(Dated: June 25, 2021)

We introduce the operational tasks of quantum state betting (QSB) played by gamblers with different risk tendencies. We do this by adapting to the quantum regime the task of horse betting with risk-aversion and side information. We prove that the advantage that informative measurements provide in QSB is exactly characterised by Arimoto’s dependence measure, with the order $\alpha$ determining the risk aversion of the gambler. In limiting cases, we show that QSB recovers the tasks of quantum state discrimination when $\alpha \to \infty$, and quantum state exclusion when $\alpha \to -\infty$. In these respective limiting cases, Arimoto’s dependence measure becomes equal to the accessible information and excludible information of the associated quantum-classical channels. Inspired by these connections, we introduce new quantum Rényi divergences for measurements, and derive a family of resource monotones for the quantum resource theory of measurement informativeness. This family of resource monotones recovers in the same limiting cases as above, the generalised robustness and the weight of informativeness. Altogether, these results establish a broad and continuous family of four-way correspondences between operational tasks, dependence measures, quantum Rényi divergences, and resource monotones, that can be seen to generalise two limiting correspondences that were recently discovered.

\section{I. INTRODUCTION}

The field of quantum information theory (QIT) was born out of the union of the theory of quantum mechanics and the classical theory of information \cite{1}. This union has also happened to kickstart what it is nowadays known as the (ongoing) second quantum revolution which, roughly speaking, aims at the development of quantum technologies \cite{2,3}. Compared with its direct predecessors however, QIT is still a relatively new field and therefore, it is important to keep unveiling, exploiting, and strengthening the links between quantum theory and classical information theory.

In this direction, the framework of quantum resource theories (QRTs) has emerged as a fruitful approach to quantum theory \cite{4,5}. A central subject of study within QRTs is that of resource quantifiers \cite{4,5}. Two well-known families of these measures are the so-called robustness-based \cite{6-18} and weight-based \cite{19-22} resource quantifiers. Importantly, these quantities have been shown to be linked to operational tasks and therefore, this establishes a type of quantifier-task correspondence. Explicitly, robustness-based quantifiers are linked to discrimination-based operational tasks \cite{9,10,12,23-25}, whilst weight-based resource quantifiers are linked to exclusion-based operational tasks \cite{26,27}. A resource quantifier is a particular case of a more general quantity known as a resource monotone \cite{28} and therefore, this correspondence can alternatively be addressed as a \textit{monotone-task} correspondence.

From a different direction, in classical information theory, the Kullback-Leibler (KL) divergence (also known as the Kullback-Leibler relative entropy) emerges as a central object of study \cite{29}. The importance of this quantity is in part due to the fact that it acts as a parent quantity for many other quantities, such as the Shannon entropy, conditional entropy, conditional divergence, mutual information, and the channel capacity \cite{30}. Within this classical framework, it has also proven fruitful to consider Rényi-extensions of these quantities \cite{31}. In particular, there is a clear procedure for how to define the Rényi-extensions of both Shannon entropy and KL-divergence, which are known as the Rényi entropy and the Rényi divergence, respectively \cite{31,32}. Interestingly however, there is yet no consensus within the community as to what is the “proper” way to Rényi-extend other quantities. As a consequence of this, there are several different candidates for Rényi conditional entropies \cite{33}, Rényi conditional divergences \cite{34}, and Rényi mutual information measures \cite{35}. The latter quantities are also known as measures of dependence \cite{34} or α-mutual information measures \cite{35}, and we address them here as (Rényi) \textit{dependence} measures. In particular, we highlight the dependence measures proposed by Sibson \cite{36}, Arimoto \cite{37}, Csiszár \cite{38}, as well as a recent proposal independently derived by Lapidoth-Pfister \cite{39}, and Tomamichel-Hayashi \cite{40}. It is known that these dependence measures (with the exception of Arimoto’s) can be derived from their respective conditional Rényi divergence \cite{34} and therefore, we address this relationship as a \textit{dependence-divergence} correspondence.

The links between the two worlds of QRTs and clas-
sical information theory are now beginning to be understood to run much deeper than just the monotone-task and dependence-divergence correspondences from above. In fact, they are intimately connected via a more general four-way monotone-task-dependence-divergence correspondence. Explicitly, the robustness-discrimination correspondence [12, 25] is furthermore connected to the information-theoretic quantity known as the accessible information [41] which can, in turn, be written in terms of dependence measures. In a similar manner the weight-exclusion correspondence [26, 27] is linked to the excludible information [26, 42], which can also be written in terms of dependence measures. Even though it was not explicitly stated in any of the above references the fourth corner in terms of “Rényi divergences”, it is nowadays a well known fact within the community, first noted by Datta, that the generalised robustness is related to the Rényi divergence of order ∞ (also called the max quantum divergence) [43], with a similar case happening for the weight and the divergence of order −∞ [26]. These two apparently “minor” remarks raise the following fascinating question: Could there exist a whole spectrum of connections between dependence measures, Rényi divergences, resource monotones, and operational tasks, with only the two extreme ends at ±∞ currently being uncovered? [26].

In this work we provide a positive answer to this question, by implementing insights from the theory of games and economic behaviour [44]. This latter theory, in short, encompasses many of the theoretical tools currently used in the economic sciences. In particular, we invoke here the so-called expected utility theory [44] and more specifically, we borrow the concept of risk-aversion; the behavioural tendency of rational agents to have a preference one way or another for guaranteed outcomes versus uncertain outcomes. This concept remains of great research interest in the economic sciences, with various Nobel prices having been awarded to its understanding [45]

In general, the concept of risk aversion is a ubiquitous characteristic of rational agents and, as such, it naturally emerges as a subject of study in various different areas of knowledge such as: the economic sciences [46], biology and behavioral ecology [47, 48], and neuroscience [49–51]. In short, it addresses the behavioural tendencies of rational agents when faced with uncertain events. Intuitively, a gambler spending money on bets with the hope of winning big, can be seen as an individual taking (potentially unnecessary) risks, in the eyes of a more conservative gambler. One of the challenges that economists have tackled, since roughly the second half of the previous century, is the incorporation of the concept of risk aversion into theoretical models describing the behaviour of rational agents, as well as its quantification, and exploitation of its descriptive power [46].

The concept risk was first addressed within theoretical models by Bernoulli in 1738 (translated into English by Sommer in 1954) [52]. Later on, the theory of expected utility, formalised by von Neumann and Morgenstern in 1944 [44], provided a framework within which to address and incorporate behavioural tendencies like risk aversion. It was then further formalised, independently and within the theory of expected utility, by Arrow, Pratt, and Finetti in the 1950’s and 60’s [53–55] who, in particular, introduced measures for its quantification. The quest for further understanding and exploiting this concept has since remained of active research interest in the economic sciences [46]. Recently, an important step was taken in the work of Bleuler, Lapidoth and Pfister (BLP) in 2020 [34], where the concept of risk aversion was implemented within the realm of classical information theory.

In this work, we invoke the concept of risk aversion as well as the operational tasks with risk addressed by BLP [34] and adapt them to a quantum setting, in what we address here as quantum state betting (QSB) games. Surprisingly, we find that when the operational tasks introduced by BLP are appropriately modified and extended to the quantum regime (as QSB games), they turn out to provide the correct approach for solving the conundrum regarding the four-way correspondence for QRTs described above. Specifically, we find that the concept of risk aversion allows us to define operational tasks (QSB games) which can be viewed as a generalisation of state discrimination and state exclusion, and consequently allows for the derivation of the desired four-way correspondence between operational tasks, dependence measures, Rényi divergences, and resource monotones. We now briefly describe our findings in more detail.

II. SUMMARY OF MAIN RESULTS

In this work we report on the existence of a continuous spectrum of connections between: operational tasks, dependence measures, Rényi divergences, and resource monotones. We summarise these findings in a quantitative manner as a list of four chains of equalities below, and succinctly describe them in a qualitative manner following Fig. 1, as follows:

- (Bottom left): We introduce the operational tasks of quantum state betting (QSB) games, and consider them being played by gamblers with a risk tendency parametrised by a coefficient α. We do this by modifying and extending, to the quantum regime, the operational tasks of horse betting (HB) games with risk introduced by BLP [34, 56, 57]. HB games were first introduced by Kelly in 1956 [56], and were recently generalised by Bleuler, Lapidoth, and Pfister (BLP) in 2020 [34], in order to address gamblers with different risk tendencies. We show that when properly modified and extended to the quantum regime into what we address here as quantum state betting (QSB) games, these tasks can be seen to generalise quantum state discrimination
Operational Tasks

- Quantum State Betting (QSB)
- Quantum State Discrimination (QSD)
- Quantum State Exclusion (QSE)
- Measure Exclusion (MEX)

Resource Monotones

- Rényi Divergences
  - $D_{\alpha}^S(M||N)$
  - $D_{\alpha}^{\infty}(M||N)$
  - $D_{\alpha}^{-\infty}(M||N)$

Dependence Measures

- $I_{\infty}(p_{G_{\infty}X})$
- $I_{\alpha}(p_{G_{\alpha}X})$
- $I_{-\infty}(p_{G_{-\infty}X})$

Altogether, these results therefore establish a four-way task-dependence-divergence-monotone correspondence for the QRT of measurement informativeness, by means of a risk aversion factor parametrised by the Rényi parameter $\alpha$. This correspondence generalises the two sets of results found by BLP [34], which characterise HB games in terms of a Rényi conditional divergence. Specifically, their work addresses HB games with and without side information in an independent manner, whilst this work on the other hand, we compare side information against no side information, and quantify the usefulness of such side information.

- (Top left): Within the quantum resource theory of measurement informativeness [12], we prove that Arimoto’s dependence measure (in a quantum setting) quantifies the advantage that side information provides in horse betting (HB) games. This finding complements and extends the results found by BLP [34], which characterise HB games in terms of a Rényi conditional divergence. Specifically, their work addresses HB games with and without side information in an independent manner, whilst this work on the other hand, we compare side information against no side information, and quantify the usefulness of such side information.

- (Top and bottom right): Building on the above-mentioned results, we introduce new quantum Rényi divergences for measurements which allow us to identify a family of resource monotones for the order induced by the simulability of measurements. This family of resource monotones recover, as limiting cases, the robustness of informativeness [12, 26] when $\alpha \to \infty$, and the weight of informativeness [26, 27] when $\alpha \to -\infty$.

This work is organised as follows. We start by describing the concept of risk aversion in the theory of games and economic behaviour in Section IIIA. We then introduce the operational tasks of quantum state betting in Sec. IIIB. In Sec. IIIC and IIID we address Arimoto’s dependence measure and the Rényi capacity both in classical and quantum domains. In Sec. IIIE we describe the quantum resource theory of measurement informativeness. Our results sections start in Sec. IV A where we relate Arimoto’s dependence measure (in the quantum domain) to the operational task of quantum state betting. In Sec. IVB and IVC we address quantum Rényi divergences and resource monotones. In Sec. IVD we address a slightly more general version of result 1, by providing an operational interpretation of Arimoto’s dependence measure without invoking quantum theory. We finish in Secs. V with conclusions, open questions, perspectives, and avenues for future research.
Summary of results. The main result of this work is a four-way quantum correspondence between operational tasks, dependence measures, quantum Rényi divergences, and resource monotones. This is qualitatively summarised in Fig. 1, and quantitatively summarised in the following four chains of equalities, going from $\alpha = 0$ until $\alpha \to -\infty$ as follows (definitions and proofs in the main text and appendices):

\[
\begin{align*}
\max_{\mathcal{E}} I_{\alpha}(X_{\mathcal{E}};G_M) &= \log \max_{\mathcal{E}} \frac{p_{\text{QSD}}(\mathcal{E},M)}{p_{\text{QSD}}(\mathcal{E},N)} = \log [1 + R(M)] = \max_{S \subseteq N} D_{\alpha}^{S}(M||N), \\
\max_{\mathcal{E}} I_{\alpha \geq 0}(X_{\mathcal{E}};G_M) &= \max_{\mathcal{E}} \max_{b_{X|G}} \max_{\alpha} w_{1/\alpha}^{CE}(b_{X|G},M,\alpha^X,\mathcal{E}) = \log [1 + M_\alpha(M)] = \max_{S \subseteq N} D_{\alpha}^{S}(M||N), \\
\max_{\mathcal{E}} I_{\alpha < 0}(X_{\mathcal{E}};G_M) &= -\log \max_{\mathcal{E}} \max_{b_{X|G}} \max_{\alpha} w_{1/\alpha}^{CE}(b_{X|G},M,\alpha^X,\mathcal{E}) = -\log [1 - M_\alpha(M)] = \max_{S \subseteq N} D_{\alpha}^{S}(M||N), \\
\max_{\mathcal{E}} I_{-\infty}(X_{\mathcal{E}};G_M) &= -\log \min_{\mathcal{E}} \frac{p_{\text{QSE}}(\mathcal{E},M)}{p_{\text{QSE}}(\mathcal{E},N)} = -\log [1 - W(M)] = \max_{S \subseteq N} D_{\alpha}^{S}(M||N).
\end{align*}
\]

III. BACKGROUND THEORY

In this section we start by addressing the preliminary theoretical tools necessary to establish our main results. We start with the concept of risk in the theory of games and economic behaviour, a pair of games involving risk, followed by the operational tasks of quantum state betting, then Arimoto’s dependence measure and the Rényi capacity in both classical and quantum information theory and, finally, the quantum resource theory of measurement informativeness.

A. The concept of risk in the theory of games and economic behaviour

In expected utility theory [44], the level of ‘satisfaction’ of a rational agent, when receiving (obtaining, being awarded) a certain amount of wealth, or goods or services, is described by a utility function [44]. The utility function of a rational agent is a function $u : A \to \mathbb{R}$, with $A = \{a_1, \ldots, a_k\}$ a set of alternatives from which the rational agent can choose from. The set $A$ is endowed with a binary relation $\leq$. The utility function is asked to be a monotone for such a binary relation; if $a_1 \leq a_2$ then $u(a_1) \leq u(a_2)$. In this work we address the set of alternatives as representing wealth and therefore, it is enough to consider an interval of the real numbers.

We are going to consider two different types of situation in this work. In the first case, the wealth will always be non-negative, and so we consider the interval being $A = [0,w^M] \subseteq \mathbb{R}$, with $w^M > 0$ a maximal amount of wealth, and the standard binary relation $\leq$. Similarly, we also will also consider a situation where the wealth is non-positive, meaning we address a utility function taking negative arguments $w < 0$, with $A = [-w^M,0] \subseteq \mathbb{R}$, as the level of (dis)satisfaction when the rational agent has to pay an amount of money $|w|$ (or when the amount $|w|$ is taken away from him).

We note here that the utility function does not necessarily need to be positive (or negative), because it is only used to compare alternatives. The condition that the utility function is monotonic is the equivalent to it being an increasing function for both positive and negative wealth. Intuitively, this represents that the rational agent is interested in acquiring as much wealth as possible (for positive wealth), and losing the least amount of wealth as possible (for negative wealth). Additionally, the utility function is asked to be twice-differentiable, both for mathematical convenience and, because it is natural to assume that smooth changes in wealth imply smooth changes in the rational agent’s satisfaction.

In order to address the concept of risk, we first need to introduce two games (or operational tasks), which involves a player Bob (the Better or Gambler, who we take to be a rational agent with a utility function $u$) and a referee Alice, who is in charge of the game. We are going to address two different games which we call here: i) gain games and ii) loss games.

1. A gain game and utility theory

In a gain game, Alice (Referee) offers Bob (Gambler) the choice between two options: i) a fixed guaranteed amount of wealth $w^G \in [0,w^M]$ or ii) a bet. The bet consists of the following: Alice uses a random event distributed according to a probability mass function (PMF) $p_W$, (i.e. $\sum_{w \in \mathcal{Z}} p_W(w) = 1$, $p_W(w) \geq 0$, $\forall w \in \mathcal{Z}$, with $W$ a random variable in the alphabet $\mathcal{Z}$), in order to give Bob a reward. Specifically, Alice will reward Bob with an amount of wealth $w^B = w$, whenever the random event happens to be $w$, which happens with probability $p(w)$ (we drop the label $W$ on $p_W(w)$ from now on). The
choice facing Bob is therefore between a fixed guaranteed amount of wealth \( w^G \in [0, w^M] \), or taking the bet and potentially earning more \( w^B > w^G \), at the risk of earning less \( w^B < w^G \).

