Abstract

Chiral molecules are instrumental for molecular recognition in living organisms. Distinguishing between two opposite enantiomers, the mirror twins of the same chiral molecule, is both vital and challenging. Photoelectron circular dichroism (PECD), an extremely sensitive probe of molecular chirality, outperforms standard optical methods by many orders of magnitude. The net photoelectron current generated via photoionization of randomly oriented chiral molecules by circularly polarized light, the key enantio-sensitive observable in PECD, is directed oppositely in the opposite enantiomers. Here we show that the physical origin of PECD in chiral molecules is linked to the concept of geometric magnetism, which enables a broad class of phenomena in condensed matter systems including the anomalous electron velocity, the Hall effect, and related topological phenomena. Following this link, we uncover the presence of a chiral geometric magnetic field in molecular photoionization and formulate fundamental principles that allow one to predict new enantio-sensitive observables associated with this field. Crucially, the emergence of these new observables is associated with ultrafast excitation of chiral electronic or vibronic currents prior to ionization and can be viewed as their unique signature. We illustrate our concept by introducing and quantifying a new effect: enantio-sensitive orientation of chiral molecules via photoionization. We name it "molecular orientation circular (or chiral) dichroism," MOCD. It opens new routes to both enantio-separation and imaging of chiral dynamics on ultrafast time scales. Our work ponders connections between the two geometrical properties, chirality and topology, and shows that geometrical fields generated by electrons provide the bridge between the two.

Introduction

Chiral molecules are characterised by their handedness, an extra degree of freedom of a purely geometrical origin. Geometrical properties in real space are determined by the nuclear configuration in molecules or the lattice configuration in solids. In quantum mechanics, they map onto geometrical or topological properties of Hilbert space vectors, leading to robust observables associated with the electronic response of solids to electromagnetic fields and new, topological, phases of matter.

Geometric magnetism, introduced by M. Berry [1], is a key concept underlying these phenomena. One of the manifestations of the geometric magnetism is the Berry curvature in solids, which enables a class of new observables in condensed matter systems related to the so-called anomalous electron velocity imparted by the Berry curvature [2]. We show that similar geometric magnetic fields and "anomalous" observables induced by such fields also arise in photoionization of chiral molecules by circularly polarized fields. We show that the photoelectron circular dichroism in photoionization of chiral molecules, PECD, is an example of such "anamolous" phenomena. Moreover, we find that PECD
is only a tip of the iceberg, the iceberg being a whole class of new enantio-sensitive observables that we expose here.

Photoelectrons ejected from randomly oriented chiral molecules via one-photon \cite{3-7} or multiphoton \cite{8-10} ionization by circularly polarized field are extremely sensitive probes of molecular chirality: the enantio-sensitive signal is of the order of magnitude of the full signal. This signal is encoded in the direction of the net photoelectron current arising in the direction orthogonal to light’s polarization plane, opposite in the two enantiomers of a chiral molecule. Equally important is the chiral electronic or vibronic current that can be excited in bound states, known as the photo-excitation circular dichroism (PXCD) \cite{11}. This bound current emerges along the propagation vector of the circularly polarized field and has opposite direction in the two opposite enantiomers.

Unlike the standard absorption circular dichroism, both PECD and PXCD are enantio-sensitive already in the electric dipole approximation. They belong to the new generation of enantio-sensitive observables associated with very strong signals. Here we show that not only the emergence and enantio-sensitivity of these currents is linked to the concept of geometric magnetism, but that this concept also allows one to predict new classes of enantio-sensitive phenomena. One of these new phenomena, exposed here, is enantio-sensitive orientation of chiral molecules by non-linear photoionization, termed "molecular orientation circular dichroism," MOCD. Crucially, these new observables originate from dynamical symmetry breaking and rely on ultrafast excitation of chiral electronic or vibronic currents and their time-resolved detection. Thus, these new observables link geometric magnetism to yet another important concept in ultrafast science – the concept of charge-directed reactivity.

Charge directed chemical reactivity \cite{12} implies that ultrafast electron dynamics represented by coherent motion of molecular holes or excitons produced by photoionization or photo-excitation can affect the outcome of chemical reactions that may follow this initial excitation and occur on longer time scales. Time-resolving hole dynamics upon photoionization is an important direction in attochemistry \cite{13-19}. Ultrafast electron currents excited prior to ionization are just as important messengers of charge-directed reactivity. Here we show that linearly polarized fields can excite electron currents that lead to opposite orientation of left and right enantiomers of the same molecule upon photoionization by circularly polarized field, thus presenting an example of enantio-sensitive charge-directed reactivity, with the geometric magnetism providing a platform for describing this type of charge-directed reactivity in chiral molecules.
Geometric magnetism: molecules vs solids

The geometric magnetism in photoionization of chiral molecules by circularly polarized fields originates from the so-called propensity field, which we have introduced recently [20]. This field emerges in photoionization of randomly oriented molecules and involves the vector product of two conjugated photoionization dipoles, which can be written either in the length ($\vec{d}_{gk}$) or the velocity gauge ($\vec{p}_{gk}$):

$$\vec{B}(\vec{k}) = i[\vec{d}_{gk} \times \vec{d}_{gk}^*] = i\frac{[\vec{p}_{gk} \times \vec{p}_{gk}^*]}{(E - E_g)^2}. \quad (1)$$

Here $E = k^2/2$ is the photoelectron energy, $E_g$ is the energy of the initial (e.g. ground) state. The field $\vec{B}(\vec{k})$ is a molecular frame property, which depends on the photoelectron momentum $\vec{k}$ in the molecular frame and emerges upon averaging over random molecular orientations.

For a given final $\vec{k}$ in the molecular frame, the direction of $\vec{B}(\vec{k})$ defines the axis in the molecular frame along which the rotational symmetry of the molecule is broken to the highest extent [21]. Its length $|\vec{B}(\vec{k})|$ defines the difference in photoionization yields triggered by fields with polarization vectors rotating in opposite directions and propagating in the direction of $\vec{B}(\vec{k})$:

$$|\vec{B}(\vec{k})| = |\vec{d}_{gk}^+|^2 - |\vec{d}_{gk}^-|^2. \quad (2)$$

Here $\vec{d}_{gk}^\pm$ are the photoionization dipoles for ionization by left or right circularly polarized fields. Thus, the vector field $\vec{B}(\vec{k})$ presents the map of maximal possible photoionization CD, individual for every molecule, and resolved on the final photoelectron momentum $\vec{k}$ in the molecular frame.

Photoionization may be viewed as light-induced transition in a two band solid, with the degenerate in $\vec{k}$ valence band and the conduction band with parabolic dispersion. This analogy allows us to expose links between geometric magnetism in different media. In particular, the second equality in Eq. (1) is also true for the Berry curvature in a two-band solid [22]:

$$\vec{\Omega}(\vec{k}) = i\frac{[\vec{p}_{vc} \times \vec{p}_{vc}^*]}{(E_c - E_v)^2}. \quad (3)$$

Here the matrix elements $\vec{p}_{vc}$ and the respective energies $E_{vc}$ are associated with transition between the valence (v) and conduction (c) bands of a two-band solid. The Berry curvature in the form given by Eq. (3) is proportional to the orbital angular momentum associated with circulating electron currents and is used to quantify local, $\vec{k}$-dependent circular dichroism in interband transitions in solids [22].

The analogies between the field Eq. (1) in molecules and the Berry curvature (Eq. (3)) run deep.
The enantio-sensitive photoionization current (PECD), orthogonal to the polarization plane of the driving laser field, can be written via the enantio-sensitive conductivity $\sigma_{zz}(k)$ characteristic for photoelectron with final energy $E = k^2/2$:

$$\vec{j}_z(k) = \sigma_{zz}[\vec{E}_{\omega} \times \vec{E}_{\omega}^*]_z.$$  \hspace{1cm} (4)

We have shown in Ref.[24] that $\sigma_{zz}(k)$ is proportional to the flux of the field $\vec{B}(\vec{k})$ through the sphere in $\vec{k}$-space with radius $k = \sqrt{2E}$ and the surface element $dS = k^2d\Theta_k \Theta_k(k/k)$, where $d\Theta_k \equiv d\phi_k d\theta_k \sin \theta_k$:

$$\sigma_{zz}(k) = \frac{1}{6k} \oint \vec{B}(\vec{k}) d\vec{S}. \hspace{1cm} (5)$$

The PECD finds its analogue in non-inversion symmetric solids known as the circular photogalvanic effect. In this phenomenon, a circularly polarized laser field induces interband transitions leading to the net electron current in the light propagation direction. This current has recently been related [25] to the Berry curvature $\Omega(\vec{k})$ [26]:

$$\vec{j}_z(k) = \sigma_{zz}[\vec{E}_{\omega} \times \vec{E}_{\omega}^*]_z,$$

$$\sigma_{zz}(k) = \frac{e^3}{6\hbar^2} \oint \vec{\Omega}(\vec{k}) d\vec{S}. \hspace{1cm} (6)$$

Eq. (7) becomes exact in the two-band approximation. This comparison of the PECD in chiral molecules and photogalvanic circular dichroism in chiral solids emphasises the analogy between the Berry curvature in chiral solids and the field $\vec{B}(\vec{k})$ arising in photoionization of chiral molecules.

