(Dated: 7 July 2021)

We report on the excitation of spin waves in micro-structured magnetic thin films by surface acoustic waves (SAWs). The spin waves as well as the acoustic waves are studied by micro-focused Brillouin light scattering spectroscopy. Besides the excitation of the ferromagnetic resonance, a process which does not fulfills momentum conservation, the excitation of finite-wavelength spin waves can be observed at low magnetic fields. By conducting micromagnetic simulations we verify that during this excitation both energy and linear momentum are conserved and fully transferred from the SAW to the spin wave.
The rapid increase in computing power in CMOS-based devices, which is described by Moore’s Law, has slowed down in recent years. One reason for this is the drastic reduction in component size combined with the Joule heating generated by the charge carriers. A promising successor technology is magnonics, in which spin waves, or their quasiparticles the magnons, are used as information carriers. Unlike CMOS, this is a wave-based logic in which the information can be encoded in both the amplitude and the phase of the spin waves. This also makes magnonic systems attractive for implementing neural networks. Over time, the functionality of various essential components, such as transistors, diodes, majority gates, directional couplers or half-adders was demonstrated. Many of these components were on the millimetre to micrometre scale. However, in order for magnonics to catch up with or even undercut the currently existing CMOS technology from the aspect of area-delay power product (ADPP), these components must be miniaturised to the nanometre scale. This is possible due to the small wavelength and the frequency of the spin waves, which is in the Gigahertz range. However, the excitation of the spin waves is challenging, as this is usually based on micro-printed antennas through which a microwave current flows. These currents lead to Joule heating, as in the case of CMOS devices, which results in similar problems. This argues for purely voltage-based excitation mechanisms, such as the use of multiferroic heterostructures. An alternative approach is to use magneto-elastic coupling between magnons and phonons. In piezoelectric materials, phonons can be excited in an energy-efficient way by means of electric fields. In this context, the coupling of spin waves with bulk acoustic waves (BAW) and with surface acoustic waves (SAWs) is of great interest. Recently, it has been shown, that the excitation of spin waves by SAWs leads to an additional absorption of SAWs. This has been used to realize non-reciprocal SAW propagation using the Dzyaloshinskii-Moriya interaction. Most of these studies use SAW transmission spectroscopy, while only a few take an optical approach to phonon-magnon coupling. Most studies, however, concentrate on the SAW transmission and not on the properties of the excited spin waves.

In this study, we investigate the excitation of spin waves by SAWs in micrometre-sized strips of cobalt-iron-boron (CoFeB) thin films. We use micro-focused Brillouin light scattering spectroscopy (µBLS) to observe both SAWs and spin waves separately, which is possible due to the different rotation of the polarisation of the light during the inelastic scattering process. We demonstrate that for a given SAW frequency \( f \), resonances for the excitation of SWs can be observed at two different magnetic bias fields. The excitation at higher fields can be identified as the acous-
Fully Resonant Magneto-elastic Spinwave Excitation by Surface Acoustic Waves

In this process, however, the wave vector is not preserved in the phonon-magnon scattering process. The second excitation at low bias fields corresponds to a wave vector-preserving excitation of spin waves. To illustrate the details of this process we use micromagnetic simulations which take into account the finite size of the magnetic elements as well as the (inhomogeneous) demagnetization fields inside them.

FIG. 1: Schematic illustration of the investigated structure (not to scale). SAWs are excited by interdigital transducers (IDTs) with 170nm finger-to-finger spacing on a piezoelectric GaN layer. The CoFeB rectangles are 10µm wide, 50µm long and 18nm thick. The external bias field is applied with an angle of 45° to the SAW propagation direction which is equivalent to the long axis of the CoFeB rectangles.

