Kitaev quantum spin liquids (QSLs) are exotic states of matter that are predicted to host Majorana fermions and gauge flux excitations. However, so far all known Kitaev QSL candidates are known to have appreciable non-Kitaev interactions that pushes these systems far from the QSL regime. Using time-domain terahertz spectroscopy (TDTS) we show that the honeycomb cobalt-based Kitaev QSL candidate, BaCo$_2$(AsO$_4$)$_2$, has dominant Kitaev interactions. Due to only small non-Kitaev terms a magnetic field required to destabilize magnetic order is 0.5 T suppresses the effects of the non-Kitaev interactions and gives rise to a field induced intermediate state also consistent with a QSL. These results may have fundamental impact for realizing quantum computation. Our results demonstrate BaCo$_2$(AsO$_4$)$_2$ as a far more ideal version of Kitaev QSL compared with other candidates.

Quantum spin liquids (QSLs) are states of matter where spins are highly correlated and fluctuate quantum mechanically even down to zero temperature [1, 2]. In contrast to conventional ordered magnets, which break spin rotational symmetries and can be described by classical order parameters, QSLs are characterized by topological order in the ground state wave-function and long range entanglement [3]. A prototype QSL was proposed by Anderson in 1973 as the resonating valence bond spin liquid in the triangular lattice [4, 5]. The elementary excitations in QSLs are fractionalized spin 1/2 quasi-particles known as spinons.

A milestone in QSLs was the exactly solvable Kitaev model reported by Alexei Kitaev in 2006 [6]. The Kitaev model consists of $S=1/2$ spins on a two dimensional honeycomb lattice with bond-dependent Ising-type interactions. The Kitaev Hamiltonian is

$$H_K = \sum_{i,j} K^{\gamma} S_i^{\gamma} S_j^{\gamma}$$  \hspace{1cm} (1)

where $\gamma = x, y, z$ denotes the three different bonds and $K$ is the Kitaev interaction constant. By expressing the spin operators $S^\gamma$ in terms of Majorana fermions, the ground state is shown to be a QSL with an ensemble of localized and itinerant Majorana fermions. Applying a magnetic field is predicted to turn them into non-Abelian anyons, which may help realize topologically protected quantum computing [7].

It has been proposed that transition metal ions in edge-sharing cubic octahedra with strong spin-orbit coupling may be promising candidates for realizing Kitaev QSLs [8]. The main focus for Kitaev QSL candidates has been on $d^5$ pseudospin-1/2 ions with $t_{2g}^2$ ($S=1/2$, $L=1$) electronic configuration, including iridates [9] and the celebrated $\alpha$-RuCl$_3$ [10, 11]. Although these materials order at low temperature, Kitaev physics may be evinced by the broad continuum at the Brillouin zone center observed in neutron scattering [12]. Even more interestingly, applying in-plane magnetic field can suppress the magnetic order and may lead to a field induced QSL regime [13–15]. The half quantization of the thermal Hall effect has been observed with a small range of magnetic field, suggesting Majorana edge currents [16].