**Symmetries of the geometric propensity field**

To further pursue the parallels between the geometric propensity field and the Berry curvature, it is instructive to consider the symmetry properties of the propensity field with respect to the following set of operations: inversion $I$, $T_k$, and the time-reversal $T$. Inversion turns $\vec{r} \rightarrow -\vec{r}$ and $\vec{k} \rightarrow -\vec{k}$. $T_k$ involves complex conjugation and $\vec{k} \rightarrow -\vec{k}$. $T$ involves complex conjugation.

In the presence of time-reversal symmetry in a periodic solid, the Bloch states obey the symmetry $T_k u_k(\vec{r}) \equiv u_{-k}^*(\vec{r}) = e^{i\chi(\vec{k})} u_k(\vec{r})$, where $\chi(\vec{k})$ is $\vec{r}$-independent phase [27]. While in bulk solids the wave functions have periodic boundary conditions, molecular scattering states have two types of boundary conditions: incoming and outgoing. It leads (Appendix A) to the fact that the electronic wave-functions in a solid and in a molecule have different properties with respect to $T_k$. As a result, for photoionization from a time-even (i.e. real) bound state, the geometric propensity field has both the $T_k$-odd $\vec{B}^*(-\vec{k}) = -\vec{B}(\vec{k})$ and $T_k$-even $\vec{G}^*(-\vec{k}) = \vec{G}(\vec{k})$ pseudovector components: $\vec{B}(\vec{k}) = \vec{G}(\vec{k}) + \vec{B}(\vec{k})$. 

5
Since $\vec{B}(\vec{k})$ is real, the $\hat{T}_k$-odd component $\vec{B}(\vec{k})$ is $\vec{k}$-odd, the $\hat{T}_k$-even component $\vec{D}(\vec{k})$ is $\vec{k}$-even. We can establish the following symmetry properties of the field $\vec{B}(\vec{k})$ for photoionization from time-even states (Appendix A):

1. In inversion symmetric systems with broken $T_k$-symmetry, only $T_k$-even $\vec{D}(\vec{k})$ is non-zero $\vec{D}(\vec{k}) = \vec{D}(\vec{k}) = 0$. This component is $\vec{k}$-even. The Berry curvature is also $\vec{k}$-even in such systems [28].

2. In non-inversion symmetric systems and $T_k$-symmetric systems only the $T_k$-odd component of the field $\vec{B}(\vec{k})$ is $\vec{k}$-odd: $\vec{B}(\vec{k}) = -\vec{B}(\vec{k}) = 0$. The Berry curvature is also $\vec{k}$-odd in such systems [28].

So far we have considered the geometric propensity field $\vec{B}(\vec{k})$ for time-even (i.e. real) bound states. In a more general case of photoionization from a complex superposition of two excited states $|i\rangle + e^{i\phi_j}|j\rangle$ (with $\omega_{ij}$ the transition frequency between these states) the propensity field acquires an additional term, which encodes coherence between the excited states:

$$\vec{B}_{ij}(\vec{k},\phi_{ij}) = \frac{1}{2} i \left[ \vec{d}_{ik} \times \vec{d}_{jk}^* \right] e^{i\phi_{ij}} + c.c. \equiv \vec{Q}_{ij}(\vec{k}) \cos \phi_{ij} + \vec{P}_{ij}(\vec{k}) \sin \phi_{ij},$$

(8)

where we have introduced the displacement $\vec{Q}_{ij}(\vec{k})$ and current $\vec{P}_{ij}(\vec{k})$ quadratures:

$$\vec{Q}_{ij}(\vec{k}) \equiv \Re \left\{ i \left[ \vec{d}_{ik} \times \vec{d}_{jk}^* \right] \right\},$$

(9)

$$\vec{P}_{ij}(\vec{k}) \equiv -\Im \left\{ i \left[ \vec{d}_{ik} \times \vec{d}_{jk}^* \right] \right\}.$$  

(10)

An example of the displacement $\vec{Q}_{ij}(\vec{k})$ and current $\vec{P}_{ij}(\vec{k})$ quadratures of the geometric propensity field for a coherent superposition of $i=$LUMO and $j=$LUMO+1 in propylene oxide (a chiral molecule) are shown in Fig.1. For more than two states, the field includes the sum over all states:

$$\vec{B}(\vec{k},t) = \frac{1}{2} \sum_{i,j} \left\{ i \left[ \vec{d}_{ik} \times \vec{d}_{jk}^* \right] \right\} e^{i\phi_{ij}}$$

(11)

Eqs.(8,11) present a more general expression for the geometric field; for $i = j = g$ (and $\phi_{gg} = 0$) Eqs.(8,11) yield Eq.(11) relevant for photoionization from the ground state. Note that if $\phi_{ij} \neq 0$, the time-reversal symmetry $T$ in molecular bound states is broken.

Applying inversion ($\vec{r} \to -\vec{r}$, $\vec{k} \to -\vec{k}$) to reverse molecular handedness, we find that the displacement and current quadratures in left- and right-handed molecules are connected via $\vec{Q}_{ij}(\vec{k}) = \vec{Q}_{ij}(\vec{k})$ and $\vec{P}_{ij}(\vec{k}) = \vec{P}_{ij}(\vec{k})$. To analyse the remaining symmetries of the field Eq.(8), it is convenient to introduce symmetric and anti-symmetric superpositions of the quadratures corresponding to left ($\vec{P}^L_{ij}$)
Figure 1 Displacement $\vec{Q}_{ij}(\vec{k})$ (left panel) and current $\vec{P}_{ij}(\vec{k})$ (right panel) quadratures of the geometric field for $i=$LUMO and $j=$LUMO+1 of the chiral molecule propylene oxide and $k=0.2$ a.u. Both the color and the length of arrows represent the strength (absolute value) of the geometric field in a given point in $k$-space. The orientation of molecular frame is shown in the inserts (left bottom corner). Note that the quadratures are shown from different viewpoints.

and right ($\vec{Q}^R$, $\vec{P}^R$) molecules:

\[
\tilde{Q}^{\pm}_{ij}(\vec{k}) = \frac{1}{2} \left[ \tilde{Q}^L_{ij}(\vec{k}) \pm \tilde{Q}^R_{ij}(\vec{k}) \right],
\]

(12)

\[
\tilde{P}^{\pm}_{ij}(\vec{k}) = \frac{1}{2} \left[ \tilde{P}^L_{ij}(\vec{k}) \pm \tilde{P}^R_{ij}(\vec{k}) \right].
\]

(13)

Note that the symmetric superpositions $\tilde{Q}^+_{ij}(\vec{k})$ and $\tilde{P}^+_{ij}(\vec{k})$ are $\vec{k}$-even, and the anti-symmetric superpositions $\tilde{Q}^-_{ij}(\vec{k})$ and $\tilde{P}^-_{ij}(\vec{k})$ are $\vec{k}$-odd.

Writing the $ij$-th element of the geometric propensity field as a superposition of its $\hat{T}$-even $\vec{D}_{ij}(\vec{k}, \phi_{ij})$, and $\hat{T}$-odd $\vec{B}_{ij}(\vec{k}, \phi_{ij})$ components,

\[
\vec{B}_{ij}(\vec{k}, \phi_{ij}) = \vec{D}_{ij}(\vec{k}, \phi_{ij}) + \vec{B}_{ij}(\vec{k}, \phi_{ij}),
\]

(14)

\[
\tilde{D}_{ij}(\vec{k}, \phi_{ij}) = \tilde{Q}^+_{ij}(\vec{k}) \cos \phi_{ij} + \tilde{P}^+_{ij}(\vec{k}) \sin \phi_{ij},
\]

(15)

\[
\tilde{B}_{ij}(\vec{k}, \phi_{ij}) = \tilde{Q}^-_{ij}(\vec{k}) \cos \phi_{ij} + \tilde{P}^-_{ij}(\vec{k}) \sin \phi_{ij}.
\]

(16)

we obtain an overview of its symmetries with respect to inversion of $\vec{k}$, $\vec{r}$ and time $t$. Note that only
the $\vec{Q}$ quadratures appear in the case of photoionization from the ground state ($i = j = g, \phi_{gg} = 0$):

\begin{align}
\vec{D}_{gg}(\vec{k}) &= \vec{Q}_{gg}(\vec{k}), \\
\vec{B}_{gg}(\vec{k}) &= \vec{Q}_{gg}(\vec{k}),
\end{align}

Eqs. (17, 18) suggest that the $\vec{Q}^{L,R}(\vec{k})$ quadratures characterize the lack of rotational symmetry of electron density (around the direction of $\vec{Q}^{L,R}(\vec{k})$). In turn, the $\vec{p}^{L,R}(\vec{k})$ quadratures describe the contribution to the rotational asymmetry coming from the circulating bound state currents (around the direction of $\vec{p}^{L,R}(\vec{k})$). By construction, the geometric propensity fields $\vec{D}_{ij}(k, \phi)$ and $\vec{B}_{ij}(k, \phi)$ reflect the local, i.e. $\vec{k}$ resolved, geometry of photoionization vector fields in molecular frame.

