Two-Hole Ground State: Dichotomy in Pairing Symmetry

(Dated: Wednesday 30th June, 2021)

A single-hole ground state ansatz for the two-dimensional $t$-$J$ model has been recently studied by variational Monte Carlo (VMC) method. Such a doped hole behaves like a “twisted” non-Landau quasiparticle characterized by an emergent quantum number in agreement with exact numerics. In this work, we further investigate the ground state of two holes by VMC. It is found that the two holes strongly attract each other to form a pairing state with a new quantum number the same as obtained by the numerical exact diagonalization (ED) and density matrix renormalization group (DMRG) calculations. A unique feature of this pairing state is a dichotomy in the pairing symmetry, i.e., a $d$-wave in terms of the electron $c$-operators and an $s$-wave in terms of the new quasiparticles, as explicitly illustrated in the ground state wave function. A similar VMC study of a two-hole wave function for the $t$-$J$ two-leg ladder also yields a good agreement with the DMRG result. We demonstrate that the pairing mechanism responsible for the strong binding here is not due to the long-range antiferromagnetic nor the resonating-valence-bound pairing in the spin background, but is the consequence of the quantum phase strings created by the hopping of holes. The resulting spin current pattern mediating the pairing force is explicitly illustrated in the VMC calculation. Physical implications to superconductivity at finite doping will be also discussed.

I. INTRODUCTION

The study of a doped antiferromagnetic (AF) Mott insulator has been conducted intensively in the past three decades as one of the greatest challenges in the condensed matter physics [1–4]. The mechanism of high-$T_c$ cuprate superconductors has been widely believed to be closely related to such a strongly correlated problem [2, 4–6]. While the low-energy physics of the AF-Mott insulator at half-filling as described by the Heisenberg Hamiltonian has been well understood [7–10], the theoretical issues remain unsettled in the presence of doped holes, where the superconducting (SC) condensation is expected to set in beyond some critical small doping concentration in two-dimension (2D) or layered materials [4, 6].

Among various theoretical proposals, the resonating-valence-bond (RVB) state [2, 11, 12] for high-temperature superconductivity stands out as one of the most influential and simplest ground state ansatzs, which takes advantage of the essential properties of a doped Mott insulator: the local spin moments form singlet pairs due to the superexchange coupling. A tremendous body of studies around the RVB idea [4, 5, 12–21] has produced some insightful understandings on the doped Mott insulator and high-$T_c$ cuprate. At the same time, a fundamental question remains to be answered: How can an RVB-type ground state emerge from a spin AF long-range ordered (AFLRO) state at half-filling by doping effect?

Another important observation made by Anderson [22] on the Mott physics is that a doped hole (electron) in the lower (upper) Hubbard band should generally induce a many-body response or “phase shift” from the background electrons to accommodate such a doped hole (electron). This “unrenormalizable phase shift” was con-
jectured [22] to cause the “orthogonality catastrophe” [23, 24], leading to a non-Fermi-liquid behavior of the doped Mott insulator. Based on the $t$-$J$ model and later the Hubbard model, this many-body phase shift has been precisely identified as the phase string effect [25–27], which can be mathematically formulated as a many-body Berry phase acquired by doped holes completing closed-paths motion. Protected by the Mott gap, such an effect fundamentally changes the Fermi statistics of the electrons [27, 28]. In general, the Berry phase or the phase-string sign structure depends on the parity of spin-hole exchanges, which characterizes the intrinsic long-range mutual (spin-charge) entanglement [29] in the doped Mott insulator.

Along this line of thinking, an RVB state at finite doping, if exists, must be qualitatively modified, since each doped hole has to introduce an “unrenormalizable phase shift” or “irreparable phase string”, which would generally lead to a two-component RVB structure [30]. A new SC ground state ansatz of this type has been previously proposed [31]:

$$|\Psi_G\rangle = e^{\hat{D}}|\text{RVB}\rangle ,$$  \hspace{1cm} (1)

in which the charge pairing and the spin RVB pairing are explicitly separated. Here the vacuum state $|\text{RVB}\rangle$ is a spin background in a short-range RVB state at finite doping [32]. It reduces to a long-range RVB state $|\phi_0\rangle$ to recover the AFLRO in the zero hole limit. In contrast, the doped holes are created in spin-singlet pairs (another “RVB”) by

$$\hat{D} = \sum_{i,j} g(i,j)\hat{c}_i\hat{c}_j ,$$  \hspace{1cm} (2)

where $\hat{c}$ is distinct from the bare electron operator $c$ by

$$c_{\sigma} \rightarrow \hat{c}_{\sigma} \equiv c_{\sigma} e^{-i\hat{\Omega}_i} ,$$  \hspace{1cm} (3)

with $\hat{\Omega}_i$ (cf. Eq. (8)) representing the many-body phase-shift/phase-string effect induced by the doped hole. Note that self-consistently the phase shift field $\hat{\Omega}_i$ is also responsible for $|\phi_0\rangle \rightarrow |\text{RVB}\rangle$ by doping [32, 33].