However, all current Kitaev QSL candidates deviate from the pure Kitaev model due to the presence of significant non-Kitaev terms such as nearest neighbor Heisenberg, off-diagonal exchange, and next-next nearest neighbor exchanges [8, 17, 18] ($J$, $\Gamma$, $\Gamma'$, and $J_3$ terms; see Supplemental Material (SM) for details). The in-plane magnetic field required to destabilize magnetic order is as large as 8 T in $\alpha$-RuCl$_3$ due to these non-idealities [13–15]. An QSL induced by out-of-plane field has not been observed in $\alpha$-RuCl$_3$, and critical fields as large as 50 T have been proposed [19]. Hence, discovering a material that can minimize the non-Kitaev terms is essential. Recent studies have shown that the Kitaev model may also be realized in materials based on $d^7$ ions with $t_{2g}^2$ ($S=3/2$, $L=1$) configuration such as Co$^{2+}$, which also have the pseudospin-1/2 magnetic moment [20–23]. The presence of the extra $e_g^2$ electrons introduces additional exchange hopping processes and is believed to strongly suppress the Heisenberg interactions and give rise to a dominant Kitaev interactions. Moreover, the more localized $3d$ orbitals are expected to manifest smaller $J_3$ couplings. Along with other Co-based Kitaev QSL candidate materials [24, 25], BaCo$_2$(AsO$_4$)$_2$ possesses edge-sharing
FIG. 1: (a) Magnetic Co$^{2+}$ ions form the honeycomb lattice in the ab plane of BaCo$_2$(AsO$_4$)$_2$. Green, blue and red bonds represent the bond-dependent Ising-type Kitaev interactions between two spins on two adjacent sites along x, y, z, respectively. (b) Transmission magnitude as a function of frequency at different temperatures from 2 K to 300 K. Absorptions occur below 1 THz and 100 K, above which the spectra overlap. (c) Imaginary part of the magnetic susceptibility $\chi''(\nu)$ at 2 K, 5 K, and 7 K. The Lorentzian fit $\chi''(\nu) = \frac{S}{(\nu^2-\nu_0^2)^2+\Gamma^2\nu^2}$ is represented by black dashed lines, where $S$ parametrizes the amplitude, $\Gamma$ is the THz linewidth and $\nu_0$ is the central frequency. (e) The temperature dependence of the spectral weight (0.2–1 THz). Error bars are smaller or comparable to the marker size. (f) $\chi''(\nu)$ at 7 K with the in-plane magnetic fields $B$ $\parallel$ $h$, where $B$ is the static magnetic field and $h$ is the THz ac magnetic field. $\chi''(\nu)$ at 7 K with in-plane magnetic field $B$ $\perp$ $h$ is shown in SM.

CoO$_6$ octahedra that form a honeycomb lattice [26]. A phase diagram consistent with a Kitaev QSL with in-plane field was recently observed in this compound using thermodynamic measurements [26]. In addition to the putative smaller non-Kitaev interactions, no stacking faults or twin domains exist in BaCo$_2$(AsO$_4$)$_2$ in contrast to $\alpha$-RuCl$_3$ [10, 26, 27]. The growth of the crystals used in these measurements is described in Ref. [26]. The absence of symmetry forbidden phonons and the narrow linewidths of the symmetry allowed ones are further testament to the high crystal quality (See SM).

It has been shown by neutron scattering that Kitaev QSLs exhibit interesting features around the Brillouin zone center [10, 12, 28]. Time-domain terahertz spectroscopy (TDS) is a pertinent technique to study these materials since it probes excitations at the Brillouin zone center due to the wavelength of the light much greater than the lattice constants. Fig. 1(b) shows the raw data of the THz transmission magnitude at zero magnetic field from 2 K to 300 K. Dissipative features occur below 1 THz and below 100 K. We can obtain the magnetic susceptibility (Fig. 1(c)) from the transmission at each temperature by referencing to the high temperature transmission [29] (Methods). It is clear that a broad continuum gradually increases upon cooling down until the Néel temperature $T_N \sim 5.4$ K, below which the continuum is replaced by a spectra with sharp peaks. The observation of a continuum at the $\Gamma$ point is consistent with the Kitaev model and the existence of fractionalized spin excitations e.g. Majorana excitations [10, 12, 28, 30–32]. Below $T_N$, excitations develop that we assign to one magnon (1M) and two magnon (2M) character (centered at 0.35 and 0.75 THz). The 1M feature is the higher energy magnon of the two expected for the hexagonal lattice. The lower energy one is resolved at fields above 2 T (SM). The one and two magnon excitations can be fit by Lorentzian functions to determine their spectral weight (See caption Fig. 1 and SM). It is interesting to note that, despite the $T_N \sim 5.4$ K, at 5 K the continuum is still visible, but that it disappears by 2 K. A sum rule analysis based on Kramers-Kronig relations relates the $\chi''(\nu)$ to the dc susceptibility $\chi'(0)$

