one excludes non-local contributions, which also contain the dispersion of the itinerant electrons \( c^{(s)} \), one gets the following effective local action

\[
S_{loc} = \int_0^\beta dt d\tau' \sum_{i,l} \left( c_{i,l}^{(s)} \right)^{-1} f_{i,l}^{(s)} + \int_0^\beta dt \sum_{i,l} \phi_{i,l}^{(s)} + \sum_l S_{imp}
\]

(B1)

One finds that fields \( \tilde{f}^{(s)} = f^{(s)} g^{-1} \) and \( \phi^{(s)} \) play a role of source fields for electronic \( c^{(s)} \) and composite variables \( \rho^{(s)} \), respectively. Therefore, if now we integrate out original fermionic degrees of freedom by expanding a partition function in powers of these effective source fields, as it was done in Eq. \( A_10 \), we get the following action

\[
S_{loc} = -\ln Z_{imp} - \int_0^\beta dt d\tau' \sum_{i,l} f_{i,l}^{(s)} + \sum_l \phi_{i,l}^{(s)} + \int_0^\beta dt d\tau' \sum_{i,l} \phi_{i,l}^{(s)} f_{i,l}^{(s)} + \int_0^\beta dt d\tau' \sum_{i,l} \phi_{i,l}^{(s)} \left[ f_{i,l}^{(s)} + \tilde{F} (f, \phi) \right]
\]

(B2)
where the first term gives the total local energy of the system, and the interaction part \( \tilde{F}[f, \varphi] \) defined in Appendix A contains all possible exact fermion-fermion, fermion-boson, and boson-boson vertex functions of the local reference problem (A2).

Importantly, we find that in the obtained action the bare fermionic Green’s function for fields \( f^{(s)} \) coincides with the exact Green’s function of the impurity problem \( g \). Integrating out \( f^{(s)} \) variables in this expression generates diagrammatic corrections to boson-boson interactions that are constructed from the exact local fermion-boson vertices connected by the exact Green’s functions of the impurity problem. We observe that the generated itinerant contributions become subtracted from the total boson-boson contributions to the full local energy of the system. Thus, after integrating \( f^{(s)} \) fields out the remaining part of the local action describes the part of the local energy related to bosonic fields \( \varphi^s \) only. Our aim is to derive the corresponding action for physical bosonic variables \( \varphi^s \). Therefore, we perform the same procedure for the action (A1), namely we exclude the non-local (itinerant) terms from this action and integrate fermionic fields as

\[
\int D[\varphi^{s*}, f] \exp \left\{ -\int_0^\beta dt\, \sum_{i,s} f^{s*}_i f_i - \int_0^\beta dt' \sum_{\sigma \tau} f^{s*}_{\sigma i} f_{\tau i} \right\} = \det \left[ \left( \delta_{\sigma\sigma'} + \int_0^\beta dt' \sum_{\tau \tau'} \sigma^\epsilon_{\sigma\tau} A^{\epsilon\tau\tau'} f^{s*}_{\tau i} f_{\tau' i} \right)^{-1} \right]
\]

After that, the total local action that describes the physics of the local magnetic moment reads

\[
S = -\text{Tr} \ln \left[ \left( \delta_{\sigma\sigma'} + \int_0^\beta dt' \sum_{\tau \tau'} \sigma^\epsilon_{\sigma\tau} A^{\epsilon\tau\tau'} f^{s*}_{\tau i} f_{\tau' i} \right)^{-1} \right] - \frac{1}{2} \int_0^\beta dt\, dt' \sum_{\sigma \tau \tau'} \rho^{\epsilon}_{\tau i l} \left[ \chi^{\epsilon \tau \tau'}_{i l} \right]^{-1} \rho^{\epsilon'}_{\tau' i l}.
\]

**Appendix C: Equation of motion for spin degrees of freedom**

In this section we derive the equation of motion for the local magnetic moment. After leaving out the fast degrees of freedom in Eq. (18), we are left with an action depending on angle variables only. It reads:

\[
S_{\text{spin}} = iS \int_0^\beta dt \sum_i \varphi_i (1 - \cos \theta) + 2S^2 \int_0^\beta dt\, dt' \sum_{ij} T^{sj}_{ij} (\tau - \tau') e^{s}_{\tau i} e^{s'}_{\tau' j},
\]

Here \( S \) accounts for fast degrees of freedom associated with local moment value, and \( T^{sj}_{ij} \) is the effective exchange given by Eq. (19). At this point we make use of the fact that the exchange is determined by the super-exchange processes due to electrons and thus has a “fast” dependence on time, while the time-dependence of the angle variables is “slow”. This allows to replace the \( \tau' \) time argument of \( e^{s'}_{\tau} \) with \( \tau \) and evaluate the \( \tau' \)-integration of \( T^{sj}_{ij} (\tau - \tau') \) to obtain the zero frequency Fourier component \( T^{sj}_{ij} (\omega = 0) \). We will discuss the corrections to this approximation below.