A basic example to show the fundamental importance of the unrenormalizable phase shift or phase string effect is the single-hole case [34–36]. The single-hole ground state may be reduced from Eq. (1) as follows

$$|\Psi_{G,1h}\rangle = \sum_i \phi_h(i)\hat{c}_{\sigma}^\dagger|\phi_0\rangle ,$$  \hspace{1cm} (4)

where $|\phi_0\rangle$ denotes the half-filling ground state of the Heisenberg model and the doped hole is created not by $c$ but $\hat{c}$ given in Eq. (3). The single-hole wave function $\phi_h(i)$ in Eq. (4) is generally no longer a Bloch-wave-like ($\propto e^{i\mathbf{k}_r\cdot r}$), which can be determined instead as a variational parameter in the variational Monte Carlo (VMC) calculation [34, 36]. As the consequence of the many-body phase shift operator $\hat{\Omega}_i$ acting on $|\phi_0\rangle$, the ground state (4) acquires nontrivial angular momenta $L_z = \pm 1$ and novel ground state degeneracy in precise agreement with the exact diagonalization (ED) and density matrix renormalization group (DMRG) studies [37].

Such a VMC approach has been powerful in establishing the best variational wave function $|\phi_0\rangle$ at half-filling [9] as well as the physical properties of the one-hole ground state $|\Psi_{G,1h}\rangle$ [34, 36] in comparison with the exact numerics. The single-hole problem has illustrated how crucial the phase string effect is to turn the doped hole into a non-Landau-like “twisted” quasiparticle with a novel quantum number. But the phase shift field also generates some severe “sign problem”, i.e. unrenormalized phase string sign structure in $\hat{D}$, to prevent an efficient VMC study of the ansatz state of Eq. (1) beyond the mean-field and gauge theory approaches [31] at a finite doping. Therefore, to bridge the gap between the one-hole and a finite doping, and to reveal the hidden pairing mechanism of doped antiferromagnet, a necessary and useful step is to use the same VMC approach to investigate the ground state of two holes injected into the spin background. Actually, a simplified two-hole doped ladder with the injected holes restricted to move only along the chain (leg) direction was already analytically analyzed [38], which reveals a new pairing mechanism by a direct comparison with DMRG [39].

In this paper, we shall examine the pairing structure of the following two-hole ground state ansatz according to Eq. (1):

$$|\Psi_{G,2h}\rangle = \hat{D}|\phi_0\rangle ,$$  \hspace{1cm} (5)

which is determined by optimizing the pair amplitude $g(i,j)$ in Eq. (2) by the VMC method. This is a paired state of the single “twisted” holes described by $\hat{c}$. Due to the internal quantum number associated with $\hat{c}$, the single hole ground states are four-fold degenerate under an open boundary condition (OBC). The two-hole ground state is found to be non-degenerate with a spin singlet pairing of two distinct “twisted” holes with a specific total quantum number $L_z = 2 \mod 4$ under the $C_4$ rotational symmetry, which has been previously already identified in the ED and DMRG calculations [37].

A tightly bound pair is found in this two-hole ground state wave function, in which one hole predominantly distributes over a square of sites tightly packed around the other hole. It looks like a slightly anisotropic $s$-wave pairing of a nodeless $g(i,j)$, with the strongest pairing for two holes at the distance of $\sqrt{2}$ (in the units of the lattice constant). Nevertheless, if measured in terms of the ordinary Cooper pairing operator $c_{\mathbf{k}\uparrow}c_{-\mathbf{k}\downarrow}$ in the singlet channel, a well-defined pure d-wave symmetry is found. Such a “dichotomy” in the pairing symmetry is directly contradictory to an ordinary BCS pairing wave function for two Landau quasiparticles. Here the d-wave symmetry measured by the Cooper pairing can be attributed to the consequence of the phase shift factor $e^{-i\hat{D}}$ in combination with the nodeless $g(i,j)$. In other words, the two-hole wave function can be regarded as composed
of an s-wave-like pairing of the “twisted” quasiparticles \( \tilde{c} \), which is more robust than a BCS-like d-wave pairing state of the bare holes as a projecting or “collapsing” state of the former.