$$\chi'(0) = \frac{2}{\pi} \int_0^\infty \frac{\chi''(\nu)}{\nu} d\nu.$$

At 2 K, the obtained dc contribution from the fits to the one and two magnon peaks is $\sim 0.07(1)$, which is much smaller than the value $\sim 0.2$ determined from dc susceptibility measurement. Hence, there must be some
FIG. 2: (a)-(b) Transmission magnitude as a function of magnetic field and frequency at 2 K in Voigt geometry with \( \mathbf{a} \parallel \mathbf{B} \parallel \mathbf{h} \) and \( \mathbf{a} \parallel \mathbf{B} \perp \mathbf{h} \), respectively. The inset indicates the direction of \( \mathbf{B} \) and \( \mathbf{h} \). The data for \( \mathbf{a} \parallel \mathbf{B} \parallel \mathbf{h} \) and \( \mathbf{a} \parallel \mathbf{B} \perp \mathbf{h} \) is similar and can be found in the SM. (c) Energies of the one and two magnon excitations represented by circles and squares, respectively. Red, orange, green and light blue points represent the one magnon excitations in the spiral ordered state (S), colinear ordered state (C), field induced Kitaev QSL state (K) and field polarized regime, respectively. Yellow and dark blue squares represent the two magnon excitations below and above \( B_{c2} \), respectively. Three critical fields are denoted by inverted triangles with binary colors. The error bars are smaller than marker size. (d) A proposed phase diagram for \( \text{BaCo}_2(\text{AsO}_4)_2 \) with in-plane magnetic field.

remaining continuum at below our measurement range even down to 2 K. The coexistence of the continuum and magnons over even a small temperature range indicates an unconventional ordered state as all spectral weight would usually be in the magnon excitations in a conventional magnet. Similar features were also observed in \( \alpha\text{-RuCl}_3 \) [10, 12, 33]. The continuous suppression of the continuum below \( T_N \) is consistent with fractionalized Majorana quasi-particles in the Kitaev model being replaced by magnons in the long-rang ordered state.

Above \( T_N \), the continuum is stable with increasing temperature and persists up to 50 K e.g. \( \sim 10 \ T_N \). In the temperature range from \( T_N \sim 5.4 \) K to 50 K, this may be the so-called Kitaev paramagnet regime, where the Kitaev physics is not destroyed by thermal fluctuations [28, 31]. By fitting the real and imaginary magnetic susceptibility to a Lorentzian form simultaneously along with the constraint of dc susceptibility, we are able to capture the broad continuum down to zero frequency as shown in Fig. 1(d) (SM). At even higher temperature \( \sim 100 \) K, the Kitaev physics eventually fades away and the material enters a conventional paramagnetic state.

The continuum is not only suppressed by increasing temperature, but also by applying magnetic field. Applying in-plane magnetic field at 7 K converts the continuum to conventional magnons similar to entering the ordered state. This is consistent with the Kitaev paramagnetic state being connected to the field polarized regime smoothly as shown in Fig. 1(f). The continuum starts decreasing its intensity at 0.6 T and the two magnon excitation develops and shifts to higher frequency.

Next, we explore the effects of applying an in-plane
magnetic field (Voigt geometry (k ⊥ B), where k is the THz wavevector) at low temperatures. Fig. 2(a) and (b) show the color plots of the transmission magnitude as a function of magnetic field and frequency at 2 K with B || h and B ⊥ h, respectively. B || h and B ⊥ h have distinct optical selection rules for one and two magnon excitations. One and two magnon excitations were distinguished by their energy and polarization dependence. B || h is the so-called “longitudinal” configuration, where THz mainly excites two magnon excitations unless the spins are not perfectly aligned with external magnetic field B (i.e. below 0.2 T). On the other hand, in the “transverse” configuration B ⊥ h, THz mainly excites one magnon excitations and is less sensitive to the two magnon feature.