Since the utility function \( u(w) \) determines Bob’s satisfaction when acquiring the amount wealth \( w \), we will see below that it can be used to model his behaviour in this game, i.e. whether he chooses the first or second option. First, considering the bet (option ii) we can consider the expected gain of Bob at the end,

\[
E[W] = \sum_{w \in \mathcal{I}} p(w)w. \tag{1}
\]

How satisfied Bob is with this expected amount of wealth is given by the utility of this value, i.e.

\[
u(E[W]) = u \left( \sum_{w \in \mathcal{I}} p(w)w \right). \tag{2}\]

Now, Bob’s wealth at the end of the bet is a random variable, this means that his satisfaction will also be a random variable, with some uncertainty. We can also ask what Bob’s expected satisfaction, i.e. expected utility will be at the end of the bet,

\[
\mathbb{E}[u(W)] = \sum_{w \in \mathcal{I}} p(w)u(w). \tag{3}\]

This represents how satisfied Bob will be with the bet on average.

We can now introduce the first key concept, that of the Certainty Equivalent (CE): it is the amount of (certain) wealth \( w^{CE} \) which Bob is as satisfied with as the average wealth he would gain from the bet. In other words, the amount of wealth which is as desirable as the bet itself. That is, it is the amount of wealth \( w^{CE} \) that satisfies

\[
\mathbb{E}[u(W)] = u(w^{CE}). \tag{4}\]

It is crucial to note that the certainty equivalent wealth depends upon the utility function \( u \) and the PMF \( p_W \), and therefore we interchangeably write it as \( w^{CE}(u, p_W) \).

We can now return to the original game, i.e. the choice between a fixed return \( w^G \), or the average return \( \mathbb{E}[W] \). The rational decision for Bob is to pick which of the two he is most satisfied with. We now see that if we set \( w^G > w^{CE} \) then he will choose to take the guaranteed amount, if \( w^G < w^{CE} \) he will choose the bet, and if \( w^G = w^{CE} \) then in fact the two options are equivalent to Bob, and he can rationally pick either. That is, we see that the certainty equivalent \( w^{CE} \) sets the boundary between which option Bob will pick.

Introducing the certainty equivalent moreover allows us to introduce the concept of Bob’s risk-aversion. To do so, we will compare Bob’s expected wealth, in relation to the certainty equivalent of the bet. There are only three possible scenarios,

\[
w^{CE} < \mathbb{E}[W], \tag{5}
w^{CE} > \mathbb{E}[W], \tag{6}
w^{CE} = \mathbb{E}[W]. \tag{7}\]

In the first case (5), Alice can offer Bob an amount of wealth \( w^G \) that is larger than \( w^{CE} \) but less than \( \mathbb{E}[W] \), \( w^{CE} < w^G < \mathbb{E}[W] \) and Bob will rationally take this amount over accepting the bet, even though he will walk away with less wealth on average than if he took the bet. In other words, Bob is reluctant to take the bet, and so we say that he is risk-averse.

In the second case (6), on the other hand, if Alice wants to make Bob walk away from the bet, and accept a fixed amount of wealth instead, she will have to offer him more than the expected gain. That is, Bob will only choose an amount \( w^G \) if \( w^G > w^{CE} > \mathbb{E}[W] \). Here Bob is risk-seeking.

Finally, in the third case (7), Bob will take the bet if Alice offers him any \( w^G \) less than the expected gains from the bet, and will take the guaranteed amount \( w^G \) if it is larger. In this case, we say that Bob is risk-neutral, as Bob is essentially indifferent between the uncertain gains of the bet and the certain gains of the guaranteed return.

If we recall that by definition the utility function \( u \) is strictly increasing in the interval \( \mathcal{I} \) (more wealth is also more satisfactory to Bob), then by applying \( u \) to the previous three equations, and using the definition of \( w^{CE} \) (4), we get

\[
\mathbb{E}[u(W)] < u(\mathbb{E}[W]), \tag{8}
\]
\[
\mathbb{E}[u(W)] > u(\mathbb{E}[W]), \tag{9}
\]
\[
\mathbb{E}[u(W)] = u(\mathbb{E}[W]). \tag{10}\]

This is an important result, which shows that Bob’s risk-aversion is characterised by the curvature of his utility function: Bob is risk-averse when his utility function is concave (8), risk-seeking when his utility function is convex (9), and risk-neutral when it is linear (10). This intuitively makes sense, since roughly speaking this corresponds to his satisfaction growing more slowly than wealth when he is risk-averse and his satisfaction growing faster than wealth when he is risk-seeking. We now move on to analyse the concept of risk in our second game.

2. A loss game and utility theory

Let us now analyse a game which we call here a loss game. Similarly to the gain game from the previous section, in an loss game we have two agents, a Referee (Alice) and a Gambler (Bob), who has to make a payment to the Referee. In an loss game Bob is now asked to choose between two options: i) paying a fixed amount of wealth \( |w^F|, w^F \in [-w^M, 0] \) or ii) a bet. Choosing the bet means
Bob has to pay an amount of wealth according to the outcome of a PMF $p_W$. Similarly to the gain game, we address some quantities of interest: expected debt ($E(W)$), expected utility ($E[u(W)]$), and the certainty equivalent ($CE$) $w^{CE}(u, p_W)$, as the amount of wealth $w^{CE}$ such that $u(w^{CE}) = E[u(W)]$. We note the $CE$ depends on the utility function $u$ representing the Player, and the PMF $p_W$ representing the bet. The $CE$ is the amount of wealth that Bob pays to Alice, which generates the same level of (dis)satisfaction, had Bob opted for the bet instead. We also note here that both the expected debt and the certainty equivalent are now negative quantities.

We now analyse the meaning of the certainty equivalent in loss games, i.e., where Bob (the Gambler) has to choose between having to pay a certain fixed amount of wealth (fixed debt) $|w^F|$, or paying an average amount (average debt) $|E[W]|$. The rational decision for Bob is to pick which of the two options he is more satisfied (equivalently, we could say least dissatisfied) with. We then see that if we set $w^F < w^{CE}$ he then will choose to take the bet, if $w^F > w^{CE}$ he will choose to pay the fixed amount, and if $w^F = w^{CE}$ he can rationally pick either. That is, we see that the certainty equivalent $w^{CE}$ again sets here the boundary between which option Bob will pick in an loss game.

We now compare Bob’s expected debt $E[W]$ and the certainty equivalent of the bet $w^{CE}$. We have the three possible scenarios,

\[
\begin{align*}
&w^{CE} < E[W], \quad \leftrightarrow \quad |w^{CE}| > |E[W]|, \quad (11) \\
&w^{CE} > E[W], \quad \leftrightarrow \quad |w^{CE}| < |E[W]|, \quad (12) \\
&w^{CE} = E[W], \quad \leftrightarrow \quad |w^{CE}| = |E[W]|. \quad (13)
\end{align*}
\]

In the first case (11), Alice can request from Bob a fixed amount of wealth $|w^F|$ as $w^{CE} < w^F < E[W]$, which is equivalent to $|w^{CE}| > |w^F| > |E[W]|$ and Bob will still prefer to pay this amount over opting for the bet, even though he will potentially have to pay less $|E[W]|$, on average, had he opted for the bet. In other words, Bob is reluctant to take the bet, and so we see that he is risk-averse.

In the second case (12), if Alice wants to make Bob walk away from choosing the bet, and accept paying a fixed amount of wealth instead, she will have to offer him a deal where he has to pay less than the CE (and in turn less than the expected debt). In other words, in this case Bob is confident that the bet will allow him to pay less than the expected debt. That is, Bob will choose paying a fixed amount $|w^F|$ only if $w^F > w^{CE} > E[W]$, which is equivalent to $|w^F| < |w^{CE}| < |E[W]|$. Here Bob can then be considered as risk-seeking, because he is hopeful/optimistic about having the chance of paying less than the expected debt.

Taking into account the utility function is still an strictly increasing function for negative wealth, together with the definition of the certainty equivalent we get:

\[
\begin{align*}
E[u(W)] &< u(E[W]), \quad (14) \\
E[u(W)] &> u(E[W]), \quad (15) \\
E[u(W)] &= u(E[W]). \quad (16)
\end{align*}
\]

This means that in an loss game we can also characterise the risk tendencies of a Gambler in terms of the concavity/convexity/linearity of his utility function as: risk-averse (concavity (14)), risk-seeking (convexity (15)), risk-neutral (linear (16)). This characterisation of risk tendencies and the types of games are going to be useful later on when introducing more elaborate games in the form of operational tasks involving the discrimination or exclusion of quantum states. We now move on to the quantification of risk.

3. Quantifying risk tendencies

We can go one step further, and not only classify whether Bob (the Gambler) is risk-averse, risk-seeking, or risk-neutral, but moreover quantify how risk-averse he is. Let us start by addressing a gain game, which means we are interested in analysing Bob being represented by an utility function on positive wealth. Since Bob’s attitude toward risk relates to the concavity/convexity/linearity of the utility function $u$, it is natural that the second derivative of the function is going to play a role. This, because $u$ is concave on an interval if and only if its second derivative is non-positive on that interval. However, it is also desirable for measures representing risk to be invariant under affine transformations of the utility function, which in this context means that they are invariant under transformations of the form $u \rightarrow a + bu$, with $a, b \in \mathbb{R}$. This is because the actual values of utility aren’t themselves physical, but only the comparison between values, and therefore rescaling or displacing the utility should not alter how risk-averse we quantify Bob to be. Given these requirements, a natural measure that emerges is the so-called Relative Risk Aversion (RRA) measure$^1$:

\[
RRA(w) := -w \frac{u''(w)}{u'(w)}. \quad (17)
\]

This measure assigns positive values for risk-averse players in a gain game (concave utility functions of positive wealth) because we have: i) $w > 0$, because we are considering the player receiving money ii) $u''(w) < 0, \forall w$, because a risk-averse player in a gain game is represented by a concave function, and iii) $u'(w) > 0$, because the utility function is a strictly increasing function. An analysis of signs then yields $RRA(w) > 0$.

---

$^1$ An additional benefit of this quantifier is that it is dimensionless, which is not satisfied by all quantifiers of risk-aversion
Similarly, we now also analyse this measure of risk-aversion when Bob plays a loss game. A loss game is characterised by negative wealth, and we have already derived the fact that that a risk-averse Gambler is also characterised by a concave utility function. We now want to quantify the degree of risk-aversion of a Gambler playing the loss game, and therefore we then can proceed in a similar fashion as before, and define the risk-aversion measure RRA.

We now check that this measure assigns negative values for risk-averse players in a loss game (concave utility functions of negative wealth) because we have: i) $w < 0$ because we are considering the player paying money; ii) $u''(w) < 0$, $\forall w$, because a risk-averse player in a loss game is represented by a concave function, and iii) $u'(w) > 0$, because the utility function is a strictly increasing function. An analysis of signs yields $RRA(w) < 0$. We can see that this is the opposite to what happens in gain games, where $RRA(w) > 0$ represents risk-averse players. We highlight this fact in Table I, and present an analysis of the sign of the RRA measure for the two types of players (risk-averse or risk-seeking) and the two types of games (gain game or loss game).

TABLE I. Analysis of the sign of the quantity $RRA(w)$ for the different regimes being considered. We have that the utility function is always strictly increasing, meaning that $u'(w) > 0$, and therefore we then only need to analyse the signs of $w$ and $u''(w)$. In particular, we have that risk-averse players are represented by positive RRA when dealing with positive wealth, and by negative RRA when dealing with negative wealth.

4. The isoelastic certainty equivalent

We now note that the RRA measure does not assign a global value for how risk averse Bob is, but allows this to depend upon the wealth $w$, i.e. Bob may be more or less risk averse depending on the wealth that is at stake. In order to remove this, it is usual to consider those utility functions where Bob’s relative risk aversion is constant, independent of wealth. In this case, (17) can be solved assuming $RRA(w) = R$, which leads to the so-called isoelastic utility function for positive and negative wealth as:

$$u_R(w) := \begin{cases} 
\text{sgn}(w) \frac{|w|^{1-R}-1}{1-R}, & \text{if } R \neq 1 \\
\text{sgn}(w) \ln(|w|), & \text{if } R = 1 \end{cases} \quad (18)$$

with the auxiliary “sign” function:

$$\text{sgn}(w) := \begin{cases} 
1, & w \geq 0; \\
-1, & w < 0.
\end{cases} \quad (19)$$

The parameter $R$ varies from minus to plus infinity, describing all possible risk tendencies of Bob, for either positive or negative wealth. For positive wealth for instance, $R$ goes from maximally risk-seeking at $R = -\infty$, passing through risk-neutral at $R = 0$, to maximally risk-averse at $R = \infty$. In Fig. 2 we can see the behaviour of the isoelastic function for positive wealth and different values of $R$.

The certainty equivalent (4) for this setup can be calculated for either positive or negative wealth as:

$$w_R^{CE} = u_R^{-1}(\mathbb{E}[u_R(W)]) = \left( \sum_{w \in \mathcal{I}} w^{1-R} p(w) \right)^{\frac{1}{1-R}}. \quad (20)$$

The certainty equivalent (CE) of the isoelastic function, or isoelastic certainty equivalent (ICE), is going to be the figure of merit in the next section, and it is going to play an important role in this paper. As we have already seen, the CE stands out as an important quantity because it: i) determines the choice of a Gambler when playing either a gain or loss game, helping to establish the characterisation of risk tendencies of said Gambler and ii) optimising the CE is equivalent to optimising the expected utility, given that the utility function is a strictly increasing function and that $u(w^{CE}) = \mathbb{E}[u(W)]$. One may be tempted here to propose the expected utility function $\mathbb{E}[u(W)]$ as the figure of merit instead of the CE, but the expected utility unfortunately suffers from having the rather awkward set of units $|w|^{1-R}$, whilst the certainty equivalent...
on the other hand has simply units of wealth \([w]\) (\$, £, ...).

### B. Quantum state betting games played by Gamblers with different risk tendencies

We now introduce the main operational tasks that we consider in this work. We start by describing quantum state betting (QSB) games being played by Gamblers with different risk tendencies, as a generalisation (to the quantum domain) of the operational tasks known as horse betting games.

Horse betting (HB) games were first introduced by Kelly in 1956 [56], a modern introduction can be found, for instance, in Cover & Thomas [30], as well as in the lectures notes by Moser [59]. Recently, Bleuler, Lapidoth, and Pfister generalised HB games in order to include a factor \(\beta = 1 - R [34]\), representing the risk-aversion of the Gambler (Bob) playing these games, with standard HB games being recovered by setting \(\beta = 0\), corresponding to \(R = 1\), i.e. a risk-averse Bob. In this subsection we address this generalisation, including risk aversion and side information, and further generalise it to the quantum domain, in what we address as quantum state betting (QSB) games. Specifically, we will address two variants of QSB games in the form of quantum state discrimination (QSD) with risk, and quantum state exclusion (QSE) with risk. We then will address the isoelastic certainty equivalent (ICE) as the figure of merit for QSB (QSE) with risk. We also note that the PMF \(p_X\) from the ensemble of states together with the conditional PMF \(p_{G|X}\) from the measurement implemented by Bob, defines the joint PMF \(p_{XG} := p_{G|X}p_X\).

Therefore, when the quantum state was \(\rho_x\), and Bob obtained the measurement outcome \(g\), he bet the proportion of his wealth \(b(x|g)\) on the actual state, and hence Alice either pays out \(w(x,g) = o(x)b(x|g)\) in the case of a gain game, or Bob has to pay Alice the amount \(|w(x,g)|\) (i.e. he loses \(|w(x,g)|\)) in a loss game. We can view gain games as a generalisation of state discrimination. Here, since Bob is winning money, it is advantageous, in general, for him to correctly identify the state that was sent. On the other hand, we see that loss games can be viewed as a generalisation of state exclusion, since now in order to minimise his losses, it is useful for Bob to be able to avoid or exclude the state that was sent.

Finally, we note that the settings of the game are specified by the pair \((o_X, E)\). It is important to stress that by assumption Bob is fully aware of the settings of the game, meaning that the pair \((o_X, E)\) is known to him prior to playing the game, and therefore he can use this knowledge in order to select an optimal betting strategy \(b_X|G\).