The pairing mechanism in the two-hole ground state can be straightforwardly examined. By projecting the ground state wave function onto different fixed hole positions, a “roton-like” configuration of spin supercurrents can be explicitly revealed, which represents the physical effect of the phase strings created by the motion of holes. As a matter of fact, by turning off the phase shift factor \( e^{-i\Omega} \), the strong binding between the holes diminishes immediately as shown in the VMC calculation, even if the AFLRO state \( |\phi_0\rangle \) can be artificially tuned into a short-range RVB state in the dimer limit. It implies that the phase strings not only renormalize the single holes to become the non-Landau “twisted” holes, but also are responsible crucially for their pairing in the two-hole ground state, which is consistent with earlier DMRG calculation for the two-hole ladder [40].

The two-hole ground state ansatz has been also applied to the case in the two-leg ladder. Previously the single-hole ground state has already produced [34] an excellent agreement with the DMRG. The present VMC calculation shows an overall agreement of the two-hole case with the DMRG results, including the pair-pair correlation and d-wave-like sign change of the Cooper pairing in the chain and rung directions. Turning off the phase shift field in the wave function indeed leads to the diminishing pairing strength, again indicating the pairing mechanism due to the phase string effect.

The rest of the paper will be organized as follows. In Sec. II, we will introduce the model and construct the two-hole ansatz wave function with an emergent phase string phase factor being built in concretely. A VMC calculation is then carried out. For completeness, a brief review of the single-hole ground state by a VMC calculation is also given. In Sec. III, the properties of the two-hole ground state will be systematically analyzed, especially the pairing structure. A dichotomy of pairing symmetry, i.e., a d-wave symmetry measured in terms of the original \( c \)-operator of the electron, and an s-wave-like symmetry in terms of “twisted” quasiparticles \( \tilde{c} \), will unveil a prototypical non-BCS feature. In Sec. IV, the binding energy and the pairing force originated from the phase string effect are examined, which shows how a kinetic-energy-driven pairing mechanism can be clearly visualized by the hidden spin current pattern generated by the hole hopping. In Sec. V we further discuss some important implications like the incoherent single-particle propagation and possible self-localization of the hole pair in the AFRLO phase, and how the superconducting ground state at finite doping may evolve from the present two hole ground state. Finally, the conclusion and perspectives are given in Sec. VI.

![FIG. 1. The composite structure of a renormalized single hole state discussed in Ref. 36: (a) The motion (blue arrow) of a doped hole (black circle) creates a sequence of ± signs (phase string) depending on \( \uparrow \) and \( \downarrow \) of the backflow spins. To avoid cancellation of the phase string effect in the hopping integral, the spin backflow currents have to bend into a roton-like pattern (red-dashed) around the hole; (b) Such a roton configuration can be explicitly manifested by a vortex of spin current around the hole as a net effect for an extra \( S_z = \pm 1/2 \). The chirality of the vortex leads to a double-degeneracy of the states with an emergent angular momentum \( L_z = \pm 1 \).](image)

II. THE GROUND STATE ANSATZ

A. The \( t-J \) model

The standard \( t-J \) model reads:

\[
\begin{align*}
H_t &= -t \sum_{\langle ij \rangle, \sigma} (\tilde{c}_{i\sigma}^\dagger c_{j\sigma} + h.c.), \\
H_J &= J \sum_{\langle ij \rangle} \left( \mathbf{S}_i \cdot \mathbf{S}_j - \frac{1}{4} n_i n_j \right),
\end{align*}
\]

with the summations over \( \langle ij \rangle \) denoting the nearest-neighbor (NN) bonds. Here \( \mathbf{S}_i \) and \( n_i \) are spin and electron number operators, respectively. The strong correlation nature of the \( t-J \) model comes from the no double occupancy constraint \( \sum_{\sigma} c_{i\sigma}^\dagger c_{i\sigma} \leq 1 \) on each site, which is imposed via the projection operator \( \mathcal{P}_s \). The superexchange coupling constant \( J \) will be taken as the units with \( t/J = 3 \) throughout the paper. The size of a square lattice is specified by \( N = N_x \times N_y \), with \( N_x = N_y = 2 \times M \) chosen to be even for an isotropic 2D square lattice and \( N \equiv N_x \times 2 \) for a two-leg ladder.

B. The single-hole ground state

Before we proceed to investigate the two-hole ground state, it would be helpful for us to briefly outline some key results of the single hole state in the previous study [34, 36].