Now we vary the resulting spin action with respect to \( \varphi_i \) and \( \theta_i \). As we consider only the first variation of the action variables at different sites can be varied independently, i.e. the equation of motion for the spin at a given site is obtained as if all other spins are kept constant. Also note that within our approach \( T^{sj}_{ij} \) is purely non-local as the introduced Green’s function for the fields \( f^{(s)} \) is non-local. Thus we can perform the sum over \( j \) in the second term of Eq. (C1) to get:

\[
S_{\text{spin}} = iS \int_0^\beta dt \sum_i \varphi_i (1 - \cos \theta) - S \int_0^\beta dt E_i \mathbf{h}_i.
\]

where \( \mathbf{h}_i \) is an effective time-dependent magnetic fields due to interaction with all other spins with the components

\[
h^{s*}_{\tau i} = -2S \sum_{j \neq i} \chi^{s*}_{ij} (\omega = 0) e^{s}_{\tau j} - 4S \sum_{j \neq i} T^{s*}_{ij} (\omega = 0) e^{s'}_{\tau j},
\]

Calculating the variation of the action with respect to the \( i \)-th spin is performed straightforwardly by expanding the scalar product in the second term of Eq. (C2), and yields:

\[
\delta S_{\text{spin}} = iS \int_0^\beta (\delta \varphi_i (1 - \cos \theta) + S \delta \theta_i \varphi_i) - S h_{ix} \int_0^\beta \cos \theta_i \delta \theta_i \varphi_i - S h_{iy} \int_0^\beta \cos \theta_i \sin \varphi_i - S h_{iz} \int_0^\beta \sin \theta_i \delta \varphi_i + S h_{x} \int_0^\beta \cos \theta_i \delta \varphi_i \cos \varphi_i + S h_{y} \int_0^\beta \sin \theta_i \cos \varphi_i \delta \varphi_i.
\]

Now, applying integrating by parts, grouping up terms proportional to \( \delta \varphi_i \) and \( \delta \theta_i \), and equating the variation to zero we obtain following equations of motion (the index \( i \) is omitted
as equations for all sites are identical):

\[ \begin{align*}
  i \sin \theta \dot{\theta} &= h_c \sin \theta \sin \varphi - h_z \sin \theta \cos \varphi \\
  i \sin \varphi &= h_c \cos \theta \sin \varphi + h_z \cos \theta \sin \varphi - h_z \sin \theta
\end{align*} \tag{C5} \]

Substituting these two equations into the expression for the time derivatives of \( \dot{e}_{it} \) components

\[ \dot{e}_{it} \equiv \left( \cos \theta \cos \varphi \dot{\theta} - \sin \theta \sin \varphi; \right. \]

\[ \left. \cos \theta \sin \varphi + \sin \theta \cos \varphi \dot{\varphi} - \sin \theta \right) \tag{C7} \]

and applying simple trigonometric identities we obtain

\[ i \dot{e}_{it} = - \left( h_c \cos \theta - h_z \sin \theta \sin \varphi; \right. \]

\[ h_z \sin \theta \cos \varphi - h_c \cos \theta; \]

\[ h_c \sin \theta \sin \varphi - h_z \sin \theta \cos \varphi \right) \]

\[ = - \hbar \dot{\tau} \times \dot{e}_{it} \tag{C8} \]

By changing \( \tau \rightarrow it \) we restore the Landau-Lifshitz equation.

Now let us discuss the effect of non-equal times in Eq. \( \text{(C1)} \). When varying the exchange term we get two terms, one from varying each of \( \dot{e} \). In the second term we can interchange the summation and integration variables \( i, s, \tau \leftrightarrow j, s', \tau' \), and make use of symmetry \( I_{ij}^{ss}(\tau) = I_{ji}^{ss}(\tau) \). This leads to the same result \( \text{(C3)} \) but with a different expression for the effective field:

\[ h_{\dot{\tau}} = - 4S \int_0^\beta d\tau' \sum_{j, s'} I_{ij}^{ss}(\tau - \tau') e_{jl}^{ss'} \tag{C9} \]

So in the general case equation of motion for the magnetic moment is a set of integro-differential equations. As the effective exchange is a fast function of time, we can expand the spin time-dependence in powers of \( \tau - \tau' \). The first order term would lead to a term proportional to the time derivative of the spin in the effective field, which would be the Gilbert damping. But this term vanishes in the Matsubara time due to the exchange being an even function of time. This is not really surprising as one can not expect dissipation effects to be visible in the equilibrium formalism. On the other hand, if at this point we perform analytical continuation to real times the Matsubara exchange transforms to a retarded function \( R_{ij}^{ss'}(\tau - \tau') \) and the contribution with the first order time derivative of the spin does not vanish. Up to this order we can write \( \text{(37)} \):

\[ h_{\dot{\tau}}(t) = - 4S \sum_{j, s'} P_{ij}^{ss'}(\Omega = 0) e_{jl}^{ss'}(t) \]

\[ - 4S \sum_{j, s'} \frac{\partial}{\partial \Omega} \text{Im} P_{ij}^{ss'}(\Omega)|_{\Omega = 0} e_{jl}^{ss'}(t) \tag{C10} \]

The second term accounts for the Gilbert damping. \( P_{ij}^{ss'}(\Omega) \) is a Fourier transform of the retarded exchange interaction \( P_{ij}^{ss'}(\tau - \tau') \) to real frequency \( \Omega \).