By tracking changes to the excitation spectrum, we can reconstruct the phase diagram for in-plane field. By comparing Fig. 2(a) and (b), one can identify three critical fields B_{c1} ∼0.2 T, B_{c2} ∼0.5 T and B_{c2} ∼0.55 T. The one magnon and two magnon energy versus magnetic field are summarized in Fig. 2(c). Below B_{c1}, BaCo$_2$(AsO$_4$)$_2$ has been reported to be in the spiral long range ordered state [26, 34, 35]. The spins in the spiral have components transverse to THz magnetic field h, therefore one magnon excitations can be observed in both B || h and B ⊥ h configuration. As B_{c1} < B < B_{c2}, it goes into a colinear ordered state with 1/3 plateau observed in magnetization measurements. The spins are orientated along the magnetic field, hence no magnon peaks are observed in B || h. In the colinear phase, the two spins in the unit cell point in opposite directions, giving rise to a splitting of the high energy spin wave mode as observed in B ⊥ h and represented by orange points.

In the region from B_{c2} < B < B_{c2}', the intensity of the upper one magnon branch is reduced abruptly with almost unchanged energy, while the energy of the lower one magnon branch drops quickly below our range as shown in Fig. 2(b). These critical fields are consistent with previous magnetization and ac susceptibility measurements [26]. We believe the abrupt suppression of the magnon excitations implies a field induced spin liquid state in the field range of B_{c2} < B < B_{c2}'. Similar features have been observed and interpreted as a signature of field induced spin liquid state in α-RuCl$_3$ [13] for the fields ranges that show the quantized thermal conductance [16]. Above B_{c2}', the system enters into a field polarized regime. Again two features appear. A two magnon excitation is apparent at 0.4 THz and moves to higher frequency with increasing field, while one magnon excitations have half the energy.

The phase diagram of BaCo$_2$(AsO$_4$)$_2$ with in-plane magnetic field can be obtained as shown in Fig. 2(d). The full spectra up to 4 T are shown in the SM. Below $T_N$ ~5.4 K, upon applying field, BaCo$_2$(AsO$_4$)$_2$ experiences a phase transition from the spiral ordered state (S) to colinear ordered state (C) at B_{c1} ~0.2 T, followed by a transition at B_{c2} ~0.5 T to the field induced Kitaev spin liquid regime (K) for B_{c2} < B < B_{c2}' ~0.55 T and ultimately into the field polarized regime. In the intermediate temperature regime, BaCo$_2$(AsO$_4$)$_2$ is a Kitaev paramagnet. It is connected continuously to the field polarized regime and conventional paramagnetic state with applying field and increasing temperature, respectively.

It has been shown that the critical fields required to suppress the magnetic ordered state and induce a QSL regime depends on the strength of the non-Kitaev interactions [36–38]. The critical fields $B_{c2}$, $B_{c2}'$ in BaCo$_2$(AsO$_4$)$_2$ are 15 times smaller than α-RuCl$_3$, indicating much smaller non-Kitaev interactions in BaCo$_2$(AsO$_4$)$_2$ (roughly 15 times smaller compared...
to \(\alpha\)-RuCl\(_3\). Moreover, as discussed in Ref. [38] and the SM one can estimate from the field dependence of the lowest energy magnon mode in the paramagnetic regime the combination of the symmetric off-diagonal exchanges \(\Gamma_{total} = \Gamma + 2\Gamma^\prime\). From such an analysis we find \(\Gamma_{total} \approx 0.1\) THz (0.4 meV). This is about 20 times smaller than estimates for these parameters for \(\alpha\)-RuCl\(_3\) [38] and are in a good agreement with theory [20, 21]. The Kitaev interaction in BaCo\(_2\)(AsO\(_4\))\(_2\) can be estimated from the bandwidth of the continuum \(K \sim 0.5\) THz (2 meV) [30, 31, 39], which is a factor of unity smaller than that in \(\alpha\)-RuCl\(_3\) [10, 36, 40]. Therefore, the Kitaev term is comparatively more dominant in BaCo\(_2\)(AsO\(_4\))\(_2\).