**Global invariants of propensity field and three classes of enantio-sensitive photoionization observables**

Enantio-sensitive photoionization observables are defined in the laboratory frame and originate from global invariants of the geometric propensity field – quantities surviving averaging over the directions of $\vec{k}$ in the molecular frame. The time-reversal symmetry of the molecular bound states and and the $\vec{k}$-inversion symmetries of the quadratures established above define the fate of such global invariants and, hence, of chiral observables in photoionization – their emergence or cancellation. In the following, we shall consider global invariants for the $ij$-th component of the geometric propensity field in the general case of any $ij$, but we shall suppress the indices $ij$ to simplify notations.

The symmetries of the geometric propensity field established above lead to three classes of enantio-sensitive observables.

**Class I** is an entirely new class of enantio-sensitive observables. It originates from the most stringent condition, which requires non-zero net propensity field, i.e. the field integrated over all angles $\phi_k, \theta_k$ characterizing the orientation of $\vec{k}$ in the molecular frame ($d\Theta_k \equiv d\phi_k d\theta_k \sin \theta_k$):

\begin{equation}
\vec{B}(k) \equiv \int \vec{B}(\vec{k})d\Theta_k \neq 0.
\end{equation}

The condition Eq. (19) is obviously not satisfied for the $k$-odd quadratures ($\vec{Q}_{ij}^-(\vec{k}), \vec{P}_{ij}^-(\vec{k})$), because their integrals will vanish. We show (Appendix B) that the condition Eq. (19) also can not be satisfied for real (time-even) bound states. These restrictions leave us with the following global invariant allowed by symmetries:

\begin{equation}
\vec{B}(k) = \sin \phi \int \vec{P}^+(\vec{k})d\Theta_k = \vec{P}^+(k) \sin \phi, \quad \phi \neq 0.
\end{equation}

The requirement $\phi \neq 0$ dictates that the net propensity field vanishes in ionization from time-even
states (see formal proof in Appendix B), which carry no current. This statement has a clear physical meaning. It reflects the fact that a circularly polarized field in the electric dipole approximation and in a linear process can not impart its spin on a randomly oriented ensemble of molecules in the molecular frame: if a clockwise current is excited in one molecule, a counter-clockwise current is excited in a molecule rotated by 180 degrees, with a total zero current when averaged over the ensemble. For the same reason, the total photoionization yield of randomly oriented chiral molecules is the same for left and right circularly polarized field in the electric dipole approximation.

Thus, the new enantio-sensitive observables of Class I can only appear if photoionization occurs from current-carrying states. Such states can be generated, e.g., in a two-photon (or multiphoton) process, with ionization following ultrafast excitation of a coherent superposition of eigenstates. The property of the net geometric propensity field to emerge only in "non-stationary" systems undergoing dynamics can make it an important player in attosecond photochemistry, which studies chemical photoreactivity driven by ultrafast electron dynamics. As we shall show in the next section, in contrast to ring currents excited in atoms or non-chiral molecules by circularly polarized fields \cite{29,31}, chiral molecules present an example of a system where excited ring currents do not vanish in the molecular frame upon averaging over random molecular orientation, because they are protected by the rotationally invariant geometric property – molecular handedness. These geometrically protected net currents lead to the net geometric field in the molecular frame \cite{20} and to the new phenomenon – the enantio-sensitive molecular orientation by ionization (see below). Since the direction of the excited current defines the rate of subsequent ionization, the enantio-sensitive molecular orientation is an example of charge directed reactivity emerging solely due to molecular handedness.

Formally, the enantio-sensitive orientation is proportional to the scalar product of the pseudovector $\vec{B}(k)$ and any polar vector $\vec{V}$ defining orientation of the molecular ion. The rotationally invariant pseudoscalar $\vec{B}(k) \cdot \vec{V}$ is a property of a randomly oriented ensemble of chiral molecules; it is non-zero if $\vec{B}(k)$ is non-zero. The scalar product maximizes for $\vec{V}$ oriented along the direction of $\vec{B}(k)$. Thus, the direction of $\vec{B}(k)$ in the molecular frame defines the orientation of the molecular ion in the laboratory frame. We quantify this new effect in the next section.

The Class II of enantio-sensitive observables in photoionization originates from the next global invariant, which requires non-zero net radial component of the propensity field:

$$B_0^0(k) \equiv \int \vec{B}(\vec{k}) \cdot \vec{k} d\Theta_k \neq 0, \vec{k} = \frac{\vec{k}}{k}$$ \hspace{1cm} (21)

Condition (Eq.(21)) is not satisfied if $\vec{B}(\vec{k})$ is $k$-even, because in this case the radial component is $k$-
odd and thus the integral in Eq. (21) vanishes. It means that the quadratures \( \tilde{Q}^- (\vec{k}) \) and \( \tilde{P}^- (\vec{k}) \) do not contribute to \( B^0_{||}(k) \), leaving us with the following global invariants allowed by symmetries:

\[
B^0_{||}(k) = B^0_{||,Q^-}(k) + B^0_{||,P^-(k)}, \tag{22}
\]

\[
B^0_{||,Q^-}(k) = \cos \phi \int \tilde{Q}^- (\vec{k}) \cdot \vec{k} d\Theta_k = Q^-_{||}(k) \cos \phi, \tag{23}
\]

\[
B^0_{||,P^-}(k) = \sin \phi \int \tilde{P}^- (\vec{k}) \cdot \vec{k} d\Theta_k = P^-_{||}(k) \sin \phi. \tag{24}
\]

The net radial component is proportional to the flux of the field, which is responsible for the photoelectron circular dichroism [20], see Eq. 5. Thus, the global integral \( B^0_{||,Q^-}(k) \) leads to the PECD current for photoionization from a real stationary state. The PECD from the superposition of states (the time-dependent PECD [52]) also involves the complementary quadrature component \( B^0_{||,P^-}(k) \). Thus, the net radial components \( Q^-_{||}(k), P^-_{||}(k) \) of both asymmetric quadratures \( \tilde{Q}^- (\vec{k}) \) and \( \tilde{P}^- (\vec{k}) \) can be accessed by the TD-PECD measurement and oscillate as \( \cos \phi \) and \( \sin \phi \) correspondingly.

The Class III of enantio-sensitive observables in photoionization originates from an infinite array of global invariants of the propensity field, which require non-zero multipoles \( l \geq 1 \) of net radial or net tangential components of the propensity field:

\[
B^{l,m}_{||}(k) \equiv \int \vec{B} (\vec{k}) \cdot \vec{k} Y_{lm} (\theta_k, \phi_k) d\Theta_k \neq 0, \tag{25}
\]

\[
B^{l,m}_{\perp}(k) \equiv k \int \vec{B} (\vec{k}) \cdot \vec{\nabla}_k Y_{lm} (\theta_k, \phi_k) d\Theta_k \neq 0, \tag{26}
\]

\[
B^{l,m}_{\perp,\perp}(k) \equiv \int \vec{B} (\vec{k}) \cdot [\vec{k} \times \vec{\nabla}_k] Y_{lm} (\theta_k, \phi_k) d\Theta_k \neq 0. \tag{27}
\]

These quantities are the spherical multipole moments of the vector field \( \vec{B} (\vec{k}) \). The parity of spherical harmonics \( Y_{lm}(\vec{k}) = (-1)^l Y_{lm}(-\vec{k}) \) dictates that even multipoles \( B^{l=2n,m}_{||}(k) \) and \( B^{l=2n,m}_{\perp}(k) \) can only emerge due to asymmetric quadratures \( \tilde{Q}^- (\vec{k}), \tilde{P}^- (\vec{k}) \), while the odd multipoles \( B^{l=2n+1,m}_{||}(k) \) and \( B^{l=2n+1,m}_{\perp}(k) \) can emerge only due to symmetric \( \tilde{Q}^+ (\vec{k}), \tilde{P}^+ (\vec{k}) \) quadratures. For the \( B^{l,m}_{\perp,\perp}(k) \) multipoles it is the other way around: the terms with even \( l \) may only appear due to symmetric \( \tilde{Q}^+ (\vec{k}), \tilde{P}^+ (\vec{k}) \) quadratures, while the terms with odd \( l \) may emerge due to \( \tilde{Q}^- (\vec{k}), \tilde{P}^- (\vec{k}) \). Additional cancellations of global invariants in Eqs. (26, 27), which may arise due to \( \hat{T}_k \) symmetries, will be considered elsewhere.

Observation of these global invariants is only possible in non-linear processes and occurs naturally in multiphoton ionization. The global invariants given by Eqs. (25, 27) lead to the multipolar \( j^{l+1}(k) \) (with multiplicity \( l + 1 \)) PECD currents. Note that the PECD current originating from the radial component of the propensity field Eq. (23, 24) can be named the "dipolar" current \( j^1(k) \), because it corresponds to \( (l = 0, m = 0) \) in Eq. 25.
The global invariants given by Eqs. (22-27) are pseudoscalars. Projection of the net geometric field (Eq. 20) on the axes of molecular frame are also pseudoscalars. Thus, the global invariants Eqs. (20-27) exist only in chiral molecules.

