Can a liquid drop on a substrate be in equilibrium with saturated vapor?

E. S. Benilov

(Dated: June 29, 2021)

It is well-known that liquid and saturated vapor, separated by a flat interface in an unbounded space, are in equilibrium. One would similarly expect a liquid drop, sitting on a flat substrate, to be in equilibrium with the vapor surrounding it. Yet, it is not: as shown in this work, the drop evaporates. Mathematically, this conclusion is deduced using the diffuse-interface model, but it can also be reformulated in terms of the maximum-entropy principle, suggesting model independence.

Physically, evaporation of drops is due to the so-called Kelvin effect, which gives rise to a liquid-to-vapor mass flux in all cases where the boundary of the liquid phase is convex.

Introduction. The diffuse-interface model (DIM) was proposed by Korteweg in 1901 [1], and later developed by Ginzburg [2] and Cahn [3]. Since then, it has been used in numerous problems including nucleation and collapse of bubbles [4–7], phase separation in polymer blends [8, 9], contact lines [10–17], etc.

It was also used in Ref. [18] to prove the nonexistence of solutions describing static two-dimensional (2D) drops on a substrate. This result, however, gives rise to numerous follow-up questions. If a drop cannot be static, how exactly does it evolve? Is it spreading out, while decreasing in size – or perhaps it acts as a center of condensation for the surrounding vapor and, thus, grows? In addition, the 2D proof of Ref. [18] was not applicable to the most interesting case, that of 3D axisymmetric drops. Does this mean that they can be static, or their nonexistence can be proved using a different method?

In the present work, the approach of Ref. [18] is modified to prove the nonexistence of static 3D drops on a substrate. This result is then reformulated in terms of the maximum entropy principle and interpreted via the Kelvin effect [19–26], with both suggesting that drops evaporate. This conclusion agrees with, and explains, that obtained in Ref. [27] numerically.

Formulation. There are two different versions of the diffuse-interface model (DIM): one assuming the fluid velocity to be solenoidal [28, 29] and another based on the full equations of compressible hydrodynamics [30, 31]. For static solutions, however, the two models yield the same boundary-value problem.

Even though the results below are applicable to an arbitrary nonideal fluid, they are easier to present for the van der Waals equation of state (say, with parameters a and b). Introduce also the Korteweg constant $K$ characterizing the intermolecular attractive force [1, 28–31].

The following nondimensional variables (marked with the subscript $nd$) will be used:

$$r_{nd} = r \frac{1}{l_i}, \quad z_{nd} = z \frac{1}{l_i}, \quad \rho_{nd} = \rho b, \quad T_{nd} = \frac{RTb}{a},$$

where $r$ is the horizontal polar radius, $z$ is the vertical coordinate, $\rho$ is the density, $T$ is the temperature, and $R$ is the specific gas constant, and $l_i = (K/a)^{1/2}$ is the characteristic interfacial thickness. Physically, $l_i$ is on a nanometer scale and, thus, will be referred to as “microscopic”.

According to the DIM, a static axisymmetric distribution of a van der Waals fluid satisfies (the subscript $nd$ omitted)

$$\frac{1}{r} \frac{\partial}{\partial r} \left( r \frac{\partial \rho}{\partial r} \right) + \frac{\partial^2 \rho}{\partial z^2} = T \left( \ln \frac{\rho}{1 - \rho} + \frac{1}{1 - \rho} \right) - 2\rho - \mu, \quad (1)$$

where $\mu$ is a constant. The physical meaning of this equation will be explained later.

Eq. (1) requires four boundary conditions – see Fig. 1.

Let the drop be horizontally and vertically localized. The latter implies that, far above the substrate, the density tends to a constant – say, $\rho_\infty$. If $\rho_\infty$ exceeds the density $\rho_v$ of saturated vapor, the setting under consideration becomes physically meaningless (because an infinitely large volume of oversaturated vapor – with or...
without a drop – is thermodynamically unstable. If, in turn, \( \rho_\infty < \rho_v \), the problem becomes trivial, as evaporation of drops surrounded by undersaturated vapor is evident without proof. Thus, assume

\[
\rho \to \rho_v \quad \text{as} \quad z \to \infty. \tag{2}
\]

The saturated-vapor density \( \rho_v \) can only be defined together with the matching liquid density \( \rho_l \) (in what follows, however, the latter will not be involved). They are both determined by the Maxwell construction, comprising the requirements that the vapor’s pressure and chemical potential match those of the liquid. Thus, for the van der Waals fluid,

\[
\frac{T \rho_v}{1 + \rho_v^2} - \frac{\rho_v^2}{1 - \rho_v} = \frac{T \rho_l}{1 + \rho_l^2} - \frac{\rho_l^2}{1 - \rho_l}, \tag{3}
\]

\[
T \left( \ln \frac{\rho_v}{1 - \rho_v} + \frac{1}{1 - \rho_v} \right) - 2 \rho_v = T \left( \ln \frac{\rho_l}{1 - \rho_l} + \frac{1}{1 - \rho_l} \right) - 2 \rho_l. \tag{4}
\]

It can be shown that, if \( T < 8/27 \) (subcritical temperature for the van der Waals fluid), Eqs. (3)–(4) admit a single solution such that \( \rho_l > \rho_v \). For higher \( T \), only the trivial solution \( \rho_l = \rho_v \) exists, so interfaces do not.