The single-hole problem has been a focus of intensive study with a history almost as long as the high-\( T_c \) problem. It had been believed for a long time that the single hole injected into the AF spin background would behave like a Landau-like quasiparticle with translational
symmetry and a finite spectral weight, known as a spin polaron [41–48]. Namely, the spin distortion of the AF background in response to the motion of the hole was expected to merely dress the bare hole’s effective mass. It is particularly worth noting that even though Shraiman and Sigia [49, 50] have previously discovered an important transverse dipolar spin twist induced by the doped hole, their semiclassical approach fails to capture the correct short-range singular structure of the spin current, reaching a conclusion of the dressed “hole” quasiparticle with a definite momentum in a translational fashion similar to the above obtained by only considering the longitudinal spin polaron effect. In other words, no Anderson’s “unrenormalizable phase shift” would be produced in the one-hole ground state to invalidate the Bloch wave behavior in the long-wavelength.

However, the recent ED and DMRG numerics [37] have revealed that something fundamentally missing in this quasiparticle picture. It has been shown that actually there are hidden spin currents always present in the spin background as generated by the motion of the doped hole in the degenerate ground states. Since it is always conserved in the $t$-$J$ model, the spin current itself can carry away momentum and change the translational symmetry of a renormalized hole even though the total (many-body) momentum remains conserved. It implies that the hole entity no longer obeys the Landau’s one-to-one correspondence assumption to behave like a Bloch wave.

In fact, with a lattice rotational symmetry under OBC, the spin current can generate a nontrivial angular momentum with a novel ground state degeneracy besides the normal degeneracy due to $S = 1/2$. As shown in Fig. 1(a), when a doped hole hops in an AF background (always labelled by the quantum numbers $S$ and $S_z$), a string of spin-dependent ± signs (i.e., the phase string) [25] will be generally created, which leads to a backflow of spin current [cf. Eqs. (11) and (12) for the definition under a conserved $S_z$] in response to the motion of the hole. However, due to the singlet nature of the spin background (in a finite but large sample size), a strong cancellation of the phase string effect would occur in the hopping integral, unless the spin backflow bends into a “roton”-like configuration for the backflow currents composed of two opposite spins [cf. Fig. 1(a)]. Note that there is also an opposite chirality of the “roton” configuration not shown in Fig. 1(a). Thus, due to the phase string effect, the hidden spin currents must play an essential role to form a composite object to facilitate the hole’s motion.

Furthermore, as introduced by the hole, there will be an extra $S_z = ±1/2$ in the otherwise spin singlet background, which can manifestly contribute to an explicit spin current as a vortex illustrated in Fig. 1(b). It can be regarded as a net effect of the underlying backflow pattern shown in Fig. 1(a). Under a $C_4$ symmetry such a hidden backflow configuration associated with the doped hole will give rise to a nontrivial angular momentum ($L_z = ±1$ for an $N = 2M \times 2M$ lattice) as a new quantum number in addition to, say, $S_z = ±1/2$ associated with the hole composite.

Therefore, in the presence of the “unrenormalizable phase shift” or the phase string effect, the hole will be renormalized to become a composite object as shown in Fig. 1. This picture has been confirmed by the finite-size ED and DMRG calculations [37]. Mathematically, the phase string or the spin current backflow pattern in Fig. 1 can be characterized by a phase shift factor $e^{-i\Omega_i}$, already mentioned in the Introduction. Here $\Omega$ is explicitly defined by

$$\hat{\Omega}_i = \sum_l \theta_i(l)n_{il},$$

where $n_{il}$ is the number operator of down spin at site $l$ and $\theta_i(l) = m\text{Im}\ln(z_i - z_l)$ ($m = ±$) denotes a statistical angle between site $i$ and site $l$ in a 2D plane with $z_i = x_i + iy_i$ being complex coordinate of site $i$. Note that $\theta_i(l)$ satisfies the condition

$$\theta_i(l) - \theta_i(l) = ±\pi,$$

which results in a sign change, $e^{-i\hat{\Omega}_i} \rightarrow -e^{-i\hat{\Omega}_i}$, accompanying the exchange between a hole and a ↓ spin to precisely keep track of the phase string effect.