Brillouin light scattering is the inelastic scattering of photons with quasiparticles, like magnons or phonons, which makes it a favourable tool to probe the phonon-magnon interaction. During the scattering process energy and momentum of the scattered quasiparticle is transferred to the photon. In this study a single-mode laser with a wavelength of $\lambda_{\text{Laser}} = 512\text{ nm}$ is used. To obtain a sufficient spatial resolution the light is focussed onto the sample by a microscope objective with a magnification of 100x and a numerical aperture of NA=0.75. This results in spatial resolution down to 250nm and a maximal detectable wave vector of $k_{\text{max}} = 16\text{ rad}/\mu\text{m}$. The backscattered light is then collected by the same objective lens and guided to the interferometer. The frequency shift of the scattered light is analysed by a polarization-sensitive Tandem-Fabry-Perot interferometer (TFPI). The investigated sample consists of single interdigital transducer (IDT), which has been fabricated on commercial GaN/Si wafer (produced by NTT-AT Japan). Undoped GaN (1 µm) is grown on a Si substrate with a 0.3 µm buffer layer. To excite SAWs an interdigital transducer
(IDT) is used with a finger-to-finger distance of 170 nm, which results in an excited SAW wavelength of \( \lambda_{\text{SAW}} = 680 \text{ nm} \) at the first harmonic resonance frequency of \( f = 6.3 \text{ GHz} \). The IDT has been contacted by microwave probes with ground-signal-ground configuration and connected to a RF-generator. Further details about the phonon excitation and propagation in this particular structure are published in Ref.\textsuperscript{30}. In this system both the Rayleigh mode and the first Sezawa mode are excited simultaneously. However, for these two modes the displacement takes place exclusively in the x-z plane. Therefore, only the components \( S_{xx} \) and \( S_{xz} \) of the strain tensor have to be considered. As shown in Fig. 1 rectangles of CoFeB are located in front of the IDT. All are 50 \( \mu \text{m} \) long, 10 \( \mu \text{m} \) wide and have a thickness of 18 nm. Additionally, a single wire antenna with a width of 1 \( \mu \text{m} \) is structured over the magnetic rectangles (not shown in Fig. 1). The external magnetic field is applied in-plane and under \( \varphi = 45^\circ \) to the wave vector of the SAWs. Under this condition, the magneto-elastic interaction is maximised\textsuperscript{21} and a strong magneto-elastic SW excitation by SAWs is expected. First, the polarisation of the inelastically scattered light is investigated in order to separate the signals originating from magnons and phonons. We use a \( \lambda/2 \)-plate in front of the polarisation-sensitive TFPI to analyse the light. For this purpose, SAWs with the frequency \( f = 6.3 \text{ GHz} \) were excited by means of the IDT. The measurement takes place on the CoFeB, while a high external magnetic field is applied which shifts the magnon band above the SAW frequency. Figure 2a) shows the normalised BLS intensity as a function of polarisation. For the SAWs (red), the polarisation of the scattered light does not change with respect to the incident polarisation. To generate a pure spin wave signal, a standard additional antenna\textsuperscript{31} and a microwave current with the same frequency and power is used. The polarisation of the inelastically scattered light is rotated by \( \pi/2 \). Therefore, the intensity of magnons and phonons can be measured separately by selecting the appropriate polarizer setting.

In the following, the spin waves excited by SAWs are studied. For this purpose, a microwave with a frequency of \( f = 6.3 \text{ GHz} \) and a power of \( P = +5 \text{ dBm} \) (neglecting losses in connecting cables and connections) is applied to the IDT. A typical BLS spectrum is shown in Fig. 2b). It can be seen that only spin waves around the RF-frequency are excited. The measurement of the magnons is carried out close to the edge of the CoFeB rectangle facing the IDT. Only the portion of the light rotated by \( \pi/2 \) is analysed. Figure 2c) shows the extracted BLS intensity around \( f = 6.3 \text{ GHz} \) for different external magnetic fields. Two maxima can be identified near \( \mu_0 H_{\text{ext}} = 6 \text{ mT} \) and \( \mu_0 H_{\text{ext}} = 33 \text{ mT} \), respectively. The maximum at the higher field values can be attributed to the excitation of the FMR\textsuperscript{32}. Here, the energy conservation is fulfilled while the momentum con-
Fully Resonant Magneto-elastic Spinwave Excitation by Surface Acoustic Waves

...ervation is broken. The second maximum is connected to a phase-matching excitation of spin waves where both energy and linear momentum are conserved as will be discussed further below in detail.