#### 2. Figure of merit for quantum state betting games

Given these two variants of QSB games, we now want analyse the behaviour of different types of Gamblers (represented by different utility functions), according to their risk tendencies. We will consider quantities of interest like in the previous sections such as: expected wealth, expected utility, and similar. In particular, we model Gamblers with utility functions displaying constant relative risk aversion (CRRA) and therefore, the utility func-

---

2 That is, similarly to in thermodynamics, we take the sign of the odds to signify whether this is a gain or a loss for Bob.

3 Note that for loss games, Bob can end up having to pay out more than the wealth he bet (similarly to how in a game gain Bob can walk away with more wealth than he started with).
tions we consider are iselastic functions \( u_R(w) \) \((18)\). The figure of merit we are interested in is then the iselastic certainty equivalent (ICE) \( w^C_R \) with \( R \in \mathbb{R} \). For risk \( R \in (-\infty, 1) \cup (1, \infty) \), this quantity is given by:

\[
\begin{align*}
    w^C_R(b_{X|G}, \mathbb{M}, o_X, \mathcal{E}) &= u_R^{-1}\left(\mathbb{E}_{XG}[u_R(w_{XG})]\right), \\
    &= \left[\sum_{g,x} [b(x|g)o(x)]^{-R} p(g|x)p(x)\right]^{\frac{1}{-R}}. \quad (21)
\end{align*}
\]

The cases \( R \in \{1, \infty, -\infty\} \) are defined by continuous extension of \((21)\). In summary, the game is specified by the pair \((o_X, \mathcal{E})\), the behavioural tendency of Bob is represented by the utility function \( u_R(w_{XG}) \) with a fixed \( R \in \mathbb{R} \), the overall strategy of Bob is specified by the pair \((b_{X|G}, \mathbb{M})\), and the figure of merit here considered is the iselastic certainty equivalent (ICE) \((20)\). We can alternatively address these operational tasks as horse betting games with risk and quantum side information, or quantum horse betting (QHB) games for short, and we describe this in more detail later on.

Bob is in charge of the measurement and the betting strategy \((b_{X|G}, \mathbb{M})\), so in particular, for a fixed measurement \( \mathbb{M} \), Bob is interested in maximising the ICE (maximising gains in a gain game, and minimising losses in a loss game) so we are going to be interested in the following quantity:

\[
    \max_{b_{X|G}} w^C_R(b_{X|G}, \mathbb{M}, o_X, \mathcal{E}),
\]

for a fixed QSB game \((o_X, \mathcal{E})\) with either positive or negative odds, and Bob’s risk tendencies being fixed, and specified by an iselastic utility function \( u_R \).

3. Quantum state betting games generalise discrimination and exclusion games

We will now show that quantum state betting games with risk can indeed be seen as generalisations of standard quantum state discrimination and exclusion games. We can see this by considering a risk-neutral \((R = 0)\) Bob playing a gain game (positive odds) which are constant: \( o^c(x) := C, \forall x \), in which case we find that the quantity of interest becomes:

\[
    \max_{b_{X|G}} w^C_0(b_{X|G}, \mathbb{M}, o^c_X, \mathcal{E}) = C \max_{b_{X|G}} \sum_{g,x} b(x|g)p(g|x)p(x),
\]

\[
    = C P^\text{QSB}_{\text{succ}}(\mathcal{E}, \mathbb{M}). \quad (22)
\]

For more details on standard quantum state discrimination games we refer to \([12, 25]\). Therefore, standard quantum state discrimination can be seen as as special instance of quantum state betting games with constant odds, and played by a risk-neutral player. Similarly, for a loss game, with negative constant odds \( o^{-c}(x) := -C, \quad C > 0, \forall x: \)

\[
    \max_{b_{X|G}} w^C_0(b_{X|G}, \mathbb{M}, o^{-c}_X, \mathcal{E})
\]

\[
    = C \max_{b_{X|G}} - \sum_{g,x} b(x|g)p(g|x)p(x),
\]

\[
    = -C P^\text{QSE}_{\text{err}}(\mathcal{E}, \mathbb{M}). \quad (23)
\]

For more details on standard quantum state exclusion games we refer to \([26, 60]\). Therefore, standard quantum state exclusion can be seen as a quantum state betting game constant negative odds, again played by a risk-neutral player. We now move on to introduce some information-theoretic quantities.

C. Arimoto’s dependence measure and Rényi channel capacity in the theory of information

We start this subsection by introducing the dependence measures of interest (also known as measures of dependence \([34]\) or \(\alpha\)-mutual information measures \([35]\)) and particularly, Arimoto’s dependence measure \([37]\). A reminder note on notation before we start: we consider random variables (RVs) \((X, G, \ldots)\) on a finite alphabet \( \mathcal{X} \), and the probability mass function (PMF) of \( X \) represented as \( p_X(x) \geq 0, \forall x \in \mathcal{X} \), and \( \sum_{x \in \mathcal{X}} p_X(x) = 1 \). For simplicity, we omit the alphabet when summing, and write \( p_X(x) \) as \( p(x) \) when evaluating. The support of \( p_X \) as \( \text{supp}(p_X) := \{x | p(x) > 0\} \), the cardinality of the support as \( |\text{supp}(p_X)| \), and the extended line of real numbers as \( \mathbb{R} := \mathbb{R} \cup \{-\infty, \infty\} \). We now start by considering the Rényi entropy.

\textbf{Definition 1.} \((\text{Rényi entropy \([31]\)})\) The Rényi entropy of order \( \alpha \in \mathbb{R} \) of a PMF \( p_X \) is denoted as \( H_\alpha(X) \). The orders \( \alpha \in (-\infty, 0) \cup (0, 1) \cup (1, \infty) \) are defined as:

\[
    H_\alpha(X) := \frac{1}{1 - \alpha} \log \left( \sum_x p(x)^\alpha \right). \quad (24)
\]

The orders \( \alpha \in \{0, 1, \infty, -\infty\} \) are defined by continuous extension of \((24)\) as: \( H_0(X) := \log |\text{supp}(p_X)| \), \( H_1(X) := H(X) \), with \( H(X) := -\sum_x p(x) \log p(x) \) the Shannon entropy \([30]\), \( H_\infty(X) := -\log \max_x p(x) = -\log \rho_{\text{max}} \), and \( H_{-\infty}(X) := -\log \min_x p(x) = -\log \rho_{\text{min}} \). The Rényi entropy is a function of the PMF \( p_X \) and therefore, one can alternatively write \( H_\alpha(p_X) \).

However, we keep the convention of writing \( H_\alpha(X) \).

The Rényi entropy is mostly considered for positive orders, but it is also sometimes explored for negative values \([61-64]\). In this work we use the whole spectrum \( \alpha \in \mathbb{R} \). We now consider the Arimoto-Rényi extension of the conditional entropy.

\textbf{Definition 2.} \((\text{Arimoto-Rényi conditional entropy \([37]\)})\) The Arimoto-Rényi conditional entropy of order \( \alpha \in \mathbb{R} \)
of a joint PMF \( p_{XG} \) is denoted as \( H_\alpha(X|G) \). The orders \( \alpha \in (-\infty,0) \cup (0,1) \cup (1,\infty) \) are defined as:

\[
H_\alpha(X|G) := \frac{\alpha}{1-\alpha} \log \left( \sum_g \left( \sum_x p(x,g)^\alpha \right)^{\frac{1}{\alpha}} \right). \tag{25}
\]

The orders \( \alpha \in \{0,1,\infty,-\infty\} \) are defined by continuous extension of (25) as: \( H_0(X|G) := \log \max_g |\text{supp}(p_{X,G} = g)| \), \( H_1(X|G) := H(X|G) \), with \( H(X|G) := -\sum_{x,g} p(x,g) \log p(x|g) \) the conditional entropy [30], \( H_\infty(X|G) := -\log \max_g p(x,g) \), and \( H_{-\infty}(X|G) := -\log \min_g p(x,g) \). Arimoto-Rényi conditional entropy is a function of the joint PMF \( p_{XG} \) and therefore, one can alternatively write \( H_\alpha(p_{XG}) \). However, we keep the convention of writing \( H_\alpha(X|G) \).

We remark that there are alternative ways to Rényi-extend the conditional entropy [33]. The Arimoto-Rényi conditional entropy is however, the only one (amongst five alternatives [33]) that simultaneously satisfy the following desirable properties for a conditional entropy [33]: i) monotonicity, ii) chain rule, iii) consistency with the Shannon entropy, and iv) consistency with the \( \infty \) conditional entropy (also known as min-entropy). Consistency with the conditional entropy means that \( \lim_{\alpha \to 1} H_\alpha(X|G) = H(X|G) \), and similarly for property iv). In this sense, one can think about the Arimoto-Rényi conditional entropy as the “most appropriate” Rényi-extension (if not the outright “proper” Rényi extension) of the conditional entropy. We now consider Arimoto’s dependence measure, and its associated Rényi channel capacity.

**Definition 3.** (Arimoto’s dependence measure [37]) Arimoto’s dependence measure of order \( \alpha \in \mathbb{R} \) of a joint PMF \( p_{XG} \) is given by:

\[
I_\alpha(X;G) := \text{sgn}(\alpha) \left[ H_\alpha(X) - H_\alpha(X|G) \right], \tag{26}
\]

with the Rényi entropy (24) and the Arimoto-Rényi conditional entropy (25). The case \( \alpha = 1 \) reduces to the standard mutual information [30] \( I_1(X;G) = I(X;G) \), with \( I(X;G) := H(X) - H(X|G) \). Arimoto’s dependence measure is a function of the joint PMF \( p_{XG} \) and therefore, one can alternatively write \( I_\alpha(p_{XG}) \) or \( I_\alpha(\rho_{G|X}) \), the latter taking into account that \( p_{XG} = \rho_{G|X} p_X \). We use these three different notations interchangeably.

**Definition 4.** (Rényi channel capacity [37, 38, 65, 66]) The Rényi channel capacity of order \( \alpha \in \mathbb{R} \), of a conditional PMF \( \rho_{G|X} \) is given by:

\[
C_\alpha(\rho_{G|X}) := \max_{p_X} I_\alpha(\rho_{G|X} p_X) \tag{27}
\]

with the maximisation over all PMFs \( p_X \), and Arimoto’s dependence measure (26). The case \( \alpha = 1 \) reduces to the standard channel capacity [30] \( C_1(\rho_{G|X}) = C(\rho_{G|X}) = \max_{p_X} I(X;G) \).

We remark that there are alternative candidates as Rényi-extensions of the mutual information [33, 35]. In particular, we highlight the dependence measures of: Sibson [36], Csiszár [38], and Bleuler-Lapidoth-Pfister [34], which we address in the appendices as \( I_\alpha(X;G) \) with the label \( V \in \{ \text{BLP} \} \), representing each case. These dependence measures are going to be useful, in particular, due to their connection to conditional Rényi divergences. We address these information-theoretic quantities in Appendix A. We now extend these information-theoretic quantities to the quantum domain.

**D. Arimoto’s dependence measure and Rényi channel capacity in a quantum setting**

We now move on to describe Arimoto’s measure of dependence in this quantum setting, as well as the Rényi channel capacity.

**Remark 1.** (Arimoto’s dependence measure in a quantum setting) We address Arimoto’s dependence between two classical random variables encoded into quantum objects. Explicitly, the random variable \( X \) is encoded in an ensemble of states \( \mathcal{E} = \{ \rho_x, p(x) \} \) and therefore, we address it as \( X_\mathcal{E} \). On the other hand, \( G \) is considered as the random variable obtained from a decoding measurement \( D = \{ D_g = |g\rangle\langle g| \} \) and therefore, we address it as \( G_D \). We consider a conditional PMF as \( p_{G|X}^{(M,S)} \), given by \( p(g|x) := \text{Tr}[D_g \Lambda_M(\rho_x)] \), \( S := \{ \rho_x \} \) a set of states, and the quantum-to-classical (measure-prepare) channel associated to the measurement \( M \) given by:

\[
\Lambda_M(\sigma) := \sum_a \text{Tr}[M_a \sigma] |a\rangle\langle a|, \tag{28}
\]

with \( \{|a\} \) an orthonormal basis. We effectively have \( p(g|x) := \text{Tr}[M_g \rho_x] \) and therefore we can think about the decoding variable \( G_D = G_{G_D} \).We are now interested in dependence measures quantifying the dependence between variables \( X_\mathcal{E} \) and \( G_M \), when encoded and decoded in the quantum setting described previously. We then consider the Arimoto’s dependence measure:

\[
I_\alpha(X_\mathcal{E};G_M) := \text{sgn}(\alpha) \left[ H_\alpha(X_\mathcal{E}) - H_\alpha(X_\mathcal{E}|G_M) \right], \tag{29}
\]

with the standard Rényi entropy (24) and the Arimoto-Rényi conditional entropy (25) for the quantum conditional PMF described above.

**Remark 2.** (Rényi capacity of a quantum conditional PMF) The Rényi capacity of order \( \alpha \in \mathbb{R} \) of a quantum conditional PMF \( p_{G|X}^{(M,S)} \) is given by:

\[
C_\alpha(p_{G|X}^{(M,S)}) := \max_{p_X} I_\alpha(p_{G|X}^{(M,S)} p_X), \tag{30}
\]

with the maximisation over all PMFs \( p_X \).
The quantity we are interested in the quantum domain is the Rényi capacity of order $\alpha$ of a quantum-classical channel.

**Definition 5. (Rényi capacity of a quantum-classical channel)** The Rényi capacity of order $\alpha \in \mathbb{R}$ of a quantum-classical channel $\Lambda_M$ associated to the measurement $M$ is given by:

$$C_\alpha(\Lambda_M) := \max_{\mathcal{S}} C_\alpha \left( p_{G|X}^{(M,S)} \right) = \max_{\mathcal{E}} I_\alpha \left( p_{G|X}^{(M,S)} \right),$$

with the maximisation over all sets of states $\mathcal{S} = \{ \rho_x \}$ or over all ensembles $\mathcal{E} = \{ \rho_x, p(x) \}$.

We now address a resource-theoretic approach for the property of measurement informativeness.

**E. The quantum resource theory of measurement informativeness**

The framework of quantum resource theories (QRTs) has proven a fruitful approach towards quantum theory [4, 5]. In this work we focus on convex QRTs of measurements, with the resource of informativeness [12].

**Definition 6. (Convex QRT of measurement informativeness [12])** Consider the set of Positive-Operator Valued Measures (POVMs) acting on a Hilbert space of dimension $d$. A POVM $M$ is a collection of POVM elements $M = \{ M_a \}$ with $a \in \{1, ..., o\}$ satisfying $M_a \geq 0 \quad \forall a$ and $\sum_a M_a = 1$. We now consider the resource of informativeness [12]. We say a measurement $N$ is uninformative when there exists a PMF $q_N$ such that $N_a = q(a) \mathbb{1}$, $\forall a$. We say that the measurement is informative otherwise, and denote the set of all uninformative measurements as $\text{UI}$.

The set of uninformative measurements forms a convex set and therefore, defines a convex QRT of measurements. We now introduce the notion of simulability of measurements, which is also called classical post-processing (CPP).

**Definition 7. (Simulability of measurements [12, 67])** A measurement $N = \{ N_x \}, x \in \{1, ..., k\}$ is simulable by the measurement $M = \{ M_a \}, a \in \{1, ..., o\}$ when there exists a conditional PMF $q_{N|A}$ such that: $N_x = \sum_a q(x|a)M_a, \forall x$. The simulability of measurements defines a partial order for the set of measurements which we denote as $N \leq M$, meaning that $N$ is simulable by $M$. Simulability of the measurement $N$ can alternatively be understood as a classical post-processing of the measurement $M$.

Two quantifiers for informativeness are the following.

**Definition 8. (Generalised robustness and weight of informativeness)** The generalised robustness [7, 12] and the weight [19, 26] of informativeness of a measurement $M$ are given by:

$$R(M) := \min_{\mathcal{N} \in \text{UI}} \{ r \mid M_a + rM_a^G = (1 + r)N_a \},$$

$$W(M) := \min_{\mathcal{N} \in \text{UI}} \{ w \mid M_a = wM_a^G + (1 - w)N_a \}.$$

The generalised robustness quantifies the minimum amount of a general measurement $M^G$ that has to be added to $M$ such that we get an uninformative measurement $N$. The weight on the other hand, quantifies the minimum amount of a general measurement $M^G$ that has to be used for recovering the measurement $M$.