Finally (and perhaps most importantly) we show that an out-of-plane magnetic field can realize a more stable QSL state as compared to in-plane magnetic field as proposed theoretically [37, 41–45]. Fig. 3(a) shows the transmission magnitude at 5 K as a function of out-of-plane magnetic field and frequency in the Faraday geometry (\(k\parallel B\)). The sharp magnon excitations are suppressed completely at \(\sim 4.5\) T. Above \(4.5\) T, a continuum appears and persists up to the highest field we can apply. This is consistent with the formation of a Majorana continuum and a field induced QSL regime being stabilized up to at least \(7\) T before entering a field polarized regime. The imaginary magnetic susceptibility \(\chi''(\nu)\) is shown in Fig. 3(b). It is clear the continuum is distinct from the conventional spin-wave excitations that would exist in a field polarized paramagnet. Furthermore, we observe the continuum in both left and right circular basis (SM). This gives further evidence against the possibility of the field polarized regime as the spin waves can typically be observed only in one circular basis and not the other due to optical selection rules [29]. The recovery of the continuum under magnetic field is strong evidence for a field induced QSL for out-of-plane field. It also gives strong evidence against possible alternative origins of the continuum as arising from over-damped magnons as magnon damping is expected to strongly decrease at higher fields where the magnons and multiple particle continuum overlap less [46, 47]. Note that we did not observe the recovery of the continuum with in-plane field, which is consistent with the expectation of an unstable in-plane field induced QSL phase. The recovery of the continuum has not been observed in \(\alpha\)-RuCl\(_3\) or other previous Kitaev QSL candidates due to the very large magnetic fields (> 50 T) that are expected to be required to suppress the ordered state [19].

We have reported a study of the cobalt based Kitaev QSL candidate BaCo\(_2\)(AsO\(_4\))\(_2\) studied by time-domain terahertz spectroscopy. At zero field, a broad continuum is consistent with the existence of fractionalized Majorana fermions. The response of the continuum to temperature and magnetic field is consistent with the Kitaev model. Applying a very small in-plane magnetic field of \(\sim 0.5\) T realizes an intermediate field regime consistent with a field induced QSL state, suggesting a dominant Kitaev term and small non-Kitaev terms. Importantly, applying an out-of-plane magnetic field is able to realize a much more stable QSL state. The recovery of the continuum with out-of-plane magnetic field is smoking-gun evidence for the field induced QSL state. The field induced Kitaev QSL is expected to possess non-Abelian anyons with topological order and may have profound impacts for quantum computing as proposed by Kitaev [6, 7, 37, 43]. We encourage further work on this promising material and in particular searches for Majorana chiral edge modes and quantized thermal conductivity that is driven by a pure out-of-plane field.

**Time-domain terahertz spectroscopy**

Time-domain THz spectroscopy was performed in a home built system at Johns Hopkins University. THz pulses, with a bandwidth between 0.2 to 2 THz, were generated by a photoconductive antenna so-called Austron switch (emitter) upon illumination by an infrared laser and then detected by another Austron switch (receiver). We measured the single crystal with $2 \times 2 \times 0.5$ mm and an aperture with the same size as an reference. The electric field profiles of the THz pulses transmitted through the sample and an identical bare aperture were recorded as a function of time by moving a delay stage and then converted to the frequency domain by Fast Fourier Transforms (FFTs). By dividing the FFTs of the sample and aperture scans, we obtain the complex transmission of the sample.