Observe that boundary condition (2) and Eq. (1) entail

\[
\mu = T \left( \ln \frac{\rho_v}{1 - \rho_v} + \frac{1}{1 - \rho_v} \right) - 2 \rho_v. \tag{5}
\]

Physically, \( \mu \) is the specific chemical potential of the van der Waals vapor (or, to be precise, differs from it by a constant).

Let the fluid be bounded by a substrate located at \( z = 0 \), in which case the DIM implies \( \text{[1]} \)–\( \text{[2]} \)

\[
\rho \to \rho_0 \quad \text{as} \quad z \to 0, \tag{6}
\]

where \( \rho_0 \) is a constant characterizing the liquid/substrate interaction. In this paper, it is assumed that the substrate is neither perfectly hydrophilic nor perfectly hydrophobic, which implies \( \rho_v < \rho_0 < \rho_l \) \( \text{[1]} \).

To clarify the physical meaning of condition (6), consider the intermolecular forces exerted on a fluid molecule in an infinitesimally-thin layer near the substrate: the solid pulls the molecule toward the substrate, while the fluid outside the boundary layer pulls it in the opposite direction. Since the former force is fixed, whereas the latter grows monotonically with the near-substrate density, the balance is achieved when the density assumes a certain value – which is what condition (6) reflects. It should also be emphasized the main conclusion of this paper (evaporation of all sessile drops) would not change even if (6) were replaced by the Neumann or mixed boundary conditions, assumed phenomenologically and used, for example, in Refs. \( \text{[3]} \)–\( \text{[5]} \) and \( \text{[8]} \)–\( \text{[9]} \), respectively.

Physically, this is because evaporation occurs at the the liquid/vapor interface, so the fluid/substrate interaction does not really affect it.

The fact that the drop is localized horizontally implies that, at large \( r \), the substrate is dry – i.e., physically, the vapor and solid are adjacent to one another, with no liquid in between. In terms of the DIM, a solid/vapor interface corresponds to a microscopic boundary layer where the density field is homogeneous horizontally, but changes vertically (from \( \rho_0 \) at the substrate toward \( \rho_v \) far above it). The vertical profile \( \rho(z) \) of this layer satisfies the one-dimensional reduction of boundary-value problem \( \text{[1]} \)–\( \text{[2]} \).

\[
\frac{d^2 \rho}{dz^2} = T \left( \ln \frac{\bar{\rho}}{1 - \bar{\rho}} + \frac{1}{1 - \bar{\rho}} \right) - 2 \bar{\rho} - \mu, \tag{7}
\]

\[
\bar{\rho} = \rho_0 \quad \text{at} \quad z = 0 \quad \text{as} \quad r \to \infty. \tag{8}
\]

\[
\bar{\rho} \to \rho_v \quad \text{as} \quad z \to \infty. \tag{9}
\]

Thus, assume that

\[
\rho \to \bar{\rho}(z) \quad \text{as} \quad r \to \infty. \tag{10}
\]

Next, to ensure that \( \rho(r, z) \) is analytic at \( r = 0 \), require

\[
\frac{\partial \rho}{\partial r} = 0 \quad \text{at} \quad r = 0. \tag{11}
\]

Finally, let

\[
\left| \int_0^\infty (\rho - \bar{\rho}) r \, dr \right| < \infty, \tag{12}
\]

which implies that the excess mass between any two horizontal planes is finite, and so is the drop’s net mass. Properties of boundary-value problem \( \text{[1]} \)–\( \text{[2]} \). Mathematically, Eqs. (1)–(12) have a lot in common with their 2D counterparts examined in Ref. \( \text{[18]} \). In what follows, the properties of the former will be briefly outlined with references to the latter.

(i) As \( z \to \infty \), Eq. (1) can be linearized against the background of \( \rho_v \) and thus becomes a Helmholtz equation,

\[
\frac{1}{r} \frac{\partial}{\partial r} \left[ r \frac{\partial (\rho - \rho_v)}{\partial r} \right] + \frac{\partial^2 (\rho - \rho_v)}{\partial z^2} - \frac{T}{(1 - \rho_v)^2} \rho_v = 0. \tag{13}
\]

It can be shown that the second expression in the square brackets is positive – which implies that all solutions of Eq. (13) are either exponentially decaying or exponentially growing (as \( z \to \infty \)). The latter is ruled out by boundary condition (2) – hence,

\[
(\rho - \rho_v) z^n \to 0, \quad \frac{\partial \rho}{\partial z} z^n \to 0 \quad \text{as} \quad z \to \infty, \tag{14}
\]
for all \( n > 0 \).