These resource quantifiers are going to be useful later on. Here we finish with the preliminary concepts and theoretical tools needed to describe our main results which we do next.

**IV. MAIN RESULTS**

We now start with the presentation of the main results of this work. First, we relate Arimoto’s dependence measure (in the quantum domain) to the operational tasks of quantum betting games with risk. As corollaries of this result, we obtain the two previous known relationships relating: i) the accessible information to quantum state discrimination, and ii) the excludible information to quantum state exclusion. Second, using the insights from the previous result, we derive new quantum measured Rényi divergences for measurements. Third, we introduce resource monotones for the order generated by the simulability of measurements, which additionally recover the resource monotones of generalised robustness of resource, as well as the weight of resource. Taking all of these results into consideration, one arrives to the equations described in the summary of results, as well as to the diagram depicted in Fig. 1. Finally, we provide an alternative interpretation of quantum state betting in terms of quantum horse betting (QHB), and address a slightly generalised version of Result 1, where one does not need to invoke quantum theory, and show that Arimoto’s dependence measure quantifies now the advantage provided by side information, when comparing Gamblers playing the operational tasks of horse betting games.

**A. Arimoto’s dependence measure and quantum state betting games played by Gamblers with different risk tendencies**

The main motivation now is to compare the performance of two gamblers via the maximised isoelastic certainty equivalent (ICE) $\max_{b_{A|G}} w_{IC}^{CE} (b_{A|G}, M, \alpha_X, \mathcal{E})$. 
Specifically, we want to compare: i) a general gambler using a fixed measurement $M$ against ii) the best uninformative gambler, meaning a gambler who can implement any uninformative measurement $N \in UI$, or equivalently, a gambler described by the quantity $\max_{R \in UI} \max_{\delta \in \{0,1\}} w^E_R(b_{\delta}, N, \alpha, \mathcal{E})$. We have the following main result.

**Result 1.** Consider the a QSB game defined by the pair $(o_X^{\text{sgn}(\alpha)c}, \mathcal{E})$ with constant odds as $o_X^{\text{sgn}(\alpha)c}(x) := \text{sgn}(\alpha)C, C > 0, \forall x$, and an ensemble of states $\mathcal{E} = \{\rho_x, p(x)\}$. Consider a Gambler playing this game using a fixed measurement $M$ in comparison to a Gambler being allowed to implement any uninformative measurement $N \in UI$. Consider both Gamblers with the same attitude to risk, meaning that they are represented by isoelastic functions $u_R(W)$ with the risk parametrised as $R(\alpha) := 1/\alpha$. Each Gambler is allowed to play the game with the optimal betting strategies, meaning they can each propose a betting strategy independently from each other. Remembering that the Gamblers are interested in maximising the isoelastic certainty equivalent (ICE), we have the following relationship:

$$I(\alpha) (X_\mathcal{E}; G_M) = \text{sgn}(\alpha) \log \max_{b_{\delta}, C} w^E_R(b_{\delta}, N, \alpha, \mathcal{E}) .$$

This means that Arimoto’s dependence measure quantifies the ratio of the isoelastic certainty equivalent with risk $R(\alpha) := 1/\alpha$ of the game defined by $(o_X^{\text{sgn}(\alpha)c}, \mathcal{E})$, when the QSB game is being played with the best betting strategy, and when we compare a Gambler implementing a fixed measurement $M$ against a Gambler using any uninformative measurement $N \in UI$.

The full proof of this result is in Appendix B. We now analyse two cases of particular interest ($\alpha \in \{\infty, -\infty\}$), as the following corollaries.

**Corollary 1.** In the case $\alpha \to \infty$ we recover the result found in [12]. Explicitly, we have:

$$C_{\infty}(M) = \max_{\mathcal{E}} I_{\infty}(X_\mathcal{E}; G_M),$$

$$= \log \max_{\mathcal{E}} \frac{P^{\text{QSD}}(\mathcal{E}, M)}{\min_{\mathcal{E}} \frac{P^{\text{QSD}}(\mathcal{E}, N)}} ,$$

with the denominator being maximised over all uninformative measurements, and $P^{\text{QSD}}(\mathcal{E}, M)$ the probability of success in the quantum state discrimination (QSD) game defined by $\mathcal{E}$, with the Gambler using the measurement $M$, given explicitly by:

$$P^{\text{QSD}}(\mathcal{E}, M) := \max_{\mathcal{E}} \sum_{g, a} \delta^g q(g|x) p(a|x) p(x) ,$$

with $p(a|x) := \text{Tr}[M_a \rho_x]$, and the maximisation over all classical post-processing $q_{\mathcal{G}A}$. We remark that the Rényi capacity of order $\infty$ has also been called as the accessible min-information of a channel, and denoted as $I_{\infty}(A_M)$ [12, 41]. This means that quantum state betting with risk $(QSB_{R(\alpha)})$ becomes quantum state discrimination (QSD) when $\alpha \to \infty$.

**Corollary 2.** In the case $\alpha \to -\infty$ we recover the result found in [26]. Explicitly, we have:

$$C_{\infty}(M) = \max_{\mathcal{E}} I_{-\infty}(X_\mathcal{E}; G_M),$$

$$= -\log \min_{\mathcal{E}} \frac{P^{\text{QSE}}(\mathcal{E}, M)}{\min_{\mathcal{E}} \frac{P^{\text{QSE}}(\mathcal{E}, N)}} ,$$

with the denominator being minimised over all uninformative measurements, and $P^{\text{QSE}}(\mathcal{E}, M)$ the probability of error in the quantum state exclusion (QSE) game defined by $\mathcal{E}$, with the Gambler using the measurement $M$ explicitly given by:

$$P^{\text{QSE}}(\mathcal{E}, M) := \min_{\mathcal{E}} \sum_{g, a} \delta^g q(g|x) p(a|x) p(x) .$$

In Appendix C we provide further details on these two corollaries.

Result 1 establishes a connection between Arimoto’s dependence measure and the operational tasks of quantum state betting (QSB) games, which recovers two known cases at $\alpha \in \{\infty, -\infty\}$ [12, 26]. We start by noting that the right hand side of (34) is a completely operational quantity, which represents the advantage that an informative measurement provides when being used as a resource for QSB games, whilst the left hand side is the raw information-theoretic dependence measure proposed by Arimoto and consequently, this result provides an operational interpretation of Arimoto’s measure in the quantum domain.

Furthermore, it interprets the Rényi parameter as characterising the risk tendency of the Gamblers as $R = 1/\alpha$. It is also interesting to note that this works for all ensembles $\mathcal{E} = \{\rho_x, p(x)\}$, all measurements $M = \{M_g\}$, as well as for the whole range of the Rényi parameter $\alpha \in \mathbb{R}$, including negative values. We summarise the interpretation of this result in Fig. 3.

We also highlight here that Result 1 lies at the intersection of three major fields: quantum theory, information theory, and the theory of games and economic behaviour. We can see here how the concept of risk-aversion, from the economic sciences, has helped us to derive and address the operational tasks of quantum state betting. We
\begin{figure}[h]
\centering
\includegraphics[width=0.5\textwidth]{figure3.png}
\caption{Possible scenarios for quantum state discrimination (QSD) and quantum state exclusion (QSE) games being played by Gamblers with different risk tendencies: risk-averse, risk-seeking, or risk-neutral, with the risk being parametrised as \( R(\alpha) = 1/\alpha \). Result 1 establishes that Arimoto’s dependence measure quantifies the shaded region for \( \alpha \in \mathbb{R} \), meaning that it characterises risk-averse Gamblers playing either QSD (\( \alpha \geq 0 \)) and QSE games (\( \alpha < 0 \)). The left bottom corner (\( \alpha \to -\infty \)) and the top-right corner (\( \alpha \to \infty \)) represent the transition between a risk-averse Gambler playing QSD games and a maximally risk-averse Gambler playing QSE games.}
\end{figure}

We believe that this result has the potential to spark further cross-fertilisation of ideas between these three major areas of knowledge, with only this particular example currently being unfolded. In particular, and building on these results, we now propose new quantum Rényi divergences for measurements.

### B. Quantum Rényi divergences

Considering that the KL-divergence is of central importance in classical information theory, it is natural to consider quantum-extensions of such quantity. There are many ways to define quantum Rényi divergences \cite{68-74}, with most of the effort being concentrated on divergences as a functions of quantum states. Recently however, divergences and entropies for additional objects like channels and measurements have been started to be explored \cite{75-77}. We are now interested in addressing quantum Rényi divergences for measurements. The approach we take here takes inspiration from both: measured Rényi divergences for states \cite{74, 78, 79}, as well as Rényi conditional divergences in the classical domain \cite{34, 36, 38}. Explicitly, we invoke the measures for Rényi conditional divergences, and use them to define measured Rényi divergences for measurements.

**Definition 9.** (Measured quantum Rényi divergence of Sibson) The measured Rényi divergence of Sibson of order \( \alpha \in \mathbb{R} \) and a set of states \( \mathcal{S} = \{ \rho_x \} \) of two measurements \( \mathbf{M} = \{ M_x \} \) and \( \mathbf{N} = \{ N_y \} \) is given by:

\[
D^S_{\alpha}(\mathbf{M}||\mathbf{N}) := \max_{p_x} D_{\alpha} \left( p_{G|x}^{(M,S)} \left| \left| q_{G|x}^{(N,S)} \right| \right| p_{X} \right),
\]

with the maximisation over all PMFs \( p_{X} \) and the conditional PMFs \( p_{G|x}^{(M,S)} \) and \( q_{G|x}^{(N,S)} \) given by \( p(g|x) := \text{Tr}(M_g \rho_x) \), \( q(g|x) := \text{Tr}(N_g \rho_x) \), respectively, and \( D(\cdot||\cdot) \) the conditional Rényi divergence of Sibson \cite{36} which is defined in Appendix A.

We now use this measured Rényi divergence in order to define a distance measure with respect to a free set of interest, the set of uninformative measurements in this case.

**Definition 10.** (Measurement informativeness measure of Sibson) The measurement informativeness measure of Sibson of order \( \alpha \in \mathbb{R} \) and set of states \( \mathcal{S} \) of a measurement \( \mathbf{M} \) is given by:

\[
E^S_{\alpha}(\mathbf{M}) := \min_{\mathbf{N} \in \text{UI}} D^S_{\alpha}(\mathbf{M}||\mathbf{N}),
\]

with the minimisation over all uninformative measurements.

Interestingly, it turns out that this quantity becomes equal to a quantity which we have already introduced.

**Result 2.** The informativeness measure of Sibson is equal to the Rényi capacity of order \( \alpha \in \mathbb{R} \) of the measurement \( \mathbf{M} \) as:

\[
E^S_{\alpha}(\mathbf{M}) = C_{\alpha} \left( p_{G|x}^{(M,S)} \right),
\]

with the quantum-classical channel associated to the measurement \( \mathbf{M} \) \cite{28}.

The proof of this result is in Appendix D. This result establishes a connection between Rényi dependence measures (which are used to define the Rényi channel capacity) and quantum Rényi divergences of measurements (which are used to define the measurement informativeness measure). We now consider the quantity \( E_\alpha(\mathbf{M}) := \max_{\mathcal{S}} E^S_{\alpha}(\mathbf{M}) = C_{\alpha}(\Lambda_M) \) and analyse the particular cases of \( \alpha \in \{ \infty, -\infty \} \).

**Corollary 3.** The measurement informativeness measure of Sibson recovers the generalised robustness and the weight of resource at the extremes \( \alpha \in \{ \infty, -\infty \} \) as:

\[
E_{\infty}(\mathbf{M}) = \log \left[ 1 + R(\mathbf{M}) \right],
\]

\[
E_{-\infty}(\mathbf{M}) = -\log \left[ 1 - W(\mathbf{M}) \right],
\]

with the generalised robustness of informativeness \cite{32} \cite{12}, and the weight of informativeness \cite{33} \cite{20}.
This result follows from the fact that the Rényi channel capacity becomes the accessible min-information and the excludible information at the extremes $\alpha \in \{\infty, -\infty\}$, together with the results from [12] and [26]. Result 3 therefore establishes a connection between Rényi dependence measures and quantum Rényi divergences of measurements. Inspired by these results, we now proceed to propose a family of resource monotones.

C. Resource monotones

Resource quantifiers are special cases of resource monotones, which are central objects of study within QRTs [5, 28]. Two common families of resource monotones are the so-called robustness-based [6, 8–17] and weight-based [8, 19–22] resource monotones. Inspired by the previous results, we now define measures which turn out to be monotones recovering, at its extremes, the generalised robustness characterising discrimination games, and the weight of resource characterising exclusion games. We now also have that the $\alpha$-measure of informativeness defines a resource monotone for the simulability of measurements.

**Definition 11.** (\(\alpha\)-measure of informativeness) The \(\alpha\)-measure of informativeness of order \(\alpha \in \mathbb{R}\) of a measurement \(M\) is given by:

\[
M_{\alpha}(M) := \text{sgn}(\alpha)2^{\text{sgn}(\alpha)E_{\alpha}(M)} - \text{sgn}(\alpha),
\]

with \(E_{\alpha}(M) := \max_{\mathcal{S}} E_{\alpha}^{\mathcal{S}}(M)\) and the measurement informativeness measure defined in (40).

The motivation behind the proposal of this resource measure is because: i) it recovers the generalised robustness and the weight of resource as \(M_{\infty}(M) = R(M)\) and \(M_{-\infty}(M) = W(M)\) and, ii) it allows the following operational characterisation.

**Remark 3.** They \(\alpha\)-measure of informativeness of order \(\alpha \in \mathbb{R}\) of a measurement \(M\) characterises the performance of the measurement \(M\), when compared to the performance of all possible uninformative measurements, when playing the same QSB game as:

\[
\max_{b_{X|G}|G} \max_{\varepsilon} \min_{\mathcal{N} \in \mathcal{U}} w_{\alpha}^{\mathcal{N}} \left( b_{X|G}, \mathcal{N}, \sigma_X^{\mathcal{N}} \right) = 1 + M_{\alpha}(M),
\]

\[
\min_{b_{X|G}|G} \max_{\varepsilon} \max_{\mathcal{N} \in \mathcal{U}} w_{\alpha}^{\mathcal{N}} \left( b_{X|G}, \mathcal{N}, \sigma_X^{\mathcal{N}} \right) = 1 - M_{\alpha}(M),
\]

for \(\alpha \geq 0\) and \(\alpha < 0\), respectively. These two equalities follow directly from the definitions and the previous results.

This result is akin to the connections between generalised robustness characterising discrimination games, and the weight of resource characterising exclusion games. We now also have that the $\alpha$-measure of informativeness defines a resource monotone for the simulability of measurements.

**Result 3.** (The $\alpha$-measure of informativeness is a resource monotone) The $\alpha$-measure of informativeness (44) defines a resource monotone for the simulability of measurements, meaning that it satisfies the following properties, (i) Faithfulness: \(M_{\alpha}(M) = 0 \iff \mathcal{M} = \mathcal{M}_{\alpha} = g(\alpha)\mathcal{I}\) and (ii) Monotonicity under measurement simulation: \(\mathcal{N} \leq \mathcal{M} \Rightarrow M_{\alpha}(\mathcal{N}) \leq M_{\alpha}(\mathcal{M})\).

The proof of this result is in Appendix E. It would be interesting to find a geometric interpretation of this measure, in a similar manner that its two extremes admit a geometric interpretation as in (32) and (33), as well as to explore additional properties, like convexity, in order to talk about it being a resource quantifier. It would also be interesting to explore additional monotones, in particular, whether the isoelastic certainty equivalent forms a complete set of monotones for the simulability of measurements, this, given that this holds for the two extremes at plus and minus infinity.

We now describe a slightly generalised version of Result 1, relating Arimoto’s dependence measure to horse betting games with side information.

D. Arimoto’s dependence measure and horse betting games with risk and general side information

We now consider horse betting (HB) games with risk and side information without making reference to quantum mechanics, and present a slightly more general version of result 1, which interprets Arimoto’s dependence measure as quantifying the advantage provided by side information when playing horse betting games.