**Magnetic susceptibility**

The complex transmission is given by the relation $\hat{T}(\nu) = [\hat{n}/(\hat{n} + 1)] \exp[2\pi i d \hat{n}(\hat{n} - 1)/c]$, where $\hat{n} = \sqrt{\pi} n$ is the complex index of refraction, $\hat{\nu}$ is the dielectric constant, $\hat{\mu} = 1 + \hat{\chi}$, $\nu$ is the speed of light and $d$ is the sample thickness. We determine $\hat{n}$ at each temperature using the Newton-Raphson method and then isolate $\hat{\chi}$ by measuring the sample at a reference temperature above which the spectrum does not change any more. At this reference temperature 100 K in this case, $\chi_{ref}$ can be taken to be zero so $\hat{n}_{off} = \sqrt{\nu}$. For the low temperature, $\hat{n}_{low} = \sqrt{\nu}(1 + \chi_{low})$. Thus, the low temperature magnetic susceptibility is given by $\chi_{low} = (\hat{n}_{low}/\hat{n}_{ref})^2 - 1$.

PHONON LINE WIDTH MEASURED BY RAMAN SCATTERING

Phonon Raman scattering spectra of single crystals of BaCo$_2$(AsO$_4$)$_2$ in $ab$ plane confirm the high quality of the crystals and the absence of detectable distortions or disorder which would lower local or global symmetries. The spectra presented in Fig. S1 and Fig. S2 were excited with 514.5 nm and 488 nm lines of the Ar$^+$-Kr$^+$ laser and recorded using Horiba Jobin-Yvon T64000 spectrometer.

The $R - 3$ symmetry of the space group is non-symmorphic and corresponds to the $C_{3h}$ point group. A symmetry analysis provides the total number of 12 Raman-active phonons $\Gamma_R = 6A_g + 6E_g$. In the Raman spectra measured in the spectral range between 100 and 900 cm$^{-1}$ in $ab$ plane we observe 10 of these phonons, which follow distinct polarization dependence as shown in Fig. S1 and can be accounted for by the $\Gamma$-point phonons of this crystal.

Raman scattering spectra were measured on cooling down to 14 K; the results are shown in Fig. S2. All phonons demonstrate a smooth temperature dependence, with a normal hardening on cooling, and the narrowing of the line width which can be accounted for by the Klemens model [1, 2]. This smooth temperature dependence and an absence of any additional phonons at low temperatures confirm the chemical cleanness of the samples, the absence of any detectable disorder or local distortions in the whole measured temperature range, including stacking faults. The low-temperature linewidth of the phonons is 4 cm$^{-1}$ or below. This is in contrast with $\alpha$-RuCl$_3$, where phonons related to disorder and stalking faults have been observed by Raman spectroscopy [3].

TABLE I: Frequencies and widths of Raman-active phonons obtained from the Raman scattering spectra at room temperature.
FIG. S1: Polarization-resolved Raman spectra measured with 514.5 nm laser at room temperature. $E_g$ modes (marked by green dashed line) are active in both $(x,x)$ and $(x,y)$ polarizations, while $A_g$ modes (marked by grey dashed line) are only active in $(x,x)$ polarization.

FIG. S2: (a) Temperature dependence of the Raman spectra in the temperature range from 14 to 310 K in $(x,x)$ polarization. (b)-(c) Temperature dependence of the positions and the line widths of $A_g$ modes (b) and $E_g$ modes (c). Blue lines are fits to the Klemens model.

FIG. S3: Data and simultaneous fit to the real and imaginary susceptibility at 7 K. The solid line is $\chi''(\nu)$, dashed line is $\chi'(\nu)$, the single point is $\chi'(0)$, and the dotted lines are fits to the Lorentzian form.
The real and imaginary part of the magnetic susceptibility can be obtained from the complex transmission by time-domain terahertz spectroscopy (TDTS). The real $\chi'(\nu)$ and imaginary $\chi''(\nu)$ susceptibility are related by the Kramers-Kronig relations. We can fit $\chi'(\nu)$ and $\chi''(\nu)$ simultaneously to the Lorentzian forms given by

$$\chi'(\nu) = \frac{S(\nu^2 - \nu_0^2)}{(\nu^2 - \nu_0^2)^2 + \nu^2\Gamma^2}, \quad (1)$$

$$\chi''(\nu) = \frac{S\Gamma\nu}{(\nu^2 - \nu_0^2)^2 + \nu^2\Gamma^2}, \quad (2)$$

where $S$ parametrizes the amplitude, $\Gamma$ is the THz linewidth and $\nu_0$ the central frequency. By fitting the dc susceptibility $\chi'(0)$, $\chi'(\nu)$, and $\chi''(\nu)$ at 7 K simultaneously, we can determine aspects of the continuum even below our THz range as shown in Supplementary Fig. S3.