Consequently, a single-hole ground state ansatz has been constructed as follows [36]

$$|\Psi_{(m\sigma)}\rangle_{1h} = \sum_i \phi_{h(m\sigma)}(i)e^{-im\text{Im}\ln(z_i - z_l)}c_{i\sigma}|\phi_0\rangle,$$

where $|\phi_0\rangle$ is the ground state of the Heisenberg Hamiltonian at half-filling. Here $m = ±$ represents opposite chiralities of the spin-current vortex, which is originally hidden in the definition of $\theta_i(l)$ above, but hereafter, redefinition on the statistical angle $\theta_i(l) \equiv \text{Im}\ln(z_i - z_l)$ in Eq. (8) will explicitly appear with $e^{-i\hat{\Omega}_i} \rightarrow e^{-i\hat{\Omega}_i}$ for the convenience of discussion below.
The variational parameters $\phi_h^{(m\sigma)}(i)$ can be determined by optimizing the kinetic energy by VMC. Detailed analyses of this wave function ansatz for the 2D square lattice have been given in Ref. 36. The agreement of the ground state properties between the ansatz states and the exact ED/DMRG results has been shown there. For the 2D case under OBC, the four degenerate ground states and their quantum numbers are listed in Table I with $\sigma = \uparrow, \downarrow$ and $m = \pm$. Specifically, it shows that the hole acquires a nonzero angular momentum $L_z = \pm 1$ corresponding to the chiral spin current (marked by $\nearrow$ and $\swarrow$ in Table I) in addition to $S_z = \pm 1/2$. Here the spin currents produced in the hopping (backflow spin current) and superexchange (neutral spin current) terms are defined by [36]

$$J_{ij}^b = -i \frac{t}{2} \sum_{\sigma} \sigma (c_{i\sigma}^+ c_{j\sigma}^+ - c_{j\sigma}^+ c_{i\sigma}^+),$$

$$J_{ij}^s = \frac{J}{4} (S_i^+ S_j^- - S_i^- S_j^+),$$

respectively.

Finally we mention that the single-hole ground state in Eq. (10) was actually first successfully applied to the one dimensional chain [35] and then two-leg ladder [34], respectively. Note that the statistical angle $\theta_j(l)$ in Eq. (8) can be further optimized [34] for the anisotropic $t$-$J$ two-leg ladder case under the constraint in Eq. (9). But so long as Eq. (9) is satisfied, the phase shift factor $e^{+i\hat{\Omega}_1}$ in Eq. (10) will be generally effective in keeping track of the singular phase string effect.

### C. Two-hole ground state ansatz

In the above subsection, we have briefly outlined the ground state ansatz for the single hole doped $t$-$J$ models in 2D and two-leg square lattice cases, respectively. It is straightforward to construct the corresponding two-hole ground state wave functions and study them based on a VMC approach.

By noting that the single hole ground state given in Eq. (10) is generally four-fold degenerate [cf. Table I] in an $N_x = N_y = 2 \times M$ lattice, with $S = 1/2$ and angular momentum $L_z = \pm 1$ under OBC, the two-hole ground state of $S^z = 0$ may be constructed by

$$|\Psi_{02h}\rangle = \sum_{ij} g_\eta(i,j) c_{i\uparrow} c_{j\downarrow} e^{-i(\hat{\Omega}_1 + \eta \hat{\Omega}_2)} |\phi_0\rangle + \cdots .$$

Here $|\phi_0\rangle$ describes a half-filling spin background. The subscript $\eta = \pm$ denotes two sectors of wave function ansatz, where the spin current vortex pattern around each hole [Fig. 1 (b)] will have either the same chirality or the opposite one in forming a paired state as illustrated by Figs. 2 (a) and (b), respectively. The rest term $\cdots$ on the right-hand-side of Eq. (13) involves the opposite chirality (the complex conjugate) of the phase shift operator: $e^{+i(\hat{\Omega}_1 + \eta \hat{\Omega}_2)}$. For a comparison, we shall also consider a bare two-hole wave function without the phase shift operator, which is denoted by $\eta = 0$:

$$|\Psi_{02h}\rangle = \sum_{ij} g_\eta(i,j) c_{i\uparrow} c_{j\downarrow} |\phi_0\rangle .$$

A detailed analysis of the wave function symmetries is given in Appendix A.

Here the pair amplitude $g_\eta(i,j)$ in $|\Psi_{\eta2h}\rangle$ will be treated as a variational parameter to be determined by VMC by optimizing the kinetic energy of the $t$-$J$ model for each $\eta = \pm, 0$. Note that the spin background $|\phi_0\rangle$ may be still chosen as the ground state of the half-filling Heisenberg model $H_J$. By doing so, one assumes that the other disturbance of the two doped holes to the spin background is negligible, except for the phase string effect via $e^{+i(\hat{\Omega}_1 + \eta \hat{\Omega}_2)}$. A further optimization of $|\phi_0\rangle$ in the VMC procedure is to be discussed below.