We consider here the Gambler now having access to a random variable \(G\), which is potentially correlated with the outcome of the ‘horse race’ \(X\) and therefore, the Gambler can try to use this for her/his advantage. This means that these horse betting games are defined by the pair \((\rho_X, p_{G|X})\), and the Gambler is in charge of proposing the betting strategy \(b_{X|G}\). We highlight here that this contrasts the case of QSB games, because there the Gambler could in principle be in charge of intervening in the conditional PMF \(p_{G|X}\), as the Gambler had access to a measurement and \(p_{G|X} = \text{Tr}(M_{\rho}p_{X})\), whilst here on the other hand, \(p_{G|X} = p_{G|X}p_{X}\) is a given, and the Gambler cannot influence \(p_{G|X}\). However, the figure of merit is still the isoelastic equivalence measure for risk \(R \in (-\infty, 1) \cup (1, \infty)\) which we now write as:

\[
\omega_{\alpha}^{G}(b_{X|G}, \rho_X, p_{XG}) := \sum_{g \neq x} [b(x|g)\rho(x)]^{1-R} p(x, g) \frac{1}{1+R}.\]

(47)
The cases $R \in \{1, \infty, -\infty\}$ are defined again by continuous extension of (47). A HB game is then specified by the pair $(\alpha, p_{GX})$, and the Gambler plays this game with a betting strategy $b_{X|G}$.

The operational tasks of HB games were characterised by Bleuler, Lapidoth, and Pfister (BLP), in terms of the BLP-CR divergence [34] (see Appendix A for more details on this). We now modify these tasks in order to consider both gain games (when the odds are positive) and loss games (when the odds are negative), and relate Arimoto’s dependence measure to HB games with the following result, which can be derived in a similar manner as result 1.

**Result 4.** Consider a horse betting game defined by the pair $(\alpha_{X}, p_{XG})$ with constant odds as $\alpha_{X} := \text{sgn}(\alpha) C$, $C > 0$, $\forall \alpha$, and a joint PMF $p_{XG}$. Consider a Gambler playing these game having access to the side information $G$, against a Gambler without access to any side information. Consider both Gamblers with the same attitude to risk, meaning they are represented by isoelastic functions $u_{R}(w)$ with the risk parametrised as $R_{\alpha} := 1/\alpha$. The Gamblers are allowed to play these games with the optimal betting strategies, which they can each choose independently from each other. Remembering that the Gamblers are interested in maximising the isoelastic certainty equivalent, we have the following relationship:

$$I_{\alpha}(X; G) = \text{sgn}(\alpha) \log \left[ \max_{b_{X|G}} w_{CE}^{G}(b_{X|G}, \alpha_{X}, p_{XG}) \right] \max_{b_{X}} w_{CE}(b_{X}, \alpha_{X}, p_{X}) . \quad (48)$$

This means that Arimoto’s dependence measure quantifies the ratio of the isoelastic certainty equivalent with risk $R_{\alpha} := 1/\alpha$ of the games defined by $(\alpha_{X}, p_{XG})$, when each HB game is played with the best betting strategy, and we compare the performance of a first Gambler who makes use of the side information $G$, against a second gambler which has no access to side information.

We emphasise that this result is purely ”classical”, as it does not invoke any elements from quantum theory. It also complements a previous relationship between HB games and the BLP-CR divergence [34]. Here on the other hand we characterise instead the ratio between the two HB scenarios, where we compare two Gamblers, a first gambler with access to side information against a second gambler having no access to side information. We now address a particular known case as the following corollary.

**Corollary 4.** In the case $\alpha = 1$, which means HB games with risk aversion given by $R = 1$, we get:

$$I(X; G) = \max_{b_{X|G}} U_{0}(b_{X|G}, \alpha_{X}, p_{XG}) - \max_{b_{X}} U_{0}(b_{X}, \alpha_{X}, p_{X}) . \quad (49)$$

with $I_{1}(X; G) = I(X; G)$ the standard mutual information, and $U_{0} := \log w_{CE}^{G}$ the logarithm of the isoelastic certainty equivalent. This is a particular case of a relationship known to hold for all odds $o(x)$ [30, 59].

**V. CONCLUSIONS**

In this work, we have proposed that using ideas of risk-aversion and utility theory are a powerful way of extending the well studied tasks of quantum state discrimination and quantum state exclusion. We have shown that this places two recently discovered four-way correspondences [12, 26] into a much broader continuous family of correspondences. For the first time, this shows that there exist deep connections between operational state identification tasks, dependence measures, Rényi divergences, and resource monotones.

In more detail, first, we introduced the operational tasks of quantum state betting games, as a generalisation of horse betting games [34, 56] to the quantum domain, where the side information is now encoded as an ensemble of states, which Bob needs to decode by means of a measurement, in order to try to use it for his advantage, and consequently propose an optimal possible betting strategy. We prove that when we consider a gambler who is risk-averse, then Arimoto’s dependence measure [37], in the quantum domain, quantifies the multiplicative increase in their isoelastic certainty equivalent when using a given (potentially informative) measurement, compared to using the best uninformative measurement (i.e. having to disregard the quantum side information).

Second, related to the above, we also proved that in a purely classical setting (meaning without invoking quantum theory), more generally Arimoto’s dependence measure quantifies how useful side-information is. In particular, it quantifies the multiplicative increase in the isoelastic certainty equivalent of the gambler when given the side information, over not having access to it. This result complements the results of Bleuler, Lapidoth, and Pfister, where HB games were characterised in terms of the Rényi divergence and the BLP-CR-divergence [34], without explicitly characterising this ratio. Our result can be seen as giving a very clean operational interpretation of Arimoto’s dependence measure, and that the Rényi parameter can be understood operationally as quantifying the risk aversion of a gambler.

Third, we proposed a set of new measured quantum Rényi divergences for measurements, in terms of the conditional Rényi divergences of Sibson [36]. Finally, we introduced a new family of resource monotones for the QRT of measurement informativeness. These resource monotones recover, as limiting cases, the generalised robustness of informativeness [7, 12] and the weight of informativeness [19, 26].

All of the above elements are elegantly connected via a four-way correspondence, which substantially extended the two correspondences previously uncovered [12, 26],...
which we now understand to be the two extremes of a
continuous spectrum.

We believe our results are the start of a much broader
and deeper investigation into the use of risk-aversion,
utility theory, and other ideas from economics, to obtain
a broader unified understanding of many topics in quan-
tum information theory. Our results raises many ques-
tions and opens up various avenues for future research, a
number of which we briefly describe below.

A. Open problems, perspectives, and avenues for
future research

1. In this first investigation, we have restricted our
attention exclusively to a very simple resource the-
ory – that of measurement informativeness. There
is no reason to believe that the results found here
are not much more general, and it will be impor-
tant to show that they extend in a straightforward
way when considering other resources for measure-
ments. Moreover, it will also be interesting to de-
velop the ideas presented here to other QRTs, with
different resourceful objects besides measurements,
such as states and channels.

2. An exciting broad possibility, is to explore more
generally the concept of risk aversion in quantum
information theory. This is a concept which we are
just starting to understand and incorporate into the
theory of information and therefore, we believe this
is an exciting avenue of research which could have
far-reaching implications when considered for addi-
tional operational tasks, like Bell-nonlocal games,
and interactive proof systems.

3. Similarly, the scenario here considered represents
the convergence of three major research fields: i) quan-
tum theory, ii) information theory and iii) the
theory of games and economic behaviour. Specifi-
cally, we borrowed the concept of risk aversion from
the economic sciences in order to solve an open
problem in quantum information theory. We be-
lieve that this is just an example of the benefits
that can be obtained from considering the cross-
fertilisation of ideas between these three major cur-
rent research fields. Consequently, it would be in-
teresting to keep importing further concepts (in addi-
tion to risk aversion), as well as to explore the
other direction, i. e., whether quantum informa-
tion theory can provide insights into the theory of
games and economic behaviour. We believe this can
be a fruitful approach for future research. In par-
ticular, horse betting games are a particular family
of a larger family of tasks which are related to the
investment in portfolios [30], and it therefore would
be interesting to explore quantum versions of the
operational tasks that emerge in these scenarios.

4. The set of connections we have established here are
by means of the Rényi entropies, and we have seen
that the parameter \( \alpha \) is intimately linked to the risk
aversion of a gambler. It is interesting to speculate
whether other types of connections might be possi-
ble. For example, Brandao [80] previously found a
family of entanglement witnesses that encompassed
both the generalised robustness and the weight of
entanglement. We do not know if this is intimately
related with our findings here, or whether our in-
sights might shed further light, e.g. operational
significance, on these entanglement witnesses and
their generalisations.

5. We were led to introduce new measured quantum
Rényi divergences for measurements in this work.
We believe that they should find relevance and ap-
lication in settings far removed from the specific
setting we considered here. It would also be in-
teresting to further explore their relevance in other
other areas within quantum information theory.

6. We have also introduced new resource monotones,
for which we do not yet have a full understand-
ing. In particular, unlike numerous other mono-
tones, these do not yet have an obvious geometric
interpretation. It would be interesting to develop
such ideas further.

7. It would be interesting to explore additional mono-
tones, in particular, whether the isoelastic certainty
equivalent \( \omega_{R(\alpha)} \) forms (for all \( \alpha \)) a complete set of
monotones for the order induced by the simulabil-
ity of measurements, this, given that this is the case
for the two extremes at \( \alpha \in \{ \infty, -\infty \} \) [12, 26].

8. We point out that we have used information-
theoretic quantities with the Rényi parameter \( \alpha \)
taking both positive and negative values. Whilst
negative values have been explored in the liter-
ature, it is fair to say that they have not been
the main focus of attention. Here we have proven
that information-theoretic quantities with negative
orders posses a descriptive power different from
their positive counterparts and therefore, it would
be interesting to explore their usefulness in other
information-theoretic scenarios.

ACKNOWLEDGEMENTS

We thank Patryk Lipka-Bartosik, Tom Purves, Noah
Linden, and Roope Uola for insightful discussions.
A.F.D. acknowledges support from COLCIENCIAS 756-
2016 and the UK EPSRC (EP/L015730/1). P.S. ac-
nowledges support from a Royal Society URF (UHQT).
Appendix A: Rényi divergence, conditional-Rényi divergences, dependence measures, and Rényi channel capacity

In this Appendix we address the information-theoretic quantities represented in Fig. 4 namely, the Rényi divergence, the conditional Rényi (CR) divergences of Sibson, Csiszár, and Bleuler-Lapidoth-Pfister, their respective dependence measures, and the Rényi channel capacity.

\[ D_\alpha(p_X||q_X) := \frac{\text{sgn}(\alpha)}{\alpha - 1} \log \left( \sum_x p(x)^\alpha q(x)^{1-\alpha} \right). \]  \hfill (A1)

The orders \( \alpha \in \{1,0,\infty,-\infty\} \) are defined by continuous extension of (A1) as:

\[ D_1(p_X||q_X) := D(p_X||q_X), \] \hfill (A2)

\[ D_0(p_X||q_X) := -\log \sum_{x \in \text{supp}(p_X)} q(x), \] \hfill (A3)

\[ D_\infty(p_X||q_X) := \log \max_x \frac{p(x)}{q(x)}, \] \hfill (A4)

\[ D_{-\infty}(p_X||q_X) := -\log \min_x \frac{p(x)}{q(x)}. \] \hfill (A5)

with the standard Kullback-Leibler (KL) divergence given by \( D(p_X||q_X) := \sum_x p(x) \log \frac{p(x)}{q(x)} \) [29, 30].

2. Conditional-Rényi divergences

Definition 13. (Sibson’s conditional-Rényi divergence [36]) The Sibson’s conditional-Rényi divergence (S-CR-divergence) of order \( \alpha \in \mathbb{R} \) of PMFs \( p_{X|G}, q_{X|G} \), and \( p_X \) is denoted as \( D_\alpha^{S}(p_{G|X}||q_{G|X}||p_X) \). The orders \( \alpha \in \mathbb{R} \) are defined as:

\[ D_\alpha^{S}(p_{G|X}||q_{G|X}||p_X) := \frac{\text{sgn}(\alpha)}{\alpha - 1} \log \left( \sum_x p(x)^\alpha q(x)^{1-\alpha} \right). \]  \hfill (A6)

The orders \( \alpha \in \{1,0,\infty,-\infty\} \) are defined by continuous extension of (A6) as:

\[ D_1^{S}(p_{G|X}||q_{G|X}||p_X) := D(p_{G|X}||q_{G|X}||p_X), \] \hfill (A7)

\[ D_0^{S}(p_{G|X}||q_{G|X}||p_X) := -\log \sum_{x \in \text{supp}(p_X)} q(x), \] \hfill (A8)

\[ D_\infty^{S}(p_{G|X}||q_{G|X}||p_X) := \log \max_x \frac{p(x)}{q(x)}, \] \hfill (A9)

\[ D_{-\infty}^{S}(p_{G|X}||q_{G|X}||p_X) := -\log \min_x \frac{p(x)}{q(x)}. \] \hfill (A10)

with the standard Kullback-Leibler (KL) divergence given by \( D(p_{G|X}||q_{G|X}||p_X) := \sum_x p(x) \log \frac{p(x)}{q(x)} \) [29, 30].
(\(-\infty,0\) \cup (0,1) \cup (1,\infty) are defined as:

\[
D^S_\alpha(p_{G|X}||q_{G|X}|p_X) := \frac{\text{sgn}(\alpha)}{\alpha - 1} \log \sum_x p(x) \left( \sum_g p(g|x)^\alpha q(g|x)^{1-\alpha} \right).
\] (A6)

The orders \(\alpha \in \{1,0,\infty,-\infty\}\) are defined by continuous extension of \((A6)\) as:

\[
D^S_1(p_{G|X}||q_{G|X}|p_X) := D(p_{G|X}||q_{G|X}|p_X), \tag{A7}
\]
\[
D^S_0(p_{G|X}||q_{G|X}|p_X) := - \log \sum_{x \in \text{supp}(p_X)} p(x) \sum_{g \in \text{supp}(p_{G|X}||p_X)} q(g|x), \tag{A8}
\]
\[
D^S_\infty(p_{G|X}||q_{G|X}|p_X) := - \log \max_{x \in \text{supp}(p_X)} \frac{p(g|x)}{q(g|x)}, \tag{A9}
\]
\[
D^{S-}_\infty(p_{G|X}||q_{G|X}|p_X) := - \log \min_{x \in \text{supp}(p_X)} \frac{p(g|x)}{q(g|x)}, \tag{A10}
\]

with the conditional Rényi divergence given by \(D(p_{G|X}||q_{G|X}|p_X) := D(p_{G|X}||p_X)\), the latter being the standard KL-divergence \([29,30]\).

**Definition 14.** (Csiszár’s conditional-Rényi divergence \([38]\)) The Csiszár’s conditional-Rényi divergence (C-CR-divergence) of order \(\alpha \in \mathbb{R}\) of PMFs \(p_{X|G},q_{X|G}\), and \(p_X\) is denoted as \(D^C_\alpha(p_{G|X}||q_{G|X}|p_X)\). The orders \(\alpha \in (-\infty,0) \cup (0,1) \cup (1,\infty)\) are defined as:

\[
D^C_\alpha(p_{G|X}||q_{G|X}|p_X) := \frac{\text{sgn}(\alpha)}{\alpha - 1} \sum_x p(x) \log \left( \sum_g p(g|x)^\alpha q(g|x)^{1-\alpha} \right). \tag{A11}
\]

The orders \(\alpha \in \{1,0,\infty,-\infty\}\) are defined by continuous extension of \((A11)\) as:

\[
D^C_1(p_{G|X}||q_{G|X}|p_X) := D(p_{G|X}||q_{G|X}|p_X), \tag{A12}
\]
\[
D^C_0(p_{G|X}||q_{G|X}|p_X) := - \sum_{x \in \text{supp}(p_X)} p(x) \log \sum_{g \in \text{supp}(p_{G|X}||p_X)} q(g|x), \tag{A13}
\]
\[
D^C_\infty(p_{G|X}||q_{G|X}|p_X) := \sum_{x \in \text{supp}(p_X)} p(x) \log \left( \max_{g} \frac{p(g|x)}{q(g|x)} \right), \tag{A14}
\]
\[
D^{C-}_\infty(p_{G|X}||q_{G|X}|p_X) := - \sum_{x \in \text{supp}(p_X)} p(x) \log \left( \min_{g} \frac{p(g|x)}{q(g|x)} \right), \tag{A15}
\]

with the conditional Rényi divergence given by \(D(p_{G|X}||q_{G|X}|p_X) := D(p_{G|X}||p_X)\), the latter being the standard KL-divergence \([29,30]\).