In particular, the quadrupolar PECD currents ($l = 1$) [33] emerge in photoionization of chiral molecules triggered by orthogonaly polarized two-color fields $\omega - 2\omega$ [34-36]. The quadrupolar currents mean that one resolves the photoelectron counts not with respect to the two opposite directions (forwards and backwards relative to the light propagation axis) as is done in the PECD experiments, but in four directions: up and down along the polarization of the fundamental field and forward and backward directions, [34]. We expect that other members of the infinite array in Eqs. (25-27) leading to higher order multipolar currents $j^n(k)$ (with multiplicity $n > 1$) can emerge in orthogonally polarized multicolor fields $\omega + n\omega$.

Together, these three classes of observables map all local properties of the geometric propensity field $\vec{B}$ onto global invariants – quantities that can be observed. Importantly, highly non-linear response is required to get access to the higher-order multipoles of Class III. This perspective demonstrates the complementary role of non-linear measurements, which allow one to access the quadratures with different symmetries not observed in linear PECD measurements. For example, the time-dependent PECD recently introduced in Ref. [32] gives access to the $\vec{P}^-$ quadrature not measured in the conventional linear PECD, which is only sensitive to the $\vec{Q}^-$ quadrature of the geometric field.

New enantio-sensitive observables

While the Class II observables and some of the Class III observables have already been detected in experiments, the Class I of enantio-sensitive observables is completely unexplored. This class is the most striking, because it requires non-zero "net" propensity field, i.e. the field averaged over all directions of the photoelectron momentum for a given final energy of the photoelectron $E$, $k = \sqrt{2E}$. Eq. (20) shows that it does not happen if one-photon ionization occurs from a real stationary state (Appendix B).

However, if we excite a superposition of states which develops current prior to photoionization, the field will acquire the $\vec{P}^+(\vec{k})$ quadrature component, which leads to net geometric field $\vec{B}(k)$ Eq. (20). Thus, the enantio-sensitive observables of Class I are signatures of chiral dynamics induced prior to ionization.

The connection between enantio-sensitive observables in photoionization and the geometric propensity field becomes evident as soon as we consider the photoionization yield $W(k)$ into energy $E = k^2/2$ for a fixed in space molecule, ionised by circularly polarised field propagating along
\( \ddot{z} \)-axis, in the electric dipole approximation:

\[
W(k, \rho) \propto \int d\Theta_k |a_{g\bar{k}}|^2, \tag{28}
\]

\[
|a_{g\bar{k}}|^2 = \frac{\pi}{2} |\mathcal{E}(\omega)|^2 \left\{ |d_{g\bar{k}}^{LB} \cdot \hat{x}|^2 + |d_{g\bar{k}}^{LB} \cdot \hat{y}|^2 + \sigma B^{LB}(\bar{k}, \rho) \cdot \hat{z} \right\}. \tag{29}
\]

Here \( a_{g\bar{k}} \) is the amplitude of ionization into the final state with photoelectron momentum \( \bar{k} \), \( \delta^2(\omega) \) is the Fourier component of the light field at the transition frequency \( \omega \), integration over \( d\Theta_k \) describes averaging over the directions of the photoelectron momentum, \( \rho \) denotes the Euler angles characterizing the orientation of the molecular frame relative to the laboratory frame, the vectors \( \hat{x}, \hat{y}, \hat{z} \) denote the axes of the laboratory frame, \( d_{g\bar{k}}^{LB} \) is the photoionization dipole in the laboratory frame (denoted by superscript \( LB \)), \( B^{LB}(\bar{k}, \rho) \) is the propensity field in the laboratory frame. Using Eq. \( \frac{29}{29} \) we formally obtain the expression for an arbitrary vectorial observable of the molecular cation \( \vec{V}^{LB}(k) \):

\[
\langle \vec{V}^{LB}(k) \rangle \equiv \int d\rho W(k, \rho) \vec{V}^{LB}(\rho) = \frac{\pi}{2} |\mathcal{E}(\omega)|^2 \sigma \int d\rho \left[ \int B^{LB}(\bar{k}, \rho) \cdot \hat{z} d\Theta_k \right] \vec{V}^{LB} = \frac{\pi}{6} |\mathcal{E}(\omega)|^2 \sigma \left( \vec{B}^{M}(k) \cdot \vec{V}^{M} \right) \hat{z}. \tag{30}
\]

Here the superscripts \( LB \) and \( M \) indicate that the respective vectors belong to the laboratory frame or the molecular frame correspondingly. Suppose \( \vec{e}^{M}_{B} \) is a unit polar vector collinear with the net propensity field \( \vec{e}^{M}_{B} \parallel \vec{B}^{M}(k) \) in the molecular frame of a given enantiomer. The scalar product \( \vec{e}^{M}_{B} \cdot \vec{B}^{M}(k) = \nu \left| \vec{B}^{M}(k) \right| \) is a pseudoscalar (\( \nu = \pm 1 \)), which has opposite signs in opposite enantiomers. The orientation of the vector \( \vec{e}^{M}_{B} \) in the laboratory frame \( \vec{e}^{LB}_{B} \) obtains from Eq.\( \frac{30}{30} \):

\[
\langle \vec{e}^{LB}_{B}(k) \rangle = \frac{\pi}{6} \delta^2(\omega) \sigma \nu \left| \vec{B}^{M}(k) \right| \hat{z}. \tag{31}
\]

Thus, Eqs.\( \frac{30}{30}, \frac{31}{31} \) predict enantio-sensitive orientation of molecular ions by ionization. The molecular frame vector \( \vec{e}^{M}_{B}(k) \parallel \vec{B}^{M}(k) \) gets oriented along the propagation axis of the probe pulse.

Non-zero \( \vec{B}^{M}(k) \) requires non-zero current prior to photoionization, which can be excited with a linearly polarized pump pulse. We have calculated the orientation of the vector \( \vec{e}^{LB}_{B} \) in the molecular cation analytically for the excitation of two intermediate states with energy difference \( \Delta E_{12} \) in randomly oriented ensemble of chiral molecules using our approach \[21, 37\]. If one ignores alignment of the molecular ensemble introduced by the pump pulse, one obtains:

\[
\langle \vec{e}^{LB}_{B}(k, \tau) \rangle = \int d\rho W(k, \rho) \vec{e}^{LB}_{B}(\rho) = \frac{2C \sigma \nu d_{1.0}^{M} \cdot d_{2.0}^{M}}{15} \sin(\Delta E_{12} \tau) \left| \vec{B}^{M}(k) \right| \hat{z}, \tag{32}
\]

\[
C = \delta^{e}(\omega_{10}) \delta^{e}_{1}(\omega_{20}) \delta^{e}_{2}(\omega_{1k}) \delta^{e}_{2}(\omega_{2k}). \tag{33}
\]
Here $d_{1,0}^M$ and $d_{2,0}^M$ are the excitation dipoles in the molecular frame. Eq. (32) shows that the molecule orients its molecular vector $\vec{e}_B^M(k) \parallel \vec{P}^+(k)$ along the light propagation axis in the laboratory frame: the direction of the geometric field $\vec{P}^+(k)$ defines molecular orientation. The direction of the vector $\vec{e}_B^{1B}(k,\tau)$ is opposite in the opposite enantiomers, because $\vec{P}^+(k) \cdot \vec{e}_B^M = \nu |\vec{P}^+(k)|$ is the molecular pseudoscalar that has opposite sign ($\nu = \pm 1$) in opposite enantiomers. The orientation also changes to the opposite when one changes the direction of rotation of the circularly polarized probe pulse $\sigma$.

The constant $C$ depends on the Fourier components of the pump and probe pulses at the excitation and photoionization frequencies correspondingly, as specified by Eq. (33).