The above three ansatz states of $|\Psi_{\eta2h}\rangle$ are determined variationally in a VMC calculation similar to the one-hole case on a 2D square lattice. The variational ground state energies on a $4 \times 4$ lattice are presented in Table II in comparison with the ED result. According to Table II, relative to the phase-string-free $|\Psi_{02h}\rangle$, both $|\Psi_{\pm2h}\rangle$ and $|\Psi_{-2h}\rangle$ have much improved variational energies as expected based on the single-hole case.

From Table II, one sees that $|\Psi_{-2h}\rangle$ has not only the lowest ground state energy, but also the same quantum number with the angular momentum $L_z = 2$ mod 4 as the ED result, which gives rises to a sign change of the

| $|\Psi_{\eta2h}\rangle$ | $E_G$ | $E_1$ | $E_J$ | $L_z$ |
|---|---|---|---|---|
| $|\Psi_{02h}\rangle$ | -17.37 | -5.88 | -11.48 | 0 |
| $|\Psi_{\pm2h}\rangle$ | -20.50 | -9.56 | -10.94 | 2 |
| $|\Psi_{-2h}\rangle$ | -22.51 | -11.20 | -11.31 | 2 |
| ED | -24.98 | -14.57 | -10.42 | 2 |
total state under a $\pi/2$ rotational of the lattice. A combination of the degenerate ground states in the single-hole doped case leads to a non-degenerate $|\Psi_{-}\rangle_{2h}$ in the two-hole case, which is consistent with the ED/DMRG results in $4 \times 4$ and larger sample sizes that the ground state of even number of holes is generally non-degenerate.

For comparison, the phase-string-free wave function $|\Psi_{0}\rangle_{2h}$ has an angular momentum $L_z = 0$, while the same chirality wave function $|\Psi_{+}\rangle_{2h}$, corresponds to $L_z = \pm 1$ in which the two holes form a triplet pairing as indicated by the pair-pair correlator. Latter in Section IV and Appendix C we shall further discuss the variational procedure to incorporate the additional feedback effect on $|\phi_0\rangle$ in Eq. (13), which can then optimize $|\Psi_{+}\rangle_{2h}$ to result in an $L_z = 2$ state with an energy comparable to that of $|\Psi_{-}\rangle_{2h}$. By contrast, $|\Psi_{-}\rangle_{2h}$ in Eq. (13), with $|\phi_0\rangle$ as the half-filling ground state and $g_{-}(i,j)$ as the sole variational parameter, can naturally capture the non-degenerate two-hole ground state with $L_z = 2$. Therefore, from now on we will mainly focus on such a variational $|\Psi_{-}\rangle_{2h}$ to further explore its internal structure and unconventional pairing properties.

Finally, we note that the ground state ansatz of Eq. (13) can be also directly applied for two holes injected into a two-leg Heisenberg ladder. The variational energy calculated on a $10 \times 2$ ladder is shown in Table III. Similar to the 2D square lattice, $|\Psi_{-}\rangle_{2h}$ for the two-leg ladder also gives rise to the best variational energy as compared with the ED result. Here the phase shift operator $\tilde{\Omega}_s$ appearing in Eq. (13) may be also further optimized for the two-leg ladder by tuning $\theta_i(l)$ under the constraint in Eq. (9), which has been effectively done [34] in the single-hole case as mentioned before. But in the above VMC calculation, we have still used the 2D version of $\theta_i(l)$, which is not qualitatively different from the optimized one for the isotropic $t$-$J$ model on the two-leg ladder [34]. As already emphasized in the one-hole case, the crucial point is that the phase shift factor $e^{\pm i\tilde{\Omega}_s}$ under the constraint Eq. (9) can always explicitly keep track of the singular phase string effect in Eq. (13).

### III. PAIRING STRUCTURE

In the previous section, we have constructed a two-hole variational ground state $|\Psi_{-}\rangle_{2h}$ in Eq. (13), in which the pairing amplitude $g_{-}(i,j)$ is determined by VMC to result in a non-degenerate ground state consistent with the ED calculation. In the following, we shall explore the intrinsic pairing structure in such a ground state.

#### A. d-wave pairing symmetry

Define the pair operator of the electrons as

$$\hat{\Delta}_{\mathbf{k}} = c_{\mathbf{k}\uparrow}^{\dagger}c_{-\mathbf{k}\downarrow} - c_{\mathbf{k}\downarrow}^{\dagger}c_{-\mathbf{k}\uparrow},$$

which involves two holes at momenta $\mathbf{k}$ and $-\mathbf{k}$ in spin singlet channel. Then the pairing structure of the two-hole ground state $|\Psi_{-}\rangle_{2h}$ may be measured by

$$\Delta_{\mathbf{k}}^{2h} = 2h(\langle\Psi_{-}|\hat{\Delta}_{\mathbf{k}}^{2h}|\phi_0\rangle),$$

which is just the usual definition of the Cooper pairing order parameter in the two-hole limit.