**Definition 15.** (Bleuler-Lapidoth-Pfister conditional-Rényi divergence \([34,57]\)) The Bleuler-Lapidoth-Pfister conditional-Rényi divergence (BLP-CR-divergence) of order \(\alpha \in \mathbb{R}\) of PMFs \(p_{X|G},q_{X|G}\), and \(p_X\) is denoted as \(D^\text{BLP}_\alpha(p_{G|X}||q_{G|X}|p_X)\). The orders \(\alpha \in (-\infty,0) \cup (0,1) \cup (1,\infty)\) are defined as:

\[
D^\text{BLP}_\alpha(p_{G|X}||q_{G|X}|p_X) := \frac{l\alpha}{\alpha - 1} \log \sum_x p(x) \left( \sum_g p(g|x)^\alpha q(g|x)^{1-\alpha} \right)^{\frac{1}{\alpha}}. \tag{A16}
\]

The orders \(\alpha \in \{1,0,\infty,-\infty\}\) are defined by continuous extension of \((A16)\) as:

\[
D^\text{BLP}_1(p_{G|X}||q_{G|X}|p_X) := D(p_{G|X}||q_{G|X}|p_X), \tag{A17}
\]
\[
D^\text{BLP}_0(p_{G|X}||q_{G|X}|p_X) := - \log \max_{x \in \text{supp}(p_X)} \sum_{g \in \text{supp}(p_{G|X}||p_X)} q(g|x), \tag{A18}
\]
\[
D^\text{BLP}_\infty(p_{G|X}||q_{G|X}|p_X) := \log \sum_{x \in \text{supp}(p_X)} p(x) \max_{g} \frac{p(g|x)}{q(g|x)}, \tag{A19}
\]
\[
D^{\text{BLP}-}_\infty(p_{G|X}||q_{G|X}|p_X) := - \log \sum_{x \in \text{supp}(p_X)} p(x) \min_{g} \frac{p(g|x)}{q(g|x)}. \tag{A20}
\]

with the conditional Rényi divergence given by \(D(p_{G|X}||q_{G|X}|p_X) := D(p_{G|X}||p_X)\), the latter being the standard KL-divergence \([29,30]\).
3. Relationship between the Rényi divergence and CR divergences

Remark 4. ([34, 57]) Relating conditional Rényi divergences to the Rényi divergence. For any conditional PMFs \( p_{G|X}, q_{G|X} \), and any PMF \( p_X \) we have:

\[
D^S_\alpha(p_{G|X}||q_{G|X}|p_X) = D_\alpha(p_{G|X}p_X||q_{G|X}p_X), \tag{A21}
\]

\[
D^C_\alpha(p_{G|X}||q_{G|X}|p_X) = \sum_x p(x)D_\alpha(p_{G|X=x}|q_{G|X=x}). \tag{A22}
\]

4. Dependence measures

Definition 16. (Dependence measures of: Sibson [36], Csiszár [38], and Bleuler-Lapidoth-Pfister [34]) The dependence measures of Sibson, Csiszár, and Bleuler-Lapidoth-Pfister of order \( \alpha \in \mathbb{R} \) of a joint PMF \( p_{XG} \) are defined as:

\[
I^V_\alpha(X;G) := \min_{q_G} D^V_\alpha(p_{G|X}||q_G|p_X), \tag{A23}
\]

with the label \( V \in \{ S, C, BLP \} \) denoting each case, the minimisation being performed over all PMFs \( q_G \), and \( D^X_\alpha(\cdot||\cdot) \) the conditional Rényi (CR) divergences of: Sibson, Csiszár, and Bleuler-Lapidoth-Pfister, of order \( \alpha \in \mathbb{R} \), as defined previously. The case \( \alpha = 1 \) reduces, for all three cases, to the standard mutual information [30] \( I^V_1(X;G) = I(X;G) \). Similarly to Arimoto’s measure, we also use the notation \( I^S_\alpha(p_{XG}) \) and \( I^C_\alpha(p_{G|X}p_X) \) interchangeably.

5. Relationship between CR-divergences

Lemma 1. Consider the conditional-Rényi divergences of Sibson, Csiszár, and Bleuler-Lapidoth-Pfister, then:

\[
\alpha \in [-\infty, 0], \quad D^{BLP}_\alpha(\cdots) \leq D^C_\alpha(\cdots) \leq D^S_\alpha(\cdots), \tag{A24}
\]

\[
\alpha \in [0, 1], \quad D^{BLP}_\alpha(\cdots) \leq D^S_\alpha(\cdots) \leq D^C_\alpha(\cdots), \tag{A25}
\]

\[
\alpha \in [1, \infty], \quad D^C_\alpha(\cdots) \leq D^{BLP}_\alpha(\cdots) \leq D^S_\alpha(\cdots), \tag{A26}
\]

Proof. The cases \( \alpha \in [0, 1] \) and \( \alpha \in [1, \infty] \) have already been proven in the literature [34]. A similar argument can be followed in order to prove the cases \( \alpha \in [-\infty, 0] \). For completeness, we address it in what follows.

Part i) We start by proving that for \( \alpha \in [-\infty, 0] \) we have \( D^C_\alpha(\cdot||\cdot) \leq D^S_\alpha(\cdot||\cdot) \). We prove it for \( \alpha \in (-\infty, 0) \) and the extremes follow because of continuity. Starting from the Sibson’s measure times the positive factor \( (\alpha - 1) \) \( \text{sgn}(\alpha) \) we get:

\[
(\alpha - 1) \text{sgn}(\alpha)D^S_\alpha(p_{G|X}||q_G|p_X) = \log \left[ \sum_x p(x) \sum_g p(g|x)\alpha q(g|x)^{1-\alpha} \right], \tag{A27}
\]

\[
\geq \sum_x p(x) \log \left[ \sum_g p(g|x)\alpha q(g|x)^{1-\alpha} \right], \tag{A28}
\]

\[
= \text{sgn}(\alpha)(\alpha - 1)D^C_\alpha(p_{G|X}||q_G|p_X). \tag{A29}
\]

In the first equality we use the definition of the Sibson’s conditional Rényi divergence (A6). The inequality follows because of Jensen’s inequality [81], and because \( \log(\cdot) \) is a concave function. In the last equality we use the definition of the Csiszár’s conditional Rényi divergence (A11). Dividing both sides by \( \text{sgn}(\alpha)(\alpha - 1) \), which is positive because \( \alpha \in (-\infty, 0) \), proves the claim.

Part ii) We now want to prove that for \( \alpha \in [-\infty, 0] \), we have \( D^{BLP}_\alpha(\cdot||\cdot) \leq D^C_\alpha(\cdot||\cdot) \). Similarly, we prove it for
cases $\alpha \in (-\infty, 0)$ with the extremes following because of continuity. Starting from Csiszár’s measure:

$$D^C_\alpha (p_{G|X}||q_G|p_X) = \frac{\text{sgn}(\alpha)}{\alpha - 1} \sum_x p(x) \log \left( \sum_g p(g|x)^\alpha q(g|x)^{1-\alpha} \right), \quad (A30)$$

$$= \frac{|\alpha|}{\alpha - 1} \sum_x p(x) \log \left( \sum_g p(g|x)^\alpha q(g|x)^{1-\alpha} \right)^{\frac{1}{\alpha}}, \quad (A31)$$

$$\geq \frac{|\alpha|}{\alpha - 1} \log \left( \sum_x p(x) \left( \sum_g p(g|x)^\alpha q(g|x)^{1-\alpha} \right)^{\frac{1}{\alpha}} \right), \quad (A32)$$

$$= D^{\text{BLP}}_\alpha (p_{G|X}||q_G|p_X). \quad (A33)$$

The first equality we use the definition of Csiszár’s conditional Rényi divergence (A11). In the second equality we multiply by one $1 = \frac{\alpha}{\alpha}$ and re-organise conveniently. The inequality follows because of Jensen’s inequality [81], because $\log(\cdot)$ is a concave function, and because the coefficient $\frac{\text{sgn}(\alpha)\alpha}{\alpha - 1}$ is negative for $\alpha \in (-\infty, 0)$. In the last equality we use the definition of the Bleuler-Lapidoth-Pfister conditional Rényi divergence (A16).

6. Relationship between dependence measures

Lemma 2. Consider the dependence measures of Sibson, Csiszár, and Bleuler-Lapidoth-Pfister, then:

$$\alpha \in [-\infty, 0], \quad I^{\text{BLP}}_\alpha (\cdot|\cdot) \leq I^C_\alpha (\cdot|\cdot) \leq I^S_\alpha (\cdot|\cdot), \quad (A34)$$

$$\alpha \in [0, 1], \quad I^{\text{BLP}}_\alpha (\cdot|\cdot) \leq I^S_\alpha (\cdot|\cdot) \leq I^C_\alpha (\cdot|\cdot), \quad (A35)$$

$$\alpha \in [1, \infty], \quad I^C_\alpha (\cdot|\cdot) \leq I^{\text{BLP}}_\alpha (\cdot|\cdot) \leq I^S_\alpha (\cdot|\cdot), \quad (A36)$$

Proof. The cases $\alpha \in [0, 1]$ and $\alpha \in [1, \infty]$ were proven in [34], and they follow by considering the previous Lemma on the less or equal order between the conditional Rényi divergences and, by considering that the dependence measures are defined in terms of the conditional Rényi divergences by minimising over $p_X$ (A23). The cases $\alpha \in [-\infty, 0]$ follow the same argument.

7. The Rényi channel capacity

Having defined these dependence measures, we now address the fact that some of them become equal when maximising over PMFs $p_X$, whilst keeping fixed the conditional PMF $p_{G|X}$.

Lemma 3. (Rényi channel capacity [37, 38, 65]) The dependence measures of Arimoto and Sibson of order $\alpha \in \mathbb{R}$ become equal when maximised over $p_X$, and we refer to this quantity as the Rényi capacity of order $\alpha$. The Rényi capacity of order $\alpha \in \mathbb{R}$, of a conditional PMF $p_{G|X}$ is:

$$C_\alpha (p_{G|X}) := \max_{p_X} I^V_\alpha (p_{G|X}p_X), \quad (A37)$$

with $V \in \{A, S\}$, the maximisation over all PMFs $p_X$, and the dependence measure of Sibson as in (A23), and Arimoto’s dependence measure as in the main text. The case $\alpha = 1$ reduces to the standard channel capacity [30] $C_1 (p_{G|X}) = C(p_{G|X}) = \max_{p_X} I(X;G)$.

This Lemma, for the cases $\alpha \geq 0$, has been proven in different places in the literature [36, 38, 65]. For completeness, here we provide a proof for the cases $\alpha < 0$. We can understand this result as $C_\alpha (p_{G|X})$ being the Rényi capacity of the classical channel specified by the conditional PMF $p_{G|X}$, which simultaneously represents the dependence measures of Arimoto and Sibson. On can similarly address Rényi capacities using the rest of dependence measures, but using these two are enough for our purposes.
Proof. The cases for \( \alpha \in [0, \infty) \) have been proven in different places in the literature [37, 38, 65]. We therefore only address here the interval \((-\infty, 0)\). Addressing Arimoto’s measure for \( \alpha \in (-\infty, 0) \):

\[
\max_{p_X} I^A_{\alpha} (p_{G|X} p_X) = \max_{p_X} \frac{|\alpha|}{\alpha - 1} \log \sum_g \left( \sum_x p(g|x)^\alpha \frac{p(x)^\alpha}{\sum_{x'} p(x')^\alpha} \right)^{\frac{1}{\alpha}}, \tag{A38}
\]

\[
\frac{2}{\alpha - 1} \log \sum_g \left( \sum_x p(g|x) r(x) \right)^{\frac{1}{\alpha}}. \tag{A39}
\]

In the first equality we replaced and reorganised the definition of Arimoto’s dependence measure (26). In the second equality we use the fact that both maximisations are equal, because from an optimal \( p^*_X \), we can construct a feasible \( r_X \) as \( r(x) = p^*(x)^\alpha / (\sum_{x'} p^*(x')^\alpha) \) and conversely, from an optimal \( r^*_X \), we can construct a feasible \( p_X \) as \( p(x) = r^*(x)^{\frac{1}{\alpha}} / (\sum_{x'} r^*(x')^{\frac{1}{\alpha}}) \). We now relate the quantity in (A39) to the quantity obtained from Sibson’s. We now consider Sibson’s CR-divergence and invoke the identity [38] \( \forall p_{G|X}, q_G, p_X: \)

\[
D^S_{\alpha} (p_{G|X}||q_G|p_X) = D^S_{\alpha} (p_{G|X}||q^*_G|p_X) + D_{\alpha} (q^*_G|q_G), \tag{A40}
\]

with the PMF \( q^*_G \) given by:

\[
q^*_G(g) := \frac{\left( \sum_x p(x) p(g|x)^\alpha \right)^{\frac{1}{\alpha}}}{\sum_g \left( \sum_x p(x) p(g|x)^\alpha \right)^{\frac{1}{\alpha}}}. \tag{A41}
\]

This identity can be checked by directly substituting (A41) into the RHS of (A40). We can now get an explicit expression for Sibson’s dependence measure, because minimising (A40) over \( q_G \) is obtained for \( q_G = q^*_G \), this, because the Rényi divergence is non-negative for \( \alpha \in (-\infty, 0) \) [32]. We therefore get:

\[
I^S_{\alpha} (p_{G|X} p_X) = \min_{q_G} D^S_{\alpha} (p_{G|X}||q_G|p_X), \tag{A42}
\]

\[
= D^S_{\alpha} (p_{G|X}||q^*_G|p_X), \tag{A43}
\]

\[
= \frac{|\alpha|}{\alpha - 1} \log \sum_g \left( \sum_x p(x) p(g|x)^\alpha \right)^{\frac{1}{\alpha}}. \tag{A44}
\]

Maximising this quantity over \( p_X \) we get:

\[
\max_{p_X} I^S_{\alpha} (p_{G|X} p_X) = \max_{p_X} \frac{|\alpha|}{\alpha - 1} \log \sum_g \left( \sum_x p(x) p(g|x)^\alpha \right)^{\frac{1}{\alpha}}, \tag{A45}
\]

which is the same quantity than in (A39) for Arimoto’s measure. Altogether, we have that starting from either Sibson or Arimoto, we arrive to the same expression when maximising over \( p_X \), as per equations (A45) and (A39). Consequently, the capacities they each define are the same, and thus proving the claim. \( \square \)

8. Information-theoretic measures in the quantum domain

Dependence measures in the quantum domain are defined via their Rényi conditional divergences counterparts as:

\[
I^V_{\alpha} (X_E; G_M) := \min_{q_G} D^V_{\alpha} \left( p_{(M,S)}^{(M,S)} || q_G | p_X \right), \tag{A46}
\]

with the quantum conditional PMFs \( p_{G|X}^{(M,E)} \) and \( q_{G|X}^{(M,E)} \) given by \( p(g|x) := \text{Tr}(M_g \rho_x) \), \( q(g|x) := \text{Tr}(N_g \rho_x) \), respectively, the minimisation over all PMFs \( q_G \), and the classical conditional Rényi divergences of: Sibson, Csiszár, and Bleuler-Lapidoth-Pfister, which we address with a label \( V \in \{ \text{S, C, BLP} \} \).
Appendix B: Proof of Result 1

We start by mentioning that the operational tasks which are of interest to us are quantum state betting (QSB) games, but that from an operational point of view, they are equivalent to “horse betting games with risk and quantum side information”, or quantum horse betting (QHB) games for short. Given this equivalence, in this appendix we would address QSB games as QHB or HB games only.

In order to prove Result 1 we need two Theorems on the operational tasks of horse betting (HB) with risk: one for HB games without side information, and other for HB games with side information. These two Theorems depend on the of Rényi divergence and the BLP conditional Rényi divergence from Appendix A.