If we include partial alignment of the randomly oriented molecules by the pump pulse, the full expression acquires an additional factor $\cos \alpha$:

$$
\langle \vec{e}_B^{1B}(k,\tau) \rangle = \int d\rho W(k,\rho)\vec{e}_B^{1B}(\rho) = \frac{2 C \sigma \nu d_{1,0}^M \cdot d_{2,0}^M}{15} \sin(\Delta E_{12} \tau) \cos \alpha \left| \vec{P}^+(k) \right| \vec{z},
$$

$$
\alpha \equiv \arccos \left( 1 - \frac{1}{2} \frac{\cos(d_{1,0}^M,\vec{e}_B^M) \cos(d_{2,0}^M,\vec{e}_B^M)}{\cos(d_{1,0}^M,\vec{e}_B^M) \cos(d_{2,0}^M,\vec{e}_B^M)} \right)
$$

For a given final energy of the photoelectron $E = k^2/2$, the strength of the effect is characterized by the ratio of the fraction of oriented ions relative to their total amount:

$$
\langle \langle \vec{e}_B^{1B}(k) \rangle \rangle = \frac{\int d\rho \vec{e}_B^{1B}(\rho) W(k,\rho)}{\int d\rho W(k,\rho)}.
$$

In the case of the intermediate excitation of two states, the total ionization yield is:

$$
\int d\rho W(k,\rho) = \frac{C}{30} \sum_{i=1}^{2} \int d\Theta_k \left[ 3 \left| \bar{d}_{i,0} \right|^2 \left| \bar{d}_{i,k} \right|^2 - \left| d_{i,0}^M \cdot d_{i,k}^M \right|^2 \right].
$$

The total fraction of the oriented ions obtains via additional averaging over the photoelectron energy in the relevant energy range:

$$
\langle \langle \vec{e}_B^{1B} \rangle \rangle_E = \frac{\int dk \int d\rho \vec{e}_B^{1B} W(k,\rho)}{\int dk \int d\rho W(k,\rho)}.
$$

Eq. (34) predicts that the enantio-sensitive orientation oscillates as a function of the pump-probe delay, reaching maximal positive or negative value for $\tau = (2n - 1)\pi/(2\Delta E_{12})$ ($n = 1, 2, 3, \ldots$). Photo-exciting randomly oriented molecular ensemble by a linearly polarized pump pulse and subsequently photoionizing it at opportune times using a circularly polarized probe will induce enantio-sensitive orientation of both the molecular cations and of the excited neutrals that where not ionised. The orientation of the neutrals will be opposite to that of the cations.
Co-rotating current: preferred by the probe

Counter-rotating current: ionization is less likely

Figure 2  Red frame includes the pictures illustrating the direction of molecular orientation $\vec{e}_B$ corresponding to the excitation of LUMO and LUMO+1 in propylene oxide for $k = 0.2 a.u.$ and respective orientation of right (a) and left (c) enantiomers in the laboratory frame. $\vec{z}$ is the direction of light propagation axis. (Vectors $\vec{e}_B$ and pseudovectors $\vec{P}^+(k)$ in different pictures belong to the common coordinate frame.) Right (b) and left (d) enantiomers oppositely oriented to molecules, shown in panels (a) and (c) respectively, have smaller ionization rates. Orientations (a) and (c) are preferred by the probe pulse, because in these molecules the circular current (green arrow) co-rotates with the probe field (red arrow).

Quantifying Enantio-sensitive molecular orientation by non-linear photoionization

To quantify the predicted effect, we have considered excitations from HOMO to LUMO and LUMO+1 states of propylene oxide. To calculate all quadratures of the propensity field, we have used the photo-excitation and photoionization dipoles computed using the DFT-based approach developed in [38]. This approach yields excellent agreement with the experimental data for one-photon ionization of chiral molecules [39–43].

Figure 2 shows the direction of the molecular orientation $\vec{e}_B^{LB}$ arising when the excitation of LUMO and LUMO+1 in propylene oxide is followed by photoionization into the states with momentum $k = 0.2 a.u.$, for the left-handed and right-handed enantiomers. The quadrature $\vec{P}^{+M}(k)$ has the same
direction in the left- and right-handed enantiomers, but the pseudoscalar $\nu$ has opposite sign for the opposite enantiomers, corresponding to the opposite orientation of left and right molecular ions with respect to the laboratory $\vec{z}$ axis.

Figure 3 shows the components of the propensity field responsible for Class I and Class II enantio-sensitive observables in this case. The net propensity field $|\vec{P}^{+M}(k)|$ quantifying the enantio-sensitive molecular orientation by ionization (the molecular orientation circular dichroism, MOCD) is substantially larger than each of the quadratures $Q^{-M}_{\parallel}(k)$ and $P^{-M}_{\parallel}(k)$ quantifying the time-dependent PECD (TD-PECD):

$$\vec{j}_{TDPECD}(k, \tau) = \int d\rho W(k, \rho) \vec{k}^L(\rho) = \frac{2C\sigma d_{10}^{M} d_{20}^{M}}{15} \left\{ \cos(\omega_{21}\tau)Q^{-M}_{\parallel}(k) + \sin(\omega_{21}\tau)P^{-M}_{\parallel}(k) \right\} \vec{z}.$$  (39)

In Eq. (39) we have omitted the terms originating from the alignment of the molecular ensemble by the pump pulse to facilitate the comparison with Eq. (32) for MOCD.

The set-up for MOCD involves a linearly polarized pump pulse to excite the superposition of states in randomly oriented neutral chiral molecules, and a circularly polarized probe to photoionize the excited molecules. It is identical to the set-up used in Ref. [32] to observe the time-dependent PECD. The difference is in the observables: the TD-PECD signal is imprinted onto the angular distributions of photoelectrons and requires measurement of the photoelectron circular dichroism. The MOCD signal is imprinted onto the angular distributions of molecular cations. Its observation becomes possible e.g. via fragmentation of the cation and observation of the angular distributions of the fragments.

The quadratures $Q^{-M}_{\parallel}(k)$ and $P^{-M}_{\parallel}(k)$ contribute to the Class II enantio-sensitive observables and encode the net radial component of the propensity field (see Eqs. (23, 24)).

Fig.3 shows that the enantio-sensitive orientation can be even stronger than the enantio-sensitive signal in TD-PECD, which yields $\sim 20\%$ in recent experiments on fenchone and camphor [32]. Importantly, TD-PECD and MOCD involve completely different components of the geometric propensity field and therefore expose different and complementary aspects of chiral dynamics in molecules.

Qualitatively, the orientation induced by photoionization can be understood as follows. First, a linearly polarized pump excites a current. In the molecular frame, the direction of the current is determined only by the geometry of the excited molecular orbitals. Suppose that the current goes from a head of a molecule to its tail in the molecular frame. For the two oppositely oriented molecules in the laboratory frame, such current will have opposite directions in the laboratory frame. Second, in the two enantiomers with the same handedness, this current will be converted into circulating currents with the same direction of rotation. Due to the so-called spin-momentum locking – the
Figure 3 Propensity field and its global invariants emerging upon excitation of LUMO and LUMO+1 orbitals in propylene oxide. (a) The symmetric quadrature $\vec{P}^M(\vec{k})$ for $k = 0.2$ a.u. and (d) its net value $|\vec{P}^M(\vec{k})|$, which governs Class I observables, such as enantio-sensitive molecular orientation (MOCD). Asymmetric quadratures $\vec{Q}^{-M}(\vec{k})$ (b) and $\vec{P}^{-M}(\vec{k})$ (c) $k = 0.2$ a.u. and the net values of their radial components $Q^{-M}_{||}(k)$ (e) and $P^{-M}_{||}(k)$ (f), which govern Class II observables, such as the TD-PECD. The maximum values of $\vec{P}^M(\vec{k})$ (a), $\vec{Q}^{-M}(\vec{k})$ (b) and $\vec{P}^{-M}(\vec{k})$ (c) are 0.41, 0.51 and 0.47 a.u., respectively.

property underlying the textbook "right hand rule" in electromagnetism or the corkscrew ability to open wine bottles in the everyday life – the circular currents in the two oppositely oriented, but otherwise equivalent enantiomers, will be rotating in opposite directions in the laboratory frame. Due to the propensity rules in one-photon ionization, explicitly quantified by the geometric propensity field, the circularly polarized probe pulse "selects" (or preferentially ionizes) one of these two opposite currents, choosing the current co-rotating with the probe pulse. It leads to the difference in the photoionization yields and thus to the emergence of the oriented molecular ions. The difference in the ionisation yields is proportional to the magnitude of the geometric propensity field.

Importantly, the net direction of orientation coincides with the axis of the excited "curly" current, i.e. the direction of the net geometric field. Molecules where this axis was oriented along the propagation axis of the pump and probe pulses will be preferentially ionised. Thus, the MOCD is also an
Figure 4  Snapshots corresponding to the half period evolution of the electronic wave-packet excited in the superposition of LUMO and LUMO+1 states of the propylene oxide. Green arrow shows the direction of $\vec{P}^+M(k)$ for this superposition. The blue arrow shows the direction of circulation of the chiral current.

Figure 5  Degree of orientation corresponding to excitation of LUMO and LUMO+1 in propylene oxide and subsequent ionization by circularly polarized field.

example of charge directed reactivity. It demonstrates that the photoionization yield, i.e. the rate of this photochemical reaction, can depend on the direction of the current excited in the chiral molecule prior to photoionization.

Fig. 4 shows the snapshots of wave-packet dynamics corresponding to the excitation of a superposition of the LUMO and LUMO+1 of propylene oxide. The green arrow shows the direction of the net geometric field in the molecular frame, which represents the axis of the excited "curly" current. Fig. 5 shows the degree of orientation of the molecular ions due to subsequent ionisation by probe pulse calculated using the DFT-based matrix elements, dipole couplings and Eqs. (34,35). The $\langle \cos \Theta \rangle = 0.12$ for $k = 0.2$ a.u. means that roughly 58 out of 100 molecules have $\vec{e}_B \vec{z} < 0$ and 42 out of 100 molecules have $\vec{e}_B \vec{z} > 0$. Thus, very significant degree of enantio-sensitive orientation results from the excitation of chiral dynamics in valence shells.