The above argument can be reworked into a formal proof similar to that for 2D drops in Ref. [18]. One only needs to replace in the latter the Fourier transformation with the Hankel transformation.

(ii) As \( r \to \infty \), Eq. (1) can be linearized against the background of \( \bar{\rho}(z) \) and written in the form

\[
\frac{1}{r} \frac{\partial}{\partial r} \left( r \frac{\partial (\rho - \bar{\rho})}{\partial r} \right) - \bar{A} (\rho - \bar{\rho}) = 0, \tag{15}
\]

where the operator

\[
\bar{A} = -\frac{\partial^2}{\partial z^2} + \left[ \frac{T}{(1 - \bar{\rho})^2} - 2 \right] \tag{16}
\]

is self-adjoint. As before, Eqs. (15)–(16) form a Helmholtz equation, but this time the expression in the square brackets in (16) can be negative for some \( z \). As a result, the exponential decay of the solutions of Eq. (15) as \( r \to \infty \) is not obvious, but still follows from the fact that the operator \( \bar{A} \) is positive-definite (see Lemma 4 of Ref. [18]). Thus,

\[
(\rho - \bar{\rho}) r^n \to 0, \quad \frac{\partial \rho}{\partial r} r^n \to 0 \quad \text{as} \quad r \to \infty \tag{17}
\]

for all \( n \).

(iii) Assume that \( \varrho(z) \) is a smooth function such that \( \varrho(0) = \rho_0 \) and \( \varrho(z) \to \rho_v \) as \( z \to \infty \) and introduce the following functional

\[
F[\varrho(z)] = \int_0^\infty \left[ \frac{1}{2} \left( \frac{\partial \varrho}{\partial z} \right)^2 + T \varrho \ln \frac{\varrho}{1 - \varrho} - \varrho^2 - \mu \varrho + p \right] \, dz
\]

where \( \mu \) is given by (5) and

\[
p = \frac{T \rho_v}{1 - \rho_v} - \rho_v^2
\]

is, physically, the pressure of saturated van-der-Waals vapor.

As shown in Ref. [18], \( F \) reaches the absolute minimum when \( \varrho = \bar{\varrho}(z) \). Thus, if [1]–[12] admit a non-trivial \((\rho \neq \bar{\rho})\) solution, it satisfies

\[
F[\rho(r, z)] > F[\bar{\rho}(z)] \quad \forall r \in (0, \infty). \tag{18}
\]

The integrals involved in \( F[\bar{\rho}(z)] \) converge due to (14).

**Nonexistence of static drops.** The nonexistence of solutions of boundary-value problem [1]–[12] will be proved by contradiction.

Assuming that a solution exists, multiply Eq. (1) by \( r^2 \partial \rho / \partial r \) and integrate from \( z = 0 \) to \( z = \infty \). Integrating by parts and using conditions (14) to interchange the derivative with respect to \( r \) and the integral with respect to \( z \), one obtains

\[
r^2 \partial F[\rho(r, z)] \overline{\partial r} - \frac{1}{2} \frac{\partial}{\partial r} \int_0^\infty \left( r \frac{\partial \rho}{\partial r} \right)^2 \, dz = 0.
\]

Integrate this equality from \( r = 0 \) to \( r = \infty \) and, replacing in the first term

\[
\frac{\partial F[\rho(r, z)]}{\partial r} \to \frac{\partial (F[\rho(r, z)] - F[\bar{\rho}(z)])}{\partial r},
\]

integrate by parts. Recalling conditions (17), one obtains

\[
\int_0^\infty r \{ F[\rho(r, z)] - F[\bar{\rho}(z)] \} \, dr = 0.
\]

Given (18), this last equality is incorrect – hence, the desired contradiction.

Thus, the only existing steady-state solution is the trivial one (describing dry substrate).

**The maximum entropy principle.** The steady-state equations [1]–[12] can be reformulated as a problem of maximization of the net entropy subject to the net energy and mass being fixed.

To this end, introduce the specific (per unit mass) entropy \( s(\rho, T) \) and the specific internal energy \( e(\rho, T) \). These two functions are supposed to satisfy the fundamental thermodynamic relation, amounting to

\[
\frac{\partial e}{\partial T} = T \frac{\partial s}{\partial T}. \tag{19}
\]

Introduce also the fluid’s chemical potential,

\[
G = \frac{\partial}{\partial \rho} \left[ \rho (e - Ts) \right]. \tag{20}
\]

For the van der Waals fluid, for example, one has (nondimensionally)

\[
e = c_v T - \rho, \quad s = c_v \ln T - \ln \frac{\rho}{1 - \rho},
\]

\[
G = T \left( \ln \frac{\rho}{1 - \rho} + \frac{1}{1 - \rho} \right) - 2\rho + c_v (1 - \ln T),
\]

where \( c_v \) is the nondimensional heat capacity at constant volume.