1. Preliminary steps

We start by addressing a simplified notation.

\[ w_R^{CE}(b_{X|G}, o_X, p_{XG}) := w_R^{CE}(b_{X|G}, M, o_X, \mathcal{E}), \]  

(B1)

with \( p(x, g) = p(g|x)p(x) \), \( p(g|x) = \text{Tr}[M_g \rho_x] \). We also notice that that optimising over uninformative measurements \( N \in \mathbb{U}_1 \), meaning \( N_g = p(g) \mathbb{1}, \forall g \), is equivalent to a horse betting game with risk but without side information because \( p(g|x) = \text{Tr}(N_g \rho_x) = p(g) \text{Tr}(\mathbb{1} \rho_x) = p(g) \) and then:

\[
\max_{b_{X|G}} \max_{b_{X,G}} \max_{p_g} w_R^{CE}(b_{X|G}, o_X, p_{XG}) = \max_{b_{X|G}} \max_{p_g} \left[ \sum_{g,x} \left[ b(x|g) o(x) \right]^{1-R} p_g(x) \right]^{\frac{1}{1-R}}, \quad \text{(B2)}
\]

\[
= \max_{b_{X|G}} \max_{p_g} \left[ \sum_{g,x} \left[ b(x|g) o(x) \right]^{1-R} p_g(x) \right]^{\frac{1}{1-R}}, \quad \text{(B3)}
\]

\[
= \max_{b_{X|G}} \left[ \sum_{x} \left( \max_{p_g} \sum_{g} b(x|g) o(x) \right)^{1-R} p(x) \right]^{\frac{1}{1-R}}, \quad \text{(B4)}
\]

\[
= \max_{b_{X|G}} \left[ \sum_{x} \left( \max_{g} b(x|g) o(x) \right)^{1-R} p(x) \right]^{\frac{1}{1-R}}, \quad \text{(B5)}
\]

\[
= \max_{b_{X|G}} \left[ \sum_{x} \left[ b(x) o(x) \right]^{1-R} p(x) \right]^{\frac{1}{1-R}}, \quad \text{(B6)}
\]

\[
= \max_{b_{X|G}} w_R^{CE}(b_{X,G}, o_X, p_{XG}). \quad \text{(B7)}
\]

This defines a HB game without side information, meaning without the random variable \( G \). We now define the auxiliary function of the logarithm of the isoelastic certainty equivalent as:

\[ U_R(b_{X|G}, o_X, p_{XG}) := \text{sgn}(o) \log \left| w_R^{CE}(b_{X|G}, o_X, p_{XG}) \right|, \quad \text{(B8)} \]

and similarly without side information as:

\[ U_R(b_{X,G}, o_X, p_{X}) := \text{sgn}(o) \log \left| w_R^{CE}(b_{X,G}, o_X, p_{X}) \right|, \quad \text{(B9)} \]

with \( \text{sgn}(o) \) as a shorthand for the sign of the odds \( o(x), \forall x \). We also highlight here that we are interested in the strategy that achieves:

\[ \max_{b_{X}} w_R^{CE}(b_{X}, o_X, p_{X}), \quad \text{(B10)} \]

and we can see that this is equivalent to finding the best strategy for the auxiliary optimisation:

\[ \max_{b_{X}} U_R(b_{X}, o_X, p_{X}). \quad \text{(B11)} \]
2. Horse betting games with risk

We now present two results on horse betting games. We remark here that we invoke these results, in contrast with the original presentation in [34], with the following modifications in the notation: i) the original version involves a parameter $\beta$, here instead we directly use the risk aversion parameter $R$, taking into account that these two parameters are related as $\beta = 1 - R$, ii) we have defined the Rényi divergence as a non-negative quantity, for all $\alpha \in \mathbb{R}$, even for negative values of alpha, and this explains the appearance of the term $\text{sgn}(R)$, iii) we allow for the odds and consequently the wealth to be negative, and this explains the appearance of the term $\text{sgn}(o)$. We now address a result that characterises this operational task in terms of the R-divergence.

**Theorem 1.** (Bleuler-Lapidoth-Pfister [34, 57]) Consider a HB game with risk defined by the triple $(o_X, p_X, R)$, and a Gambler playing this game with a betting strategy $b_X$. The logarithm of the isoelastic certainty equivalent is characterised by the R-divergence $D_R(\cdot || \cdot)$ as:

$$U_R(b_X, o_X, p_X) = \text{sgn}(o) \log |c^o| + \text{sgn}(o) \text{sgn}(R) D_{1/R}(p_X || r^o_X) - \text{sgn}(o) \text{sgn}(R) D_R(h^{(R,o,p)}_X || b_X),$$  \hspace{1cm} \text{(B12)}

with the parameter and the PMF:

$$c^o := \left( \sum_x \frac{1}{o(x)} \right)^{-1}, \quad r^o(x) := \frac{c^o}{o(x)},$$  \hspace{1cm} \text{(B13)}

and the PMF:

$$h^{(R,o,p)}_X(x) := \frac{p(x)^{1-R} o(x)^{-1/R} \sum_{x'} p(x') \# o(x')^{1-R}}{\sum_{x'} p(x') \# o(x')^{1-R}}.$$  \hspace{1cm} \text{(B14)}

*Note that the quantities $r^o_X$ and $h^{(R,o,p)}_X$ define valid PMFs even for negative odds ($o(x) < 0$, $\forall x$).*

We are particularly interested in the best possible betting strategy for a given game $(o_X, p_X)$ and fixed $R$, so we have the following two corollaries.

**Corollary 5.** (Bleuler-Lapidoth-Pfister [34, 57]) Consider a classical horse discrimination (HD) game $(o^+_X, \text{sgn}(o) = 1)$ being played by a risk-averse Gambler ($R \geq 0$, meaning $\text{sgn}(R) = 1$). We then want to maximise the logarithm of the isoelastic certainty equivalent over all possible betting strategies. The gambler plays optimally when choosing $b^*(x) = h^{(R,o,p)}_X(x)$ and then:

$$\max_{b_X} U_R(b_X, o^+_X, p_X) = U_R(b^*_X, o^+_X, p_X),$$  \hspace{1cm} \text{(B15)}

This is because the Rényi divergence $D_R(\cdot || \cdot)$ is non-negative $\forall R \in \mathbb{R}$.

**Corollary 6.** Consider a classical horse exclusion (HE) game $(o^-_X, \text{meaning}(o) = -1)$ being played by a risk-averse Gambler ($R < 0$, meaning $\text{sgn}(R) = -1$). We then want to maximise the logarithm of the isoelastic certainty equivalent over all possible betting strategies. The gambler plays optimally when choosing $b^*(x) = h^{(R,o,p)}_X(x)$ and then:

$$\max_{b_X} U_R(b_X, o^-_X, p_X) = U_R(b^*_X, o^-_X, p_X),$$  \hspace{1cm} \text{(B16)}

This is because the Rényi divergence $D_R(\cdot || \cdot)$ is non-negative $\forall R \in \mathbb{R}$.

3. Horse betting with risk and side information

We now address a result that characterises this operational task in terms of the BLP-CR-divergence and the R-divergence.
Theorem 2. (Bleuler-Lapidoth-Pfister [34, 57]) Consider a HB game with risk and side information defined by the triple \((o_X, p_{XG}, R)\), and a Gambler playing this game with a betting strategy \(b_{X|G}\). The utility function of log-wealth is characterised by the the BLP-CR-divergence \(D_{\alpha}^{\text{BLP}}(\cdot||\cdot)\) and R-divergence \(D_\alpha(\cdot||\cdot)\) as:

\[
U_R(b_{X|G}, o_X, p_{XG}) = \text{sgn}(o) \log |c^o| + \text{sgn}(o) \text{sgn}(R) D_{1/R}^{\text{BLP}}(p_{X|G}|r_X^o|p_G) - \text{sgn}(o) \text{sgn}(R) D_R \left( h_{X|G}^{(R,o,p)} \right| h_G^{(R,o,p)} \right| b_{X|G} h_G^{(R,o,p)} \right), 
\]

(B17)

with the parameter and the PMF:

\[
c^o := \left( \sum_x \frac{1}{o(x)} \right)^{-1}, \quad r^o(x) := \frac{c^o}{o(x)},
\]

(B18)

and the conditional PMF and PMF:

\[
h_{X|G}^{(R,o,p)}(x|g) := \frac{p(x|g) o(x)^{1-R}}{\sum_x p(x'|g) o(x')^{1-R}},
\]

(B19)

\[
h_G^{(R,o,p)}(g) := \frac{p(g) \sum_{x'} p(x'|g) o(x')^{1-R} x^R}{\sum_{g'} p(g') \sum_{x'} p(x'|g') o(x')^{1-R} x^R}.
\]

(B20)

Note that the quantities \(r^o, h_{X|G}^{(R,o,p)}, h_G^{(R,o,p)}\) define valid PMFs even for negative odds \((o(x) < 0, \forall x)\).

We are particularly interested in the best possible betting strategy \(b_{X|G}\) for a given game \((o_X, p_{XG})\) and fixed \(R\), so we have the following two corollaries.

Corollary 7. (Bleuler-Lapidoth-Pfister [34, 57]) Consider a horse discrimination (HD) game \((o_X^+, \text{ meaning } \text{sgn}(o) = 1)\) being played by a risk-averse Gambler \((R > 0, \text{ meaning } \text{sgn}(R) = 1)\) with access to side information. We then want to maximise the logarithm of the isoelastic certainty equivalent over all possible betting strategies. The Gambler plays optimally when choosing \(b^*(x|g) = h_{X|G}^{(R,o,p)}(x|g)\) and then:

\[
\max_{b_{X|G}} U_R(b_{X|G}, o_X^+, p_{XG}) = U_R(b_{X|G}^+, o_X^+, p_{XG}),
\]

(B21)

\[
= \log |c^o| + D_{1/R}^{\text{BLP}}(p_{X|G}|r_X^o|p_G),
\]

with the BLP-CR-divergence \(D_{\alpha}^{\text{BLP}}(\cdot||\cdot)\). This is because the Rényi divergence \(D_R(\cdot||\cdot)\) is non-negative \(\forall R \in \mathbb{R}\).

Corollary 8. Consider a classical horse exclusion (HE) game \((o_X^-)\) being played by a risk-averse Gambler \((R < 0)\) with access to side information. We then want to maximise the logarithm of the isoelastic certainty equivalent over all possible betting strategies. The Gambler plays optimally when choosing \(b^*(x|g) = h_{X|G}^{(R,o,p)}(x|g)\) and then:

\[
\max_{b_{X|G}} U_R(b_{X|G}, o_X^-, p_{XG}) = U_R(b_{X|G}^-, o_X^-, p_{XG}),
\]

(B22)

\[
= -\log |c^o| + D_{1/R}^{\text{BLP}}(p_{X|G}|r_X^o|p_G),
\]

with the BLP-CR-divergence \(D_{\alpha}^{\text{BLP}}(\cdot||\cdot)\). This is because the Rényi divergence \(D_R(\cdot||\cdot)\) is non-negative \(\forall R \in \mathbb{R}\).

4. Proving Result 1

In order to prove Result 1 we need two Lemmas. Let us start by rewriting the Rényi entropy in a more convenient form:

\[
H_\alpha(X) = -\log [p_\alpha(X)],
\]

(B23)

\[
p_\alpha(X) := \left( \sum_x p(x)^\alpha \right)^{\frac{1}{\alpha-1}}.
\]

(B24)

We are now ready to establish a first Lemma.
Lemma 4. (Operational interpretation of the Rényi entropy) Consider a PMF $p_X$, the Rényi probability of order $\alpha \in \mathbb{R}$ can be written as:

$$\text{sgn}(\alpha) C p_\alpha(X) = \max_{b_X} w_{1/\alpha}^{CE}(b_X, o_X^{\text{sgn}(\alpha)C}, p_X),$$

with the maximisation over all possible betting strategies $b_X$, and constant odds $o_X^{\text{sgn}(\alpha)C}(x) := \text{sgn}(\alpha) C > 0, \forall x$.

Proof. We start by considering a HB game with constant odds $o_X^{\text{sgn}(\alpha)C}(x) := \text{sgn}(\alpha) C > 0, \forall x$, and consider a risk-aversion coefficient parametrised as $R(\alpha) := 1/\alpha$. We first notice that the best strategy for the Gambler is given by (B14):

$$b^*(x) = \frac{p(x)^\alpha}{\sum_{x'} p(x')^\alpha}.\tag{B26}$$

Considering now the isoelastic certainty equivalent and replacing the constant odds and the best strategy we get:

$$w_{1/\alpha}^{CE}(b_X^*, o_X^{\text{sgn}(\alpha)C}, p_X) = \left[ \sum_x p(x) \left[ b^*(x) o_X^{\text{sgn}(\alpha)C}(x) \right]^{\frac{\alpha-1}{\alpha}} \right]^{\frac{1}{\frac{\alpha-1}{\alpha}}},\tag{B27}$$

$$= \text{sgn}(\alpha) C \left[ \sum_x p(x) \left[ b^*(x) \right]^{\frac{\alpha-1}{\alpha}} \right]^{\frac{1}{\frac{\alpha-1}{\alpha}}},\tag{B28}$$

$$= \text{sgn}(\alpha) C \left[ \sum_x p(x) \left[ \frac{p(x)^\alpha}{\sum_{x'} p(x')^\alpha} \right]^{\frac{\alpha-1}{\alpha}} \right]^{\frac{1}{\frac{\alpha-1}{\alpha}}},\tag{B29}$$

$$= \text{sgn}(\alpha) C \left[ \sum_x p(x) \left( \frac{p(x)^\alpha}{\sum_{x'} p(x')^\alpha} \right)^{\frac{\alpha-1}{\alpha}} \right]^{\frac{1}{\frac{\alpha-1}{\alpha}}}.\tag{B30}$$

Reorganising we get:

$$w_{1/\alpha}^{CE}(b_X^*, o_X^{\text{sgn}(\alpha)C}, p_X) = \text{sgn}(\alpha) C \left[ \sum_x \left( \frac{p(x)^\alpha}{\sum_{x'} p(x')^\alpha} \right)^{\frac{\alpha-1}{\alpha}} \right]^{\frac{1}{\frac{\alpha-1}{\alpha}}},\tag{B31}$$

$$= \text{sgn}(\alpha) C \frac{1}{\sum_{x'} p(x')^\alpha} \left[ \sum_x p(x)^\alpha \right]^{\frac{\alpha-1}{\alpha}},\tag{B32}$$

$$= \text{sgn}(\alpha) C \left[ \sum_x p(x)^\alpha \right]^{\frac{\alpha-1}{\alpha}},\tag{B33}$$

$$= \text{sgn}(\alpha) C p_\alpha(X),\tag{B34}$$

and therefore proving the claim. \hfill \Box

We now move on to rewrite the Arimoto-Rényi conditional entropy in a more convenient form:

$$H_\alpha(X|G) = -\log [p_\alpha(X|G)],\tag{B35}$$

$$p_\alpha(X|G) := \left( \sum_g \left( \sum_x p(x, g)^\alpha \right)^{\frac{1}{\alpha}} \right)^{\frac{\alpha}{(\alpha-1)}}.\tag{B36}$$

We are now ready to establish a second Lemma.