**SUPPLEMENTAL DATA**

**FIG. S4:** Color plot of $\chi''(\nu)$ as a function of the temperature from 5.5 K to 100 K and frequency from 0.2 THz to 1 THz at zero field. It is clear that the continuous dissipation occurs below 50 K and increases gradually as cooling down.

**FIG. S5:** $\chi''(\nu)$ at 20 K with in-plane magnetic field $B\parallel h$, where $B$ is the static magnetic field and $h$ is the THz ac magnetic field.
Fig. S4 is a color plot of $\chi''(\nu)$ as a function of the temperature from 5.5 K to 100 K and frequency from 0.2 THz to 1 THz at zero field. It is clear that a dissipative response occurs below 50 K and increases gradually as one cools down.

As shown in Fig. S5, the continuum is suppressed by an in-plane magnetic field at 20 K. Below 1 T, the continuum is almost unaffected by the external magnetic field. Above 1 T, the continuum starts to decrease and instead a two magnon excitation appears. At 3 T the continuum is almost fully suppressed, indicating a smooth connection from Kitaev paramagnet state to the field polarized state.

Fig. S6 shows Voigt geometry geometry data with in-plane field $B \parallel a$ up to deep in the field polarized regime 3 T. Data up to 1 T has been shown in the main text. Comparing Fig. S8 with the plot in main text that shows fields up to 1 T, we find the lower magnon branch of the hexagonal lattice in the high field range.

The transmission magnitude in Voigt geometry with $B \parallel a^*$ is similar to the $B \parallel a$ case. The energies of the one and two magnon excitations and the critical fields remain the same for $B \parallel a^*$. The only distinction between these two configurations is the slightly different intensities.

We show in Fig. S10 the imaginary magnetic susceptibility taken at 2 K with Faraday geometry and out-of-plane field. The applied field barely suppresses the magnetic ordered state at 7 T, suggesting a much larger field required to obtain the QSL regime at low temperature.

We show $\chi''(\nu)$ in the circular transmission basis at 5K up to 7 T in Fig. S11. At zero field, the material is in the spiral ordered phase and the magnon peaks are observed in both left and right channels. Applying a magnetic fields
FIG. S8: Summary of the one and two magnon excitations, represented by circles and squares, respectively. Red, orange, green and light blue points represent the one magnon excitations in the spiral ordered state (S), colinear ordered state (C), field induced Kitaev QSL state (K) and field polarized regime, respectively. Yellow and dark blue squares represent the two magnon excitations below and above $B_{c2}$, respectively. The three critical fields are denoted by inverted triangles with binary colors. The error bars are smaller than marker size.

FIG. S9: (a)-(b) The color plot of the transmission magnitude as a function of magnetic field from 0 to 1 T and frequency from 0.2 to 1 THz at 2 K in Voigt geometry with $a^* \parallel B \parallel h$ and $a^* \parallel B \perp h$, respectively. Suppresses the magnon peaks and a continuum develops around 4.5 T. The identity of the field polarized state is that magnetic excitations appear only in one channel and not the other due to the optical selection rule [5]. The fact that the continuum shows up in both left and right channel rules out the possibility of the field polarized state. Hence, a stable field induced spin liquid state is realized from 4.5 T to the highest attainable field 7 T in our lab before it enters the field polarized regime at much higher fields.