We expect that more localised cite-specific core excitations could allow one to initiate chiral "curly" currents from different locations inside the molecule and probe the orientation of the most efficient "molecular cork-screw".
Propensity field in the plane-wave continuum

Figure 5 shows that MOCD does not vanish for photoionization into $k \geq 1$ a.u. Indeed, some quadratures of the propensity field survive in the plane wave continuum. As follows from the symmetries of the propensity field described in section III, only the $\hat{T}$-odd component $\vec{B}(\vec{k})$ of the propensity field (Eq. 16) involving quadratures $\vec{Q}^-(\vec{k})$ and $\vec{P}^+(\vec{k})$ can survive in the plane wave continuum (in this Section we consider the fields in the molecular frame but suppress the superscript $M$). The plane wave continuum excludes the contribution of chiral electron-core scattering to MOCD, but the effect remains. It happens because the propensity field can originate solely from chiral dynamics in the bound states.

Another interesting aspect of MOCD and $\vec{B}(\vec{k})$ in the plane wave-continuum is that one can immediately introduce the analogue of the Berry connection, i.e. the "vector potential" underlying the geometric field $\vec{B}(\vec{k})$. In the plane wave continuum, the dipole matrix element contributing to the propensity field is related to the Fourier image of the bound state $\Phi_1(\vec{k})$: $\vec{a}_k = i\nabla_k \Phi_1(\vec{k})$. Thus, the propensity field stemming from the bound dynamics excited in states $|1\rangle$ and $e^{i\phi}|2\rangle$ can be written as:

$$\vec{B}_{12}(\vec{k}, \phi) = \frac{1}{2}i \left[ \nabla_k \Phi_1(\vec{k}) \times \nabla_k \Phi_2^*(\vec{k}) \right] e^{i\phi} + c.c. \equiv \nabla_k \times \vec{A}_{12}(\vec{k}, \phi),$$

(40)

where we have introduced the vector-potential $\vec{A}_{12}(\vec{k}, \phi)$:

$$\vec{A}_{12}(\vec{k}, \phi) = \frac{1}{2}i \Phi_1(\vec{k}) \nabla_k \Phi_2^*(\vec{k}) e^{i\phi} + c.c. \equiv \vec{A}_{12}^Q(\vec{k}) \cos \phi + \vec{A}_{12}^P(\vec{k}) \sin \phi,$$

(41)

$$\vec{A}_{12}^Q(\vec{k}) \equiv -\Im \langle \Phi_1(\vec{k}) | \nabla_k \Phi_2^*(\vec{k}) \rangle,$$

(42)

$$\vec{A}_{12}^P(\vec{k}) \equiv -\Re \{ \Phi_1(\vec{k}) \nabla_k \Phi_2^*(\vec{k}) \}.$$

(43)

It is easy to show that the quadratures of the propensity field are connected to the quadratures of the vector potential $\vec{A}_{12}(\vec{k}, \phi)$ in the standard way:

$$\vec{Q}_{12}(\vec{k}) = \nabla_k \times \vec{A}_{12}^Q(\vec{k}),$$

(44)

$$\vec{P}_{12}(\vec{k}) = \nabla_k \times \vec{A}_{12}^P(\vec{k}).$$

(45)

Eq. (44) is reminiscent of the similar link between the Berry curvature and the Berry connection (its vector potential):

$$\vec{\Omega}_{11}(\vec{k}) = \nabla_k \times \left[ -\Im \langle \Phi_1(\vec{k}) | \nabla_k \Phi_1^*(\vec{k}) \rangle \right].$$

(46)
Note that in this case \( \Re\langle \Phi_1(\vec{k})|\nabla_k \Phi_1^*(\vec{k}) \rangle = 0 \), because the normalized state vectors obey to the equation: \( \langle \Phi_1(\vec{k})|\Phi_1^*(\vec{k}) \rangle = 1 \).

In our case the vector potential involves two different states and depends on their coherences.

The existence of the vector potential may bring us one step closer to understanding the connection between the two geometrical properties: topology and chirality in photoionization.

**Outlook**

Geometric magnetism underlies extremely efficient enantio-sensitive observables in molecular photoionization. The geometric propensity field in chiral molecules, described here, is a newly recognised member of the family of geometric fields. Several classes of enantio-sensitive observables rely on its global invariants. We see several future directions associated with the phenomenon of geometric magnetism in photoionization of chiral molecules.

First, from the experimental perspective, an interesting new step would be the detection of enantio-sensitive orientation by ionization. Valence shell MOCD can be induced by exciting electronic or vibronic degrees of freedom and thus can be achieved with pulses of various duration. While faster purely electronic dynamics requires shorter pulses, one can also rely on slow vibronic dynamics, enabling one to use longer pulses for molecular orientation. MOCD can also be induced by core excitations with short, few femtosecond, X-ray pulses. This may allow one to choose the direction of current in the molecular frame and thus its orientation more precisely due to localized excitation and cite-specific photoionization. In this case, probing the induced electronic excitations should likely be done before the core-hole decay due to e.g. the Auger process. Molecular fragmentation, which may be induced by such decay, could be beneficial for detection of the orientation of the molecular frame by detecting angular distributions of its fragments.

Second, \( \vec{B}(\vec{k}) \)-field encodes the "local" (\( \vec{k} \)-resolved) information about geometrical properties of chiral molecules underlying both continuum and bound current and also their interplay: the net radial component of the propensity field quantifies PECD, while the net propensity field quantifies the MOCD. Thus, it would be interesting to detect the local structure of the geometric field experimentally. Our preliminary investigations show that this field could be imaged via resonant excitation followed by ionization, but requires non-collinear arrangement of the pump and probe beams [21].

Third, establishing the connection between the \( \vec{B}(\vec{k}) \) field topology and the topology of the respective bound and continuum states is another interesting and yet unexplored aspect of the geometric magnetism in chiral molecules. One of the possible directions along these lines is the classification of the molecular high symmetry points – the points in \( \vec{k} \)-space in the molecular frame where \( \vec{B}(\vec{k}) = 0 \).
and thus the CD is absent for any orientation of light polarization plane with respect to the molecular frame. For such $\vec{k}$, the chiral molecule is rotationally symmetric with respect to the axis of arbitrary orientation. What does the location of these points in $\vec{k}$-space tell one about the geometry of bound and continuum states involved into photoionization?

Fourth, the existence of chiral geometric fields leads to new enantio-sensitive phenomena, such as time dependent molecular orientation on the electronic time scale. The interesting future direction is to use this enantio-sensitive molecular orientation which occurs in neural molecules and molecular ions for (i) quantification of helical currents in chiral molecules, (ii) enantio-separation and (iii) ultrafast molecular imaging with oriented chiral molecules. Identifying other enantio-sensitive observables of Class I is another interesting direction. Finally, geometric magnetism in chiral molecules may connect chiral effects in photoionization with a broad class of topological phenomena.

These analogies, developed in this paper, should allow one to explore the link between chiral and topological phenomena, and possibly induce new topology-driven phenomena such as quantized circular dichroism in photoionization of chiral molecules. For example, one could consider light-induced intersections of the Floquet states, to induce quantization of the enantio-sensitive photo-electron current $\vec{J}$ when varying the laser frequency and intensity along a closed loop around a resonance.

**Appendix A: Symmetries of the propensity field in k-space**

In this section we apply symmetry operations, usually used to consider symmetry properties of the Berry curvature in solids, to the propensity field. We show that the propensity field has the same properties with respect to inversion $I$ and $T_{k}$ as the Berry curvature.

Inversion turns $\vec{r} \rightarrow -\vec{r}$ and $\vec{k} \rightarrow -\vec{k}$. $T_{k}$ involves complex conjugation and $\vec{k} \rightarrow -\vec{k}$ and is highly relevant in solids. $T_{k}$ is very convenient for classification of properties of the geometric propensity field in relation to its global invariants of Class III. In this section we consider geometric propensity field relevant for the photoionization from real (time-even) bound states. Below we illustrate the following symmetry properties of the propensity field:

1. In inversion symmetric gas phase systems with broken $T_{k}$-symmetry only $T_{k}$-even component of the geometric propensity field $\mathcal{D}(\vec{k})$ is non-zero $\mathcal{D}(\vec{k}) = \mathcal{D}(-\vec{k}) \neq 0$. This component is $\vec{k}$-even. The Berry curvature in solids is also $\vec{k}$-even in such systems. [28].