The calculated $\Delta_{\mathbf{k}}^{2h}$ on a $20 \times 20$ lattice is shown in Fig. 3. The nodal lines of the pairing order parameter (white dashed lines) with a sign change after a $\pi/2$ rotation in the $\mathbf{k}$-space clearly illustrates a d-wave symmetry of $\Delta_{\mathbf{k}}^{2h}$, which is also consistent with the angular momentum $L_z = 2$ of $|\Psi_{-}\rangle_{2h}$.

The d-wave pairing symmetry can be also directly probed in the pair-pair correlation function. Define the pair operator on lattice

$$\hat{\Delta}_{ij} = c_{i\uparrow}c_{j\downarrow} - c_{i\downarrow}^{\dagger}c_{j\uparrow}^{\dagger}$$

$$\begin{array}{l|l|l}
|\Psi_{0}\rangle_{2h} & -21.03 & -6.29 & -14.73 \\
|\Psi_{+}\rangle_{2h} & -23.30 & -9.51 & -13.79 \\
|\Psi_{-}\rangle_{2h} & -25.70 & -11.07 & -14.63 \\
ED & -27.74 & -14.00 & -13.74 \\
\end{array}
$$

\tag{18}
\]

for the NN bonds and the next nearest neighboring (NNN) bonds, respectively (cf. the insets in Fig. 4). Here \( \mathbf{e}_x(\mathbf{e}_y) \) denotes the unit vector along \( x(y) \)-direction. As illustrated in Fig. 4(a) and (b), the sign change between \( C_{i,i+x}^{s,\|} \) and \( C_{i,i+x}^{s,\perp} \) clearly confirms the d-wave symmetry. It is noted that in Fig. 4 a large 2D square lattice of \( 64 \times 64 \) is used to show the d-wave behavior in real space. Here in carrying out the numerical calculation we have used a fitted parameter \( g_{-}(i,j) \) for the NN and NNN sites, with the phases given by

\[
g_{-}(i,j) = e^{i\varphi_{ij}} e^{i\theta_{ij}} |g_{-}(i,j)| \tag{19}
\]

where the first phase factor on the right-hand-side of Eq. (19) is given by

\[
\varphi_{ij} = \frac{1}{2} \sum_{l(\neq i,j)} (\theta_i(l) - \theta_j(l)).
\tag{20}
\]

Namely, based on the variational results of the sample sizes up to \( N = 20 \times 20 \), the quantity \( g_{-}(i,j) \times e^{i\varphi_{ij}} e^{i\theta_{ij}}(j) \) is found to be a pure s-wave-like constant amplitude \( |g_{-}(i,j)| \) (see below), up to a global phase, for both the NN and NNN bonds.

As shown in Fig. 4(c), the nodal direction pair-pair correlation function is actually finite at very short distance before decaying quickly to zero. It suggests that, in contrast to a pure d-wave symmetry of Cooper pairing, the two doped holes actually do form pairing along the diagonal direction with a finite \( |g_{-}(i,j)| \), but its phase coherence is not maintained over a couple of lattice constants because of the phase shift factor \( e^{\mp l\Omega_i} \) in \( |\Psi_{-}\rangle_{2h} \). In the following, we shall show a dichotomy in the pairing structure of \( |\Psi_{-}\rangle_{2h} \), which significantly goes beyond a simple d-wave pairing of the bare holes.

**B. Dichotomy: s-wave-like pairing between the holes**

The tight binding between the two doped holes can be also directly measured by the hole-hole density correla-
such a generalized s-wave-like pairing is thus related to \(g_-(i, j)\), i.e., the pair amplitude for the “twisted” quasiholes created by \(\hat{c}_i = c_i e^{\mp \Omega_i}\) in the ground state \(|\Psi_-\rangle_{2h}\) of Eq. (13), as mentioned in the above subsection. Even though \(g_-(i, j)\) is the largest at \(j = i + \hat{e}_x + \hat{e}_y\), Fig. 4 (c) shows an exponential decay of the Cooper pair correlation along the diagonal direction beyond a couple of lattice constants due to \(e^{\mp \Omega_i}\). Clearly the phase shift operator \(e^{\mp \Omega_i}\) plays an essential role in the dichotomy of the pairing symmetry. In this sense, the d-wave symmetry of Cooper pair may be regarded as “emergent”, which is in sharp contrast to the intrinsic s-wave-like pairing of the non-Landau quasiparticles described by \(\hat{c}\).