**FITS TO LOWEST MAGNON MODE AND EXTRACTION OF $\Gamma_{total}$**

For materials like $\alpha$-RuCl$_3$ and hexagonal cobaltates, a postulated minimal microscopic 2D spin Hamiltonian is the generalized Kitaev-Heisenberg model e.g.
\[ H_1 = \sum_{\langle ij \rangle^\gamma} \left[ KS_i^\gamma S_j^\gamma + JS_i \cdot S_j + \Gamma \left( S_i^\alpha S_j^\beta + S_i^\beta S_j^\alpha \right) + \Gamma' \left( S_i^\gamma S_j^\alpha + S_i^\alpha S_j^\gamma + S_i^\beta S_j^\gamma + S_i^\gamma S_j^\beta \right) \right] + J_3 \sum_{\langle ij \rangle_3} S_i \cdot S_j + \mu_B \sum_{\langle i \rangle} B \cdot g \cdot S_i, \]

where \( \langle ij \rangle^\gamma \) indicates the bonds \( \gamma = \{X,Y,Z\} \), with the triads of \( \{\alpha,\beta,\gamma\} \) being \( \{y,z,x\} \) on X bonds, \( \{z,x,y\} \) on Y bonds, and \( \{x,y,z\} \) on Z bonds. \( K \) is the orbital dependent Kitaev interaction. \( J \) is the isotropic Heisenberg interaction. \( \Gamma \) is a symmetric off-diagonal exchange. \( \Gamma' \) is an additional symmetric off-diagonal exchange of a different form, which is only symmetry allowed if there is a \( c \)-axis trigonal distortion. \( J_3 \) is a next nearest neighbor Heisenberg interaction that will presumably play a larger role in the iridates with their more extended orbitals. We will assume it can be approximated as zero in the more localized 3d orbitals relevant here. These non-Kitaev terms are believed to stabilize a variety of classical broken symmetry states.

Linear spin-wave theory shows that the \( q=0 \) magnon energy depends on a combination of only two parameters [6], which derive from the off-diagonal exchange \( \Gamma_{\text{tot}} = \Gamma + 2\Gamma' \). For in-plane magnetic field the relation is

\[ \varepsilon_0^{(0)} = \sqrt{g\mu_B B (g\mu_B B + 3S(\Gamma + 2\Gamma')).} \]
FIG. S12: Fit to lower magnon peaks in the field polarized regime with linear spin-wave theory. The g-factor = 4.25 and obtained off-diagonal exchange constants $\Gamma_{total} \approx 0.077(2)$ THz (0.32(1) meV). The error bars are smaller or comparable to the maker size.

Here we have taken the g-factor to be diagonal and uniform for in-plane fields. We can combine the free parameter of Eq. 4 into a $\Gamma_{total} = \Gamma + 2\Gamma'$. This result is expected to be exact in the $B \to \infty$ limit where fluctuations are suppressed.

In Fig. S12 we show the field dependence of the lowest magnon mode over the range above which it is resolved, plotted alongside a fit using Eq. 4. One can see that the our data is largely in the range where Eq. 4 admits a largely linear dependence, thereby setting a limit on $\Gamma_{total}$. In this analysis we constrain the in-plane g-factor as 4.25 as a g-factor value for trigonally distorted octahedral cobalt compounds typically range from 3.9 to 4.6 [7–9]. One can see that the data is best fit by a $\Gamma_{total} \approx 0.077(2)$ THz (0.32(1) meV). If we assume that quantum fluctuations in this part of the field induced paramagnetic regime renormalize parameters similar to the approximately 30% amount that they appear to do in $\alpha$-RuCl$_3$ [6] this indicates a bare value of $\Gamma_{total} \approx 0.1$ THz (0.4 meV). This is more than an order of magnitude smaller than estimates for the same parameters for $\alpha$-RuCl$_3$ [6]. These small values are in a good agreement with theory predictions [10, 11] that predict that the non-Kitaev exchanges are much smaller in the 3$d^7$ cobaltates.