FIG. 2: a) normalized BLS intensity as a function of the polarization. The polarization of the light scattered by magnons is rotated by $\pi/2$, while the light scattered by SAWs is unchanged in polarization. b) BLS spectrum from spin waves excited by SAWs at a frequency of $f = 6.3$ GHz and an external field of $\mu_0 H_{ext} = 6$ mT. c) BLS intensity as a function of the external magnetic field. Two peaks can be identified corresponding to FMR (higher fields) and to wave vector preserving excitation (lower fields). d) Extracted field values from $\mu$BLS measurements for FMR (red) and resonant excitation (black). FMR data is fitted by Kittel equation. The field values for the resonant excitation from micromagnetic simulations are shown in blue.

Since the IDTs have a finite length, it is also possible to excite SAWs away from the IDT resonance at 6.3 GHz. In this case, the excited wave vector of the waves adapts to the dispersion of the excited frequency and the intensity of the waves decreases drastically. However, since the...
scattering process is a linear process, qualitatively similar results can be observed for frequencies not coinciding with the IDT resonance. Figure 2d) shows the bias field values of the intensity maxima for different excitation frequencies. The maxima at higher field values (red) correspond to the acoustically driven FMR\textsuperscript{21} and can be described very well by the Kittel formula\textsuperscript{33}:

\[ f = \frac{\gamma \mu_0}{2\pi} \sqrt{(H_{\text{eff}} + H_k \cos(\varphi))(H_{\text{eff}} + H_k \cos(\varphi) + M_S)} \]  

A saturation magnetisation of \( M_S = 1150 \text{kA/m} \) and a gyromagnetic ratio of \( \gamma = 182 \text{rad/nsT} \) are found. Furthermore, a small unidirectional anisotropy field \( H_k = 2.91 \text{mT} \) pointing along the x-axis is included (see Appendix). For the spin waves excited at low fields, only a slight increase in resonance field with the excitation frequency is visible. In the following, using micromagnetic simulations we will illustrate that this excitation is the result of a direct conversion of a phonon into a magnon, in which both the frequency and the wave vector is preserved. Since the wave vector of the SAW increases almost linearly with its frequency, the resonance field for the resonant scattering to the spin wave of the same frequency is increasing only slightly, in contrast to the non-resonant excitation of the FMR.

To verify our hypothesis, we conduct micromagnetic simulations using Mumax\textsuperscript{34}. The software platform Aithericon was used to automatically start and analyse the simulation series and to manage the produced data\textsuperscript{35}. The parameters used for the simulation are as follows: \( M_S = 1150 \text{kA/m} \), \( A_{\text{ex}} = 15 \text{pJ/m} \), \( B_1 = B_2 = -8.8 \text{MJ/m}^3 \) and \( \alpha = 0.0043 \). For the uniaxial in-plane anisotropy along the x-axis, an anisotropy constant of \( K_u = 1600 \text{J/m}^3 \) was used (see Appendix). The dimensions of the simulated rectangle corresponds to the experimental ones. The simulated volume is divided into 2560x512x1 cells. To mimic the SAWs we assume a plane wave for the strain components \( S_{xx} \) and \( S_{xz} \) with wave vector \( k_{\text{SAW}} \) and frequency \( f \). The ratio of \( S_{xx} \) and \( S_{xz} \) is unity and their phase is shifted by \( \pi/2 \), which results in the approximation of circular motion. The effective magnetic field resulting from the SAW is calculated. The amplitude of the acoustic wave is chosen small enough such that non-linear effects in the spin wave system can be neglected.