The van der Waals equation (1) can now be extended to the general case, in the form

\[
\nabla^2 \rho = G - \mu', \tag{21}
\]

where \( \nabla^2 \) is the axisymmetric Laplace operator and \( \mu' \) is related to its van der Waals counterpart, \( \mu' = \mu + c_v (1 - \ln T) \).

Next, introduce the net excess mass \( M \), the net excess entropy \( S \), and the net excess full energy \( E \),

\[
M = \int (\rho - \bar{\rho}) \, dV, \quad S = \int (\rho s - \bar{s}) \, dV,
\]
\[ E = \int \left\{ \rho e - \bar{\rho} \bar{e} + \frac{1}{2} \left[ \left( \frac{\partial \rho}{\partial r} \right)^2 + \left( \frac{\partial \rho}{\partial z} \right)^2 \right] \right\} dV, \quad (22) \]

where \( \bar{s} = s(\bar{\rho}, T) \), \( \bar{e} = e(\bar{\rho}, T) \), \( dV = 2\pi r dr dz \), and the integrals are evaluated over the semispace \( z > 0 \). The derivative terms in the expression for \( E \) represent the energy of the intermolecular attraction, as the DIM describes it.

All of the results obtained earlier for the van der Waals equation [1] can be reproduced for the general equation [21]. For example, the positivity of the expression in the square brackets in Eq. (13) is, essentially, the condition of thermodynamic stability of the vapor

\[ \frac{\partial G}{\partial \rho} > 0 \quad \text{if} \quad \rho = \rho_v. \]

Even more importantly, the general equation [21] can be used to find out the physical meaning of the nonexistence of solutions describing sessile drops.

Observe that Eq. [21] follows from the requirement that the net entropy be maximum subject to the net mass and energy be fixed, i.e.,

\[ \delta (S + \eta M + \lambda E) = 0, \]

where \( \eta \) and \( \lambda \) are the Langrange multipliers. Varying Eq. [21] and recalling boundary conditions [2] and [6], which imply

\[ \delta \rho = 0 \quad \text{at} \quad z = 0, \]

\[ \delta \rho \to 0 \quad \text{as} \quad z \to \infty, \]

one obtains

\[ \int \left[ \frac{\partial (\rho s)}{\partial \rho} + \lambda \frac{\partial (\rho e)}{\partial \rho} - \lambda \nabla^2 \rho + \eta \right] \delta \rho dV + \int \left[ \frac{\partial (\rho s)}{\partial T} + \lambda \frac{\partial (\rho e)}{\partial T} \right] \delta T dV = 0. \]

Setting \( \lambda = -1/T \), one can make the second term in this equation vanish subject to relation [19], whereas \( \eta = \mu'/T \) makes the first term vanish subject to condition [20] and the steady-state equation [21].

Thus, since \( \bar{\mu}(z) \) (describing the solid/vapor interface) is the only solution of Eq. [21], it corresponds to the maximum entropy and all other solutions evolve towards it. This means evaporation of the liquid phase, with the excess mass and energy spreading out to infinity.

The only DIM-specific part of the above variational problem is the intermolecular part of energy [22]. It seems unlikely that another form of this term would fundamentally change the properties of the functionals involved. Hence, one could conjecture that drops on a solid substrate evaporate in any model conforming to an H-Theorem and mass and energy conservation – such as, for example, the Enskog–Vlasov kinetic equation for dense fluids [34–39] (which is generally viewed as much more accurate model than the DIM).

**Physical interpretation.** The nonexistence of drops on a substrate can be explained through the so-called Kelvin effect [19, 40, 41], which gives rise to a mass flux through a liquid/vapor interface provided it is curved. The direction of the flux depends on the sign of the interfacial curvature: for a volume of liquid with a convex boundary, the flux is directed from the liquid toward the vapor, and vice versa. The boundary of a drop on a flat substrate is convex, it comes as no surprise that it evaporates. One can further conjecture that drops floating in saturated vapor evaporate too. The only kind of drops that do not evaporate are those in a sufficiently acute corner, so that their surface is concave (and vapor is condensing on it).

Finally, the quantitative theory of the Kelvin effect can be used to show that the timescale of evaporation ranges from several hours to several days. This estimate (to be published in the full version of this work) suggests that the evaporation of drops into saturated vapor can be observed experimentally, not to mention that it should certainly be observable via molecular dynamics.

---