2. In non-inversion symmetric and $T_{k}$-symmetric gas phase systems only $T_{k}$-odd component of the propensity field $\mathcal{D}(\vec{k}) \neq 0$. This component is also $\vec{k}$-odd: $\mathcal{D}(\vec{k}) = -\mathcal{D}(-\vec{k}) = 0$. The Berry curvature is also $\vec{k}$-odd in solids with same symmetries [28].
\( T_k \)-symmetry breaking in molecular scattering states

In periodic solids the periodic part of the Bloch functions in time-reversal invariant systems satisfy the following condition:

\[
\hat{T}_k u_k(\vec{r}) \equiv u^*_k(-\vec{r}) = e^{i\chi(\vec{k})} u_k(\vec{r}). \tag{47}
\]

It leads to the following symmetry of the Berry curvature in non-inversion symmetric systems:

\[
\vec{\Omega}(\vec{k}) = -\vec{\Omega}(-\vec{k}).
\]

Consider non-inversion symmetric molecules in time-reversal invariant (real) bound state and the diagonal propensity field relevant for photoionization from this state

\[
\vec{B}_{nn}(\vec{k}) = i[\vec{d}_n \times \vec{d}^*_n]. \tag{48}
\]

In case of a solid, symmetry dictates that the only non-zero component of the Berry curvature must be \( \vec{k} \)-odd: \( \vec{\Omega}(\vec{k}) = -\vec{\Omega}(-\vec{k}) \). Does it also apply to the geometric propensity field?

The geometric propensity field depends not only on the property of the ground state, but also on the properties of the molecular scattering states. It turns out that molecular scattering states do not posses \( \hat{T}_k \) symmetry due to different (from periodic solids) boundary conditions. This symmetry is broken already in the continuum of a hydrogen atom. Consider the incoming \( \Psi_k^{(-)}(r \to \infty) \) and outgoing \( \Psi_k^{(+)}(r \to \infty) \) boundary conditions for scattering in the Coulomb potential, in the so-called Redmond form [44]:

\[
\begin{align*}
\Psi_k^{(+)}(r \to \infty) &\propto e^{i\vec{k}\vec{r} - i\nu \ln(kr - \vec{k}\vec{r})}, \tag{49} \\
\Psi_k^{(-)}(r \to \infty) &\propto e^{i\vec{k}\vec{r} + i\nu \ln(kr + \vec{k}\vec{r})}. \tag{50}
\end{align*}
\]

It is easy to check that the incoming and outgoing asymptotic solutions are interconverted by the symmetry operation \( \hat{T}_k \):

\[
\hat{T}_k \Psi_k^{(\pm)}(r \to \infty) = \Psi_k^{(\mp)*}(r \to \infty) = \Psi_k^{(\mp)}(r \to \infty). \tag{51}
\]

The photoionization matrix element by definition involves only the incoming scattering solution \( \tilde{d}_{gk} = -\langle \Psi_k^{(-)} | \vec{r} | \Psi_g \rangle \). Since \( \Psi_k^{(-)*}(\vec{r}) \neq \Psi_k^{(-)}(\vec{r}) \), we obtain \( \tilde{d}_{gk}^* \neq \tilde{d}_{kg}^* \), which means that the propensity field has both \( \hat{T}_k \)-odd \( \vec{\mathcal{B}}^*(-\vec{k}) = -\vec{\mathcal{B}}(\vec{k}) \) and \( \hat{T}_k \)-even \( \vec{\mathcal{B}}^*(\vec{k}) = \vec{\mathcal{B}}(\vec{k}) \) pseudovector components: \( \vec{B}(\vec{k}) = \vec{\mathcal{B}}(\vec{k}) + \vec{\mathcal{B}}(\vec{k}) \). Since the propensity field is real, its \( \vec{\mathcal{B}}(\vec{k}) \) component is \( \vec{k} \)-odd, while its \( \vec{\mathcal{B}}(\vec{k}) \) component is \( \vec{k} \)-even.
The lack of $\vec{k}$-inversion symmetry of the geometric propensity filed stems from the lack of $T_k$-symmetry in molecular scattering states. The lack of $\vec{k}$-inversion symmetry of the geometric propensity field is consistent with the same property of the Berry curvature in non-inversion symmetric systems with broken $T_k$-symmetry.

Geometric propensity field in systems with inversion symmetry $I$ without $T_k$-symmetry

As an example, consider the propensity field corresponding to photoionization from a state $n$

$$\vec{B}_{mn}(\vec{k}) = i[\vec{d}_{nk} \times \vec{d}^*_{nk}].$$

(52)

and its properties in a system which has inversion symmetry, time-even bound states, but does not have $T_k$-symmetry in continuum states. Perhaps, the simplest example of such system is a Hydrogen atom. Indeed, in the Coulomb potential both $I$ and $T$ hold

$$I \Psi_{\pm}(\vec{r}) = \Psi_{\pm}(\vec{r}),$$

(53)

$$I \Psi_n(\vec{r}) = \Psi_n(\vec{r}),$$

(54)

$$T \Psi_n(\vec{r}) = \Psi^*_n(\vec{r}) = \Psi_n(\vec{r}),$$

(55)

while $T_k$ symmetry is broken (see Eq. (51)). The photoionization dipole is:

$$\vec{d}_{nk} = -\int \Psi^{(-)*}_{-\vec{k}}(\vec{r})\vec{r}\Psi_n(\vec{r})d\vec{r} = \int \Psi^{(-)*}_{\vec{k}}(-\vec{r})(-\vec{r})\Psi_n(-\vec{r})d\vec{r} = -\vec{d}_{n-\vec{k}}.$$  

(56)

Using Eq.(52) we obtain for $\vec{B}(\vec{k})$

$$\vec{B}(\vec{k}) = i[\vec{d}_{n-k} \times \vec{d}^*_{n-k}] = i[\vec{d}_{nk} \times \vec{d}^*_{nk}] = \vec{B}(\vec{k}).$$

(57)

Thus, in inversion symmetric systems with broken $T_k$-symmetry the propensity field has only one non-zero component: the $T_k$-even component $\vec{D}(\vec{k})$. Its symmetry is consistent with Eq. (57), i.e. $\vec{D}(\vec{k}) = \vec{D}(\vec{-k})$. The $T_k$-odd component of the propensity field $\vec{A}(\vec{k})$ does not satisfy condition Eq. (57) and therefore $\vec{A}(\vec{k}) = -\vec{A}(\vec{-k}) = 0$. 

22
Inversion-symmetric and $T_k$-symmetric system

An example of such system is a short-range inversion symmetric potential with plane wave continuum $\Psi^{(PW)}_{\vec{k}}(r) = e^{i\vec{k}\vec{r}}$.

\begin{align*}
T_k \Psi_{\vec{k}}^{(PW)}(r) &= \Psi_{-\vec{k}}^{PW}(\vec{r}) = e^{i\vec{k}\vec{r}}, \\
I \Psi_{\vec{k}}^{(PW)}(r) &= \Psi_{-\vec{k}}^{PW}(-\vec{r}) = e^{i\vec{k}\vec{r}}, \\
T \Psi_{\vec{n}}(\vec{r}) &= \Psi_{\vec{n}}(-\vec{r}) = \Psi_{\vec{n}}(\vec{r}), \\
I \Psi_{\vec{n}}(\vec{r}) &= \Psi_{\vec{n}}(\vec{r}) = \Psi_{\vec{n}}(\vec{r}).
\end{align*}

The photoionization dipole in inversion symmetric system satisfies

\begin{equation}
\vec{d}_{nk} = -\int e^{-i\vec{k}\vec{r}} \Psi_{\vec{n}}(\vec{r}) d\vec{r} = \int e^{-i(\vec{k})(\vec{r})} \Psi_{\vec{n}}(\vec{r}) d\vec{r} = -\vec{d}_{n-\vec{k}}.
\end{equation}

Thus, using Eq.(52) we obtain for $\vec{B}(-\vec{k})$ in the presence of inversion symmetry:

\begin{equation}
\vec{B}(-\vec{k}) = i[\vec{d}_{n-\vec{k}} \times \vec{d}_{n-\vec{k}}^*] = i[\vec{d}_{nk} \times \vec{d}_{nk}^*] = \vec{B}(\vec{k}).
\end{equation}

In this case, only $T_k$-even component of the propensity field is non-zero: $\vec{D}(\vec{k}) \neq 0$, $\vec{\mathcal{D}}(\vec{k}) = 0$. (This result, of course, coincides with the statement in Eq. (57)). The photoionization dipole in the $T_k$-symmetric system satisfies:

\begin{equation}
\vec{d}_{\vec{k}} = -\int e^{-i\vec{k}\vec{r}} \Psi_{\vec{n}}(\vec{r}) d\vec{r} = -\int e^{i(\vec{k})(\vec{r})} \Psi_{\vec{n}}(\vec{r}) d\vec{r} = \vec{d}_{\vec{n}-\vec{k}}.
\end{equation}

Analogously, using Eq.(52) we obtain that in the presence of $T_k$-symmetry

\begin{equation}
\vec{B}^*(\vec{k}) = -i[\vec{d}_{\vec{n}-\vec{k}}^* \times \vec{d}_{\vec{n}-\vec{k}}^*] = -i[\vec{d}_{nk}^* \times \vec{d}_{nk}^*] = -\vec{B}(\vec{k}).
\end{equation}