By performing a Fourier transform of the dynamic magnetization components in time and space we obtain the spin wave intensity in k-space. To determine which wave vectors are excited, Fig. 3 shows in colour-code the simulated spin-wave intensity in reciprocal space exemplary for the frequency \( f_{\text{SAW}} = 6.3 \text{GHz} \). It can be seen that the magneto-elastic field generated by the SAWs drives the magnetisation for all fields with the wave vector of the SAWs, which is indicated by green circles. However, this excitation is not necessarily an eigenstate of the magnonic system,
Fully Resonant Magneto-elastic Spinwave Excitation by Surface Acoustic Waves

FIG. 3: Normalized FFT intensity in reciprocal space for different external magnetic fields extracted for the SAW frequency $f_{\text{SAW}} = 6.3$ GHz. The isofrequency curves for the investigated structure (obtained from micromagnetic simulations using a point-like spin wave source) and an infinitely extended film are shown in solid blue and dashed black lines, respectively. The excitation with the wave vector of the SAW, which is only resonant for $\mu_0 H_{\text{ext}} = 6$ mT, is indicated by green circles.

and relaxation into states on the isofrequency curve (illustrated in blue) occurs. During the relaxation, the wave vector along the propagation direction of the SAWs (x-axis) is preserved. Most importantly, at $\mu_0 H_{\text{ext}} = 6$ mT, it can be seen that the direct excitation by the magneto-elastic field coincides with the magnonic isofrequency curve. This results in a resonant excitation which shows a drastically increased amplitude (note the different scales), in good agreement with the experimental findings in Fig. 2c). To obtain a quantitative picture, we compare the excited spin-wave intensity in the simulations with our experimental results. Since µBLS collects all spin waves up to maximum wave vector $k_{\text{max}} = 16$ rad/µm also the simulated spin-wave intensities are integrated up to this value. The obtained values are shown in Fig. 4 for different external fields. All curves show a clear maximum at low magnetic fields, which corresponds to the resonant excitation. The extracted values are shown in blue in Fig. 2c) and match well to the measured values of the resonant excitation. However, the excitation of the FMR is not significantly visible in the simulations. A closer analysis shows that the intensity for fields above the FMR decreases drastically, since in this region only the excitation of edge modes is possible. The absence of excitation at the FMR in the simulation can have several reasons. On the one hand, no inhomogeneities are considered in the simulation, which would be needed to break the wavevector conservation rule in the scat-
 Fuller Resonant Magneto-elastic Spinwave Excitation by Surface Acoustic Waves

tering process. On the other hand, only the Rayleigh mode is considered in the simulations. To what extent the interference between Rayleigh- and Sezawa mode and the associated interference pattern can also contribute to the excitation of the FMR is still part of further investigations.

FIG. 4: Integrated SW intensity as function of the external field from micromagnetic simulations.

We would like to note that in the particular case of this study, the resonant excitation is possible due to the anisotropy present in the magnetic structures. This anisotropy is composed of the shape anisotropy of the microstructure and the uniaxial in-plane anisotropy, which presumably is caused in the film growth process. In an infinitely extended film without any anisotropies, the magnetisation points always along the external magnetic field. In the present case, this implies that the magnetisation always remains at 45° to the wave vector of the SAWs. For CoFeB rectangles of finite width, however, the anisotropy causes the magnetization not to point in the same direction as the external field at low magnetic fields, but to turn towards the direction of the long axis (x direction). This is clearly shown by the isofrequency curves in Fig. 3a)-c), which are extracted from micromagnetic simulations using a spinwave point source. The isofrequency curves for an infinitely extended film, which are shown by the dashed black lines, were simulated with periodic boundary conditions. These isofrequency curves are always rotated 45° to the wave vector of the SAWs. The isofrequency curves for finite structures, shown in blue, on the other hand, rotate with decreasing external field towards the propagation direction of the SAWs. In the present system this makes the overlap between the wave vector of the SAWs and that of the spin waves possible in the first place.
Fully Resonant Magneto-elastic Spinwave Excitation by Surface Acoustic Waves

In this work, we have studied the excitation of spin waves by surface acoustic waves in micrometre-sized CoFeB rectangles. Our investigations with micro-focused BLS spectroscopy have found that spin waves can be excited at two different magnetic fields for a given frequency $f$. One excitation is identified as the FMR. The second excitation appears at low external magnetic fields. Through micromagnetic simulations, we were able to show that for this resonant excitation, the wave vector of the SAW coincides with the one of the excited spin wave.