Lemma 5. (Operational interpretation of the Arimoto-Rényi conditional entropy) Consider a joint PMF $p_{XG}$, the Arimoto-Rényi conditional entropy of order $\alpha \in \mathbb{R}$ can be written as:

$$\text{sgn}(\alpha) C p_\alpha(X|G) = \max_{b_{X|G}} w_{1/\alpha}^{CE}(b_{X|G}, o_X^{\text{sgn}(\alpha)C}, p_{XG}),$$

with the maximisation over all possible betting strategies $b_{X|G}$, and constant odds $o_X^{\text{sgn}(\alpha)C}(x) := \text{sgn}(\alpha) C > 0, \forall x$. 
Proof. We start by considering a HB game with constant odds \( \sigma_{\text{sgn}(\alpha)}(x) := \text{sgn}(\alpha)C, C > 0, \forall x, \) and consider a risk-aversion coefficient parametrised as \( R(\alpha) := 1/\alpha. \) We now notice that the best strategy for the Gambler with access to side information is given by (B19):

\[
b^*(x|g) = g^{(R, \alpha, p)(x|g)},
\]

(B38)

\[
= p(x|g)^{\frac{1}{\alpha}} \sigma_{\text{sgn}(\alpha)}(x)^{\frac{R}{R}},
\]

(B39)

\[
= \sum_{x'} p(x'|g)^{\frac{1}{\alpha}} \sigma_{\text{sgn}(\alpha)}(x')^{\frac{R}{R}}.
\]

(B40)

\[
= \sum_{x'} p(x'|g)^{\frac{1}{\alpha}} (\sigma_{\text{sgn}(\alpha)}(C)^{\frac{R}{R}}),
\]

(B41)

\[
= \sum_{x'} p(x'|g)^{\frac{1}{\alpha}}.
\]

(B42)

Considering now the isoelastic certainty equivalent and replacing the constant odds and the best strategy we get:

\[
u_{1/\alpha}^{CE}(b_{X|G}^*, \sigma_{\text{sgn}(\alpha)}, p_{X|G}) = \left[ \sum_{x, g} p(x, g) b^*(x|g) \sigma_{\text{sgn}(\alpha)}(x)^{\frac{R}{R}} \right]^{\frac{1}{\alpha}}
\]

(B43)

\[
= \text{sgn}(\alpha)C \left[ \sum_{x, g} p(x, g) \left[ \frac{p(x|g)^{\alpha}}{\sum_{x'} p(x'|g)^{\alpha}} \right]^{\frac{R}{R}} \right]^\frac{1}{\alpha},
\]

(B44)

\[
= \text{sgn}(\alpha)C \left[ \sum_{x, g} p(x, g) \frac{p(x|g)^{\alpha}}{\sum_{x'} p(x'|g)^{\alpha}} \right]^{\frac{R}{R}},
\]

(B45)

Using \( p(x, g) = p(x|g)p(g) \) and reorganising:

\[
u_{1/\alpha}^{CE}(b_{X|G}^*, \sigma_{\text{sgn}(\alpha)}, p_{X|G}) = \text{sgn}(\alpha)C \left[ \sum_{g} p(g) \frac{p(x|g)^{\alpha}}{\sum_{x'} p(x'|g)^{\alpha}} \right]^{\frac{R}{R}},
\]

(B46)

\[
= \text{sgn}(\alpha)C \left[ \sum_{g} p(g) \frac{\sum_{x} p(x|g)^{\alpha}}{\sum_{x'} p(x'|g)^{\alpha}} \right]^{\frac{R}{R}},
\]

(B47)

\[
= \text{sgn}(\alpha)C \left[ \sum_{g} p(g) \left[ \sum_{x} p(x|g)^{\alpha} \right]^{\frac{1}{\alpha}} \right]^{\frac{R}{R}},
\]

(B48)

\[
= \text{sgn}(\alpha)C \left[ \sum_{g} \left[ \sum_{x} p(x|g)^{\alpha} p(g)^{\alpha} \right]^{\frac{1}{\alpha}} \right]^{\frac{R}{R}},
\]

(B49)

\[
= \text{sgn}(\alpha)C p_{\alpha}(X|G),
\]

(B50)

and therefore proving the claim.

We are now ready to prove Result 1.

Proof. (of Result 1) Consider the Arimoto’s dependence measure of order \( \alpha \in \mathbb{R} \), we have the following chain of
equalities:

\[ I_\alpha(X;G) = \text{sgn}(\alpha)[H_\alpha(X) - H_\alpha(X|G)], \]  
\[ = \text{sgn}(\alpha) \log \left[ \frac{p_\alpha(X|G)}{p_\alpha(X)} \right], \]  
\[ = \text{sgn}(\alpha) \log \left[ \frac{\text{sgn}(\alpha) C_\alpha p_\alpha(X) - \text{sgn}(\alpha) C_\alpha p_\alpha(X)}{\text{sgn}(\alpha) C_\alpha p_\alpha(X)} \right], \]  
\[ = \text{sgn}(\alpha) \log \left[ \frac{\max_{b\in\Omega} w_{1/\alpha}(b_{X|G}, \sigma_{\text{sgn}(\alpha)} X, p_{X|G})}{\max_{b\in\Omega} w_{1/\alpha}(b_{X}, \sigma_{\text{sgn}(\alpha)} X, p_{X})} \right]. \]  

The first equality is the definition of the Arimoto’s dependence measure. The second equality comes from replacing the Rényi entropy and the Arimoto-Rényi conditional entropy. The third inequality we have multiplied and divided by \( \text{sgn}(\alpha) C \). The fourth and last equality follows from invoking Lemma 5 and Lemma 6. This proves the claim. 

**Appendix C: Proof of Corollaries 2 and 3**

**Proof.** (of Corollary 2) In the case \( \alpha \to \infty \), we have:

\[ \max_{\varepsilon} \max_{X_{\varepsilon}} I_\infty(X_{\varepsilon}; G_M) = \log \left[ \frac{\max_{b_{X|G}} w_0^{CE}(b_{X|G}, M, \sigma_X, \varepsilon)}{\max_{b_{X|G}} \max_{N \in \Omega} w_0^{CE}(b_{X|G}, N, \sigma_X, \varepsilon)} \right]. \]  

To prove the claim, it is enough to prove:

\[ \max_{b_{X|G}} w_0^{CE}(b_{X|G}, M, \sigma_X, \varepsilon) = CP_{\text{succ}}^{QSD}(\varepsilon, M). \]  

We have already shown this in the main document, but we can also double check it from Lemma 5 from which we have that for \( \alpha \geq 0 \):

\[ \max_{b_{X|G}} w_{1/\alpha}^{CE}(b_{X|G}, M, \sigma_X, \varepsilon) = C p_\alpha(X|G), \]  
\[ = C \left[ \sum_g \left[ \sum_x p(x, g)^\alpha \right]^\frac{1}{\alpha} \right]^{\frac{1}{\alpha-1}}. \]  

Considering now \( \alpha \to \infty \) we have:

\[ \max_{b_{X|G}} w_0^{CE}(b_{X|G}, M, \sigma_X, \varepsilon) = C \sum_g \max_x p(x, g). \]  

Further analysing this quantity we have:

\[ \sum_g \max_x p(x, g) = \sum_g \max_{q(x|g)} \sum_x q(x|g)p(x, g), \]  
\[ = \max_{q(x|g)} \sum_{g, x} q(x|g)p(g|x)p(x), \]  
\[ = \max_{q(x|g)} \sum_{g, x} \left[ \sum_a \delta_a^x q(a|g) \right] p(g|x)p(x), \]  
\[ = \max_{q(x|g)} \sum_{a, g, x} \delta_a^x q(a|g)p(g|x)p(x), \]  
\[ = P_{\text{succ}}^{QSD}(\varepsilon, M). \]
In the first line we use the identity:

$$\max_{q(x)} \sum_x q(x)f(x) = \max_x f(x). \quad (C11)$$

This proves the claim.

**Proof.** (of Corollary 3) The proof of Corollary 3 follows a similar argument than that of Corollary 2.

**Appendix D: Proof of Result 2**

**Proof.** (of Result 2) For $\alpha > 1$ we have:

$$E^S_{\alpha}(M) = \min_{N \in U_1} D^S_{\alpha}(M||N), \quad (D1)$$

$$= \min_{N \in U_1} \max_{p_X} D^S_{\alpha} \left( \frac{M, S}{p_G, X} \right), \quad (D2)$$

$$= \min_{q_G} \max_{p_X} D^S_{\alpha} \left( \frac{M, S}{q_G, X} \right), \quad (D3)$$

$$= \min_{q_G} \max_{p_X} \frac{1}{\alpha - 1} \log \left[ \min_{q_G} \max_{p_X} \sum_x p(x) \sum_g p(g|x)^\alpha q(g)^{1-\alpha} \right], \quad (D4)$$

$$= \frac{1}{\alpha - 1} \log \left[ \min_{q_G} \max_{p_X} \sum_x p(x) \sum_g p(g|x)^\alpha q(g)^{1-\alpha} \right], \quad (D5)$$

$$= \frac{1}{\alpha - 1} \log \left[ \max_{p_X} \min_{q_G} f^S_{\alpha}(q_G, p_X) \right], \quad (D6)$$

$$= \frac{1}{\alpha - 1} \log \left[ \max_{q_G} \min_{p_X} f^S_{\alpha}(q_G, p_X) \right], \quad (D7)$$

$$= \max_{p_X} \min_{q_G} \frac{1}{\alpha - 1} \log \left[ f^S_{\alpha}(q_G, p_X) \right], \quad (D8)$$

$$= \max_{p_X} D^S_{\alpha} \left( \frac{M, S}{q_G, X} \right), \quad (D9)$$

$$= \max_{p_X} f^S_{\alpha} \left( \frac{M, S}{p_G, X} \right), \quad (D10)$$

$$= C_{\alpha} \left( \frac{M, S}{p_G, X} \right). \quad (D11)$$

In the first equality we use the definition of $E^S_{\alpha, S}(M)$. In the second equality we replace $D^S_{\alpha}(M||N)$. In the third equality we notice that minimising over uninformative measurements is equivalent to minimising over PMFs $q_G$. In the fourth equality we replace the Sibson’s CR-divergence. In the fifth equality we move the optimisation inside log(·) because the term $\alpha - 1$ is positive and because log(·) is an increasing function. In the sixth equality we introduce the function:

$$f^S_{\alpha}(q_G, p_X) := \sum_x p(x) \sum_g p(g|x)^\alpha q(g)^{1-\alpha}. \quad (D12)$$

In the seventh equality we use Sion’s minimax theorem [82, 83] because the function $f^S_{\alpha}(q_G, p_X)$ is being optimised over convex and compact sets, and because it is a convex-concave function. Specifically, the function $f^S_{\alpha}(q_G, p_X)$ is convex in $q_G$ because the function $f(q) = q^{1-\alpha}$ with $\alpha > 1$ and positive values of $q$, is convex, and because the sum of convex functions is convex. The function $f^S_{\alpha}(q_G, p_X)$ is concave in $p_X$ because it is linear in $p_X$. In the eighth equality we take the maximisation out of log(·) because $\alpha - 1$ is positive and because log(·) is an increasing function. In the ninth equality we use the definition of Sibson’s CR-divergence. In the tenth equality we use the definition of Sibson’s dependence measure. In the eleventh and final equality we use Lemma 3. The cases for $0 < \alpha < 1$ and $\alpha < 0$ follow a similar argument, taking into account the sign of $\alpha - 1$, and the convexity/concavity of the function $f(q) = q^{1-\alpha}$. □
Appendix E: Proof of Result 3

\textit{Proof.} (of Result 3) It is straightforward to check that \( M_\alpha(M) \) is a resource monotone (meaning that it satisfies i)faithfulness and ii)monotonicity) if and only if \( E_\alpha(M) \) is a resource monotone. We now prove these properties for \( E_\alpha(M) \). In short, we will expand this function in terms of the Rényi divergence, and exploit the properties of this function.

**Part i)** Faithfulness. Consider \( M \in UI \), and let us see that this implies \( E_\alpha(M) = 0 \) with \( \alpha \geq 0 \):

\[
E_\alpha(M) = \max_{S} \min_{q_G} \max_{p_X} D_{\alpha}^{(M,S)} \left( p_{G|X}^{(M,S)} \mid \mid q_G^* \right),
\]

\[
= \max_{S} \min_{q_G} \max_{p_X} D_{\alpha} \left( p_{G|X} \mid \mid q_G \mid \mid p_X \right),
\]

\[
= \max_{S} \min_{q_G} \max_{p_X} D_{\alpha} \left( p_{G|X} \mid \mid q_G p_X \right),
\]

\[
= \max_{S} \min_{q_G} \max_{p_X} D_{\alpha} \left( p_G p_X \mid \mid q_G p_X \right),
\]

\[
\leq \max_{S} \min_{q_G} \max_{p_X} D_{\alpha} \left( p_G p_X \mid \mid q_G p_X \right),
\]

\[
\leq \max_{p_X} \min_{q_G} \max_{S} \max_{\alpha} 0 = 0.
\]

In the first equality we use the definition of the measure. In the second equality we write Sibson’s dependence measure in terms of the Rényi divergence. In the third equality we use the assumption that \( M \in UI \). In the fourth equality we use Sion’s minimax theorem [82, 83], using the same arguments as in Result 2. In the fifth inequality we use that \( q_G = p_G \) is a feasible option. In the sixth equality we invoke the property of the Rényi divergence which reads \( D_{\alpha}(G|X|q_X) = 0 \) if and only if \( q_X = p_X \). This chain means that \( E_\alpha(M) \leq 0 \), and remembering that that \( E_\alpha(M) \) is non-negative (being an optimisation over the Rényi divergence which is itself non-negative) implies \( E_\alpha(M) = 0 \) as desired.

Consider now that \( M \) achieves \( E_\alpha(M) = 0 \), and let us prove that \( M \in UI \). We have:

\[
0 \leq E_\alpha(M)
\]

\[
= \max_{S} \min_{q_G} \max_{p_X} D_{\alpha} \left( p_{G|X} \mid \mid q_G \mid \mid p_X \right),
\]

\[
= \max_{S} \min_{q_G} \max_{p_X} D_{\alpha} \left( p_{G|X} \mid \mid q_G \mid \mid p_X \right),
\]

\[
= \max_{S} \min_{q_G} \max_{p_X} D_{\alpha} \left( p_{G|X} \mid \mid q_G \mid \mid p_X \right),
\]

\[
= \max_{S} \min_{q_G} \max_{p_X} D_{\alpha} \left( p_{G|X} \mid \mid q_G \mid \mid p_X \right),
\]

The first equality is the assumption. In the second equality we invoke the definition of the measure. In the third equality we use Sion’s minimax theorem [82, 83] as per Result 2. In the fourth equality we expand Sibson’s CR-divergence in terms of the Rényi divergence. In the fifth equality we denote the optimal PMF as \( q_G^* \). We now notice that the latter equality implies:

\[
D_{\alpha} \left( p_{G|X} \mid \mid q_G^* \right) = 0,
\]

from which we get that \( p_{G|X}^{(M,S)} = q_G^* \). This means that \( p(g|x) = q(g), \forall g, x \), or that \( \text{Tr}[M_g \rho_x] = \text{Tr}[q(g) \mathbb{I} \rho_x] \), \( \text{Tr}[(M_g - q(g) \mathbb{I}) \rho_x] = 0, \forall g, x \) which implies \( M_g = q(g) \mathbb{I} \), \( \forall g \), or that \( M \in UI \) as desired.

**Part ii)** Monotonicity for the order induced by the simulability of measurements. Given two measurements \( N = \{ N_g \}, M = \{ M_g \} \) such that \( N \leq M \), we now show that this implies \( E_\alpha(N) \leq E_\alpha(M) \). Let us consider that \( N \leq M \), meaning that \( \forall g \) and some \( g \) we have:

\[
N_g = \sum_y s(g|y) M_y.
\]

This implies that for any set of states \( S = \{ \rho_x \} \):

\[
r(g|x) := \text{Tr}[N_g \rho_x] = \sum_y s(g|y) p(y|x),
\]

\[
E_\alpha(N) \leq E_\alpha(M),
\]

\[
\text{for any } S = \{ \rho_x \} \text{.
}

From the assumptions we get that \( E_\alpha(N) \leq E_\alpha(M) \).
with \( p(y|x) = \text{Tr}[M_y \rho_x] \). We now invoke the data processing inequality for the Rényi divergence [32] and get:

\[
D_{\alpha} \left( r^{(N,S)}_{G|X} \right) \leq D_{\alpha} \left( p^{(M,S)}_{G|X} \right),
\]

(E15)

with arbitrary PMFs \( p_X \) and \( p_G \). Recognising that these quantities are the Sibson’s CR-divergence leads to:

\[
D_{\alpha}^{S} \left( r^{(N,S)}_{G|X} \right) \leq D_{\alpha}^{S} \left( p^{(M,S)}_{G|X} \right).
\]

(E16)

We now perform the optimisations \( \max_S, \min_q, \max_p \) on both sides of the inequality and get:

\[
E_{\alpha}(\mathbb{N}) \leq E_{\alpha}(\mathbb{M}).
\]

(E17)

This finishes the proof for the cases \( \alpha \geq 0 \). The cases \( \alpha < 0 \) follow a similar argument.

---