In this case, only $T_k$-odd component of the propensity field is non-zero: $\vec{D}(\vec{k}) \neq 0$, $\vec{\mathcal{D}}(\vec{k}) = 0$. The combination of the two requirements means that in the presence of both $T_k$ and inversion symmetry the propensity field is zero. The same symmetry property is valid for the Berry curvature: it is zero in inversion symmetric and $T_k$-symmetric systems.
Here we prove that the $T_k$-even component $\mathbf{D}_{ij}(\mathbf{k}, \phi_{ij})$ (see Eq. 15) does not contribute to the net geometric field for real bound states and thus the symmetric quadrature $\mathbf{Q}_{ij}^+(\mathbf{k})$ does not contribute to Class I enantio-sensitive observables for real bound states:

$$\int \mathbf{Q}_{ij}^+(\mathbf{k}) d\Theta_k = 0,$$

(66)

We first prove this statement for $i = j$ and then extend the analysis to the case $j \neq i$. Consider real (time-even) bound states of a molecule:

$$T \Psi_i(\mathbf{r}) = \Psi_i^*(\mathbf{r}) = \Psi_i(\mathbf{r}),$$

(67)

$$T \Psi_j(\mathbf{r}) = \Psi_j^*(\mathbf{r}) = \Psi_j(\mathbf{r}).$$

(68)

The net propensity field can be formulated via a kernel of an operator $B_k^s(\mathbf{r}, \mathbf{r}')$:

$$B_k^s(\mathbf{r}, \mathbf{r}') = -i \varepsilon_{sqp} r_q G_k(\mathbf{r}, \mathbf{r}') r_p',$$

(69)

where $G_k(\mathbf{r}, \mathbf{r}')$ is a projector on the molecular continuum states:

$$G_k(\mathbf{r}, \mathbf{r}') = \int d\Theta_k \Psi_k^{(-)}(\mathbf{r}) \Psi_k^{(-)*}(\mathbf{r}').$$

(70)

and $s, p, q$ label coordinate axis in the $\mathbf{k}$-space. The diagonal matrix element $B_{ii}^s(k)$ of the operator (69) yields the $s$-component of the net propensity field:

$$B_{ii}^s(k) = \langle \Psi_i(\mathbf{r}) | B^s(\mathbf{r}, \mathbf{r}') | \Psi_i(\mathbf{r}') \rangle = -i \varepsilon_{sqp} \langle \Psi_i(\mathbf{r}) | r_q G_k(\mathbf{r}, \mathbf{r}') r_p' | \Psi_i(\mathbf{r}') \rangle = -i \varepsilon_{sqp} \int d\Theta_k \int d\mathbf{r}' \int d\mathbf{r} \Psi_i(\mathbf{r}) r_q \Psi_k^{(-)}(\mathbf{r}) \Psi_k^{(-)*}(\mathbf{r}') r_p' \Psi_i(\mathbf{r}') = -i \varepsilon_{sqp} \int d\Theta_k d^s_{ik} d^p_{ik} = \int d\Theta_k \left( -i [\mathbf{d}^s_{ik} \times \mathbf{d}^p_{ik}] \right)^s = \int d\Theta_k \left( i [\mathbf{d}^s_{ik} \times \mathbf{d}^p_{ik}] \right)^s = \int d\Theta_k B^s(\mathbf{k}).$$

(71)

The projector $G_k(\mathbf{r}, \mathbf{r}')$ has the following property:

$$TG_k(\mathbf{r}, \mathbf{r}') T = G_k(\mathbf{r}', \mathbf{r}).$$

(72)
Thus,

\[ \mathbf{B}_{i}^{s}(k) \equiv \langle \mathbf{\Psi}_{i}(\vec{r})|\mathbf{B}^{s}(\vec{r},\vec{r}')|\mathbf{\Psi}_{g}(\vec{r}') \rangle = -i\varepsilon_{sqp}\langle \mathbf{\Psi}_{i}(\vec{r})|r_{q}G_{k}(\vec{r}',\vec{r})r'_{p}|\mathbf{\Psi}_{i}(\vec{r}') \rangle =\

= -i\varepsilon_{sqp}\langle \mathbf{\Psi}_{i}(\vec{r})T|Tr_{q}G_{k}(\vec{r},\vec{r}')r'_{p}T|T\mathbf{\Psi}_{i}(\vec{r}') \rangle = -i\varepsilon_{sqp}\langle \mathbf{\Psi}_{i}(\vec{r}')|r_{q}TG_{k}(\vec{r}',\vec{r}')Tr'_{p}|\mathbf{\Psi}_{i}(\vec{r}) \rangle =

= -i\varepsilon_{sqp}\langle \mathbf{\Psi}_{i}(\vec{r}')|r'_{p}G_{k}(\vec{r}',\vec{r})r_{q}|\mathbf{\Psi}_{i}(\vec{r}) \rangle =

\quad i\varepsilon_{sqp}\langle \mathbf{\Psi}_{i}(\vec{r}')|r'_{p}G_{k}(\vec{r}',\vec{r})r_{q}|\mathbf{\Psi}_{i}(\vec{r}) \rangle = -\mathbf{B}_{i}^{s}(k). \quad (73) \]

The condition formulated in Eq. (73) is only satisfied if \( \mathbf{B}_{i}^{s}(k) = -\mathbf{B}_{i}^{s}(k) = 0 \). We can now extend this conclusion to \( \mathbf{B}_{ij}^{s}(k) \). We have proven that for real bound states \( \mathbf{\Psi}_{i}(\vec{r}), \mathbf{\Psi}_{j}(\vec{r}) \), and their real superposition \( \mathbf{\Psi}_{i}(\vec{r}) + \mathbf{\Psi}_{j}(\vec{r}) \):

\[ \mathbf{B}_{i+j,i+j}^{s}(k) = \langle \mathbf{\Psi}_{i}(\vec{r}) + \mathbf{\Psi}_{j}(\vec{r})|\mathbf{B}^{s}(\vec{r},\vec{r}')|\mathbf{\Psi}_{i}(\vec{r}) + \mathbf{\Psi}_{j}(\vec{r}') \rangle = 0, \quad (74) \]

\[ \mathbf{B}_{i,i}^{s}(k) = \langle \mathbf{\Psi}_{i}(\vec{r})|\mathbf{B}^{s}(\vec{r},\vec{r}')|\mathbf{\Psi}_{i}(\vec{r}') \rangle = 0, \quad (75) \]

\[ \mathbf{B}_{j,j}^{s}(k) = \langle \mathbf{\Psi}_{j}(\vec{r})|\mathbf{B}^{s}(\vec{r},\vec{r}')|\mathbf{\Psi}_{j}(\vec{r}') \rangle = 0. \quad (76) \]

Thus,

\[ \mathbf{B}_{i+j,i+j}^{s}(k) = \mathbf{B}_{i,i}^{s}(k) + \mathbf{B}_{j,j}^{s}(k) + \mathbf{B}_{i,j}^{s}(k) + \mathbf{B}_{j,i}^{s}(k) = \mathbf{B}_{i,j}^{s}(k) + \mathbf{B}_{j,i}^{s}(k) = 0. \quad (77) \]

Eq. (77) means that the net propensity field must satisfy:

\[ \mathbf{B}_{i,j}^{s}(k) = -\mathbf{B}_{j,i}^{s}(k), \quad (78) \]

\[ \Re \mathbf{B}_{i,j}^{s}(k) \equiv Q_{ij}^{s}(k) = 0, \quad (79) \]

\[ \Im \mathbf{B}_{i,j}^{s}(k) \equiv P_{ij}^{s}(k) \neq 0. \quad (80) \]

Note that by definition \( \tilde{Q}_{ij}(\vec{k}) = \tilde{Q}_{ij}^{+}(\vec{k}) + \tilde{Q}_{ij}^{-}(\vec{k}) \) and therefore

\[ \tilde{Q}_{ij}(k) \equiv \int \tilde{Q}_{ij}^{+}(\vec{k})d\Theta_{k} + \int \tilde{Q}_{ij}^{-}(\vec{k})d\Theta_{k} = \tilde{Q}_{ij}^{+}(k) = 0, \quad (81) \]

\[ \tilde{P}_{ij}(k) \equiv \int \tilde{P}_{ij}^{+}(\vec{k})d\Theta_{k} + \int \tilde{P}_{ij}^{-}(\vec{k})d\Theta_{k} = \tilde{P}_{ij}^{+}(k) \neq 0, \quad (82) \]

where we have used the fact that second integrals in Eqs. (81,82) vanish because the \( \tilde{Q}_{ij}(\vec{k}), \tilde{P}_{ij}(\vec{k}) \) are \( \vec{k} \)-odd.
Thus, the net propensity field
\[ \bar{B}(k) = \sin \phi \int \bar{P}^+(k) d\Theta_k = \bar{P}^+(k) \sin \phi, \] (83)
is zero for photoionization from real ($\phi = 0$) bound states.

Acknowledgments

We gratefully acknowledge many enlightening discussions with Prof. Misha Ivanov. We thank Dr. Rui Emanuel Ferreira da Silva and Dr. Alvaro Jimenez Galan for their comments on the manuscript and Dr. Emilio Pisanty for suggesting an acronym "MOCD". OS is grateful to Ms. Julia Riedel for applying right pressure at right times.

We have introduced the enantio-sensitive conductivity to enable comparison with the analogous effect in solids.

Note that Juan et al use $\beta = -i\sigma$ to formulate Eqs.6,7.