Appendix A: Analysis of anisotropy

In the following, we will discuss how the determination of the anisotropy constants for the simulation was determined.

By means of Kerr microscopy (longitudinal mode), the hysteresis curve was obtained for a rectangle as described in the manuscript, as well as for a square with 350 µm edge length. This larger structure can be assumed to be an infinitely extended film. To determine the anisotropy, the hysteresis was measured for different angles $\varphi$. Figure 5 shows the two hysteresis curves for the extreme cases of the hard and the easy axis. The coercive field $H_c$ was taken from the hysteresis curves. As can be seen in Figure 6, both the rectangle and the film show an easy anisotropy axis.

FIG. 5: Hysteresis loops for a) a rectangle and b) a film with dimensions as described in Fig. 1 measured by Kerr microscopy. $\varphi = 0^\circ$ corresponds to the long axis of the rectangle.
Fully Resonant Magneto-elastic Spinwave Excitation by Surface Acoustic Waves

lying along the long axis of the rectangle. The anisotropy of the strip is more pronounced than for the film, since the shape anisotropy and the growth-induced anisotropy add up in this case. Using the Stoner-Wohlfarth model, a lower bound for the anisotropic constant can be estimated:

\[ K_u = 2\mu_0 H_c M_S. \] (A1)

This yields an anisotropy constant for the growth-induced anisotropy of \( K_u = 755 \text{ J/m}^3 \). Since

![Coercive field \( H_c \) as function of the angle \( \varphi \). Film and rectangle show a unidirectional anisotropy along the x-axis.](image)

this is only a lower limit due to the formation of domain walls, which the model does not take into account, the value of \( K_u = 1600 \text{ J/m}^3 \) was adjusted to the measured values by means of micromagnetic simulations as follows. For the simulation, an excitation frequency of \( f = 6.3 \text{ GHz} \) was chosen and the field \( \mu_0 H_{\text{ext}} = 6.4 \text{ mT} \), which agrees with the experimental value. An elastic wave, as described in the manuscript, was used for excitation, while the anisotropy constant is varied for uniaxial anisotropy. The evaluation is also performed as described above. Figure [7] shows the integrated FFT intensity obtained as a function of the anisotropy constant.

**Appendix B: Magneto-elastic interaction in micromagnetic simulations**

In the main text, the modeling of elastic waves in MuMax3 is discussed. A plane wave is assumed for the individual strain components. MuMax3 calculates the resulting magneto-elastic field for
FIG. 7: Integrated FFT intensity as function of the anisotropy constant $K_u$. The maximum was chosen for the simulations shown in the manuscript.

Each time step and cell according to equation (B1)\textsuperscript{37,38}:

$$
B_{\text{mel}} = - \left( \begin{array}{c}
2B_1 m_x S_{xx} + B_2 (m_y S_{xy} + m_z E_{xz}) \\
2B_1 m_y S_{yy} + B_2 (m_x S_{yx} + m_z S_{yz}) \\
2B_1 m_z S_{zz} + B_2 (m_x S_{zx} + m_y S_{zy})
\end{array} \right) .
$$

(B1)

Furthermore, it was pointed out that the wavelength of the SAWs changes with frequency $f$. The values shown in Figure 8 are taken from Ref.\textsuperscript{39} and Ref.\textsuperscript{30}.

FIG. 8: Wavelength of the SAW as function of the Frequency.