FIG. 5. Phase diagram for the 3D Hubbard model as a function of temperature \( T \) and local Coulomb interaction \( U \). Red and orange lines correspond to the exact \( \text{[13]} \) and the approximate \( \text{[14]} \) criteria for the formation of the local magnetic moment, respectively. Light blue line depicts the “fingerprint” condition proposed in Ref. \( \text{[81]} \) (see main text) multiplied by a factor of \( \pi^2/6 \). Green line is the AFM phase transition boundary predicted by DMFT \( \text{[82]} \).

Appendix D: Approximate criterion for the formation of the local magnetic moment

In this section we relate the criterion for the formation of the local magnetic moment to the self-energy of electrons. As has been shown in the Ref. \( \text{[39]} \), the fermionic frequency dependence of the four-point vertex and, as a consequence, of the three-point vertex can be neglected provided that collective electronic fluctuations in the corresponding (charge, spin etc.) channel are strong. In this case the local exchange interaction \( \text{[51]} \) written in Matsubara frequency space can be approximated as

\[ j_{\omega}^{loc} = \sum_{v, \sigma} N_{\nu \omega}^{loc} g_{v \sigma \nu \omega} N_{\nu \omega}^{\star} \]

\[ \approx N_{\nu \omega}^{\star} \sum_{v, \sigma} g_{v \sigma \nu \omega} g_{v \sigma \nu \omega} N_{\nu \omega} \tag{D1} \]

where we introduced a fermionic-frequency-independent three-point vertex \( N_{\nu \omega}^{loc} \). Using the definition of the three-point vertex function \( \text{[A1,2]} \), one gets the following expression for the approximate local exchange interaction

\[ j_{\omega}^{loc} \approx N_{\nu \omega}^{\star} \tag{D2} \]

which corresponds to the renormalized local coupling between the magnetic moment and electronic degrees of freedom of the fermion-boson problem \( \text{[15]} \). The three-point vertex at the zeroth Matsubara frequency \( \omega = 0 \) can be obtained from the variation of the self-energy with respect to the local magnetic moment \( M_{\omega = 0} \) according to Eq. \( \text{(24)} \). Therefore, the criterion for the formation of the local magnetic moment \( \text{[5]} \)
can be rewritten as

\[
C_{\omega=0} = (\Pi_{\omega=0}^{\text{imp}})^{-1} - \rho_{\text{loc}} \\
= (\Pi_{\omega=0}^{\text{imp}})^{-1} - \Sigma_{\nu}^{\text{imp}} \\
= U^s - \partial_M \Sigma_{\nu}^{\text{imp}(\nu)} \\
= -\partial_M \Sigma_{\nu}^{\text{imp}(\nu)} = 0 \tag{D3}
\]

In this expression \( \Sigma_{\nu}^{\text{imp}} = \Sigma_{\nu}^{\text{imp}} - \Sigma^H \) is the self-energy without the static Hartree contribution \( \Sigma^H = -\frac{1}{2} U (M) \), where \( U^s = -U/2 \) is the bare interaction in the spin channel. The presence of the local magnetic moment in the system is signaled by the positive value of the local self-exchange interaction \( C_{\omega=0} > 0 \). The later corresponds to the negative value of the variation of the self-energy \( \partial_M \Sigma_{\nu}^{\text{imp}} < 0 \), which describes how electrons at a given lattice site react on the formation of the local magnetic moment. In particular, the negative value of the variation indicates that the presence of the local moment in the system is energetically favorable, because it minimizes the self-energy of the electrons.

As follows from Eq. (D3), the approximate condition for the formation of the local magnetic moment can also be written as

\[
\Lambda_{\nu}^{s(\nu=0)} = (\Pi_{\omega=0}^{\text{imp}})^{-1} \tag{D4}
\]

We note that the inverse of the polarization operator that stays at the right-hand side of this equation is the high-frequency asymptotics of the three-point vertex function, i.e. \( \Lambda(\nu \to \infty, \omega) = (\Pi_{\omega}^{\text{imp}})^{-1} \). Therefore, it is convenient to use the zeroth fermionic frequency \( \nu_0 = \pi/\beta \) to approximate the fermionic-frequency-independent three-point vertex \( \Lambda(\nu, \omega = 0) \approx \Lambda(\nu_0, \omega = 0) \). As Fig. 5 shows, the orange line that corresponds to the approximate condition (D4) lies close to the red line that was obtained using the exact criterion for the formation of the local magnetic moment (D3). It is also interesting to note that in the low-temperature regime the result obtained via the “fingerprint” condition \( \Lambda_{\nu}^{s(\nu=0)} \) being multiplied by the scaling factor of \( \sum_{\nu=1}^{\infty} 1/\nu^2 = \pi^2/6 \) (light blue line in Fig. 5) is in a very good agreement with the result obtained via the approximate criterion (D4).