Therefore, the ground state \(|\Psi_-\rangle_{2h}\) manifests a dichotomy in pairing symmetry, which indicates that the hole pairing in the doped \(t\)-\(J\) model is non-BCS-like. Indeed, such a dichotomy has already been found in a two-leg \(t\)-\(J\) model \([38]\) in the limit that the interchain hopping \(t_\perp \to 0\) such that the phase shift operator \(\hat{\Omega}_i\) can be analytically derived in a one-dimensional form. In particular, the hole NNN pairing along the diagonal bond also gets substantially suppressed in sharp contrast to a much enhanced coherent NNN pairing in terms of the twisted quasiparticles explicitly identified there \([38]\). In the following, we shall further examine the two-hole pairing state in the two-leg ladder in the isotropic limit of \(t_\perp = t\) based on the present VMC scheme.

### C. Two-hole ground state in the two-leg \(t\)-\(J\) ladder

Previously we have briefly discussed applying the two-hole wave function ansatz in Eq. (13) to the case of an isotropic \(t\)-\(J\) two-leg ladder. The VMC calculation of the variational energies in comparison with ED has been presented in Table III, in which it shows that \(|\Psi_-\rangle_{2h}\) is the most competitive in the variational energy.

In Fig. 6, the hole density distributions in a 40 \(\times\) 2 ladder obtained by both variational methods and DMRG are shown. It can be seen that \(|\Psi_-\rangle_{2h}\) gives rise to almost the same hole distribution as the DMRG result. The pair-pair correlation functions \(C_{i,j}^{s,\parallel}\) and \(C_{i,j}^{s,\perp}\) are also calculated for the two-leg ladder as shown in Fig. 7 for the ground state \(|\Psi_-\rangle_{2h}\). The d-wave sign changes are clearly seen there. Here the apophysis of the line shape in Fig. 7 may be related to the hole density distribution as indicated in Fig. 6. The agreement of the line shape with the DMRG result in Fig. 7 implies that \(|\Psi_-\rangle_{2h}\) indeed captures the long-wave-length physics of
the two-hole ground state in an isotropic two-leg ladder. Note that the magnitude of the pair-pair correlation for $|\Psi_{-}\rangle_{2h}$ calculated by VMC is about a couple of times stronger than DMRG, which may be ascribed to a local longitudinal polaron effect in $|\phi_0\rangle$ not considered in the variational wave function. In particular, it includes the aforementioned phase shift factor in the isotropic form, which should be adjusted for the two-leg case as shown before in the one-hole case [34].

IV. PAIRING MECHANISM

In the last section, the pairing structure in the wave function ansatz $|\Psi_{-}\rangle_{2h}$ is investigated. A strong binding of the two doped holes is found with a novel feature of dichotomy in the pairing symmetry, which indicates a non-BCS nature of the hole pairing. In the following, we shall further explore the detailed pairing mechanism, which points to a new kinetic-energy-driven pairing force beyond the RVB pairing mechanism.

A. Binding energy

So far we have mainly focused on the two-hole ground state in the VMC calculation. Given the half-filling spin background $|\phi_0\rangle$, the variational procedure to determine $g_\eta(i,j)$ can be reduced to a quadratic eigenvalue problem as discussed in Appendix B. Consequently, a series of excited states in the form of two-hole ansatz wave function Eq. (13) may also be available if one restricts the Hilbert space to ignore spin excitations of the vacuum state $|\phi_0\rangle$ in Eq. (13).

For such low-lying excited states obtained, two holes remain in a tightly bound pair as indicated by the hole-hole density correlator similar to that shown in Fig. 5 for the ground state. On the other hand, the hole pair will become broken up in higher excited states, where no real space binding is seen in the hole-hole density correlators. For a finite size sample, we can identify the energy difference between the first unpaired state and the ground state as an estimation of the binding energy $E_{\text{pair}}$ for the hole pairing.

In practice, to reduce the finite-size effect, we fix the half-filling ground state $|\phi_0\rangle$ obtained in a larger lattice size $N_x \times N_y$, say, at 24 $\times$ 24. Then we calculate $E_{\text{pair}}$ with the two holes restricted within a central subregion $n \times n$: $n \leq 24$. Fig. 8 shows a scaling behavior of $E_{\text{pair}}$ as a function of $n$, which only involves the hopping energy, which shows that $E_{\text{pair}}$ saturates to a constant value with a length scale $\lambda_0$, i.e.,

$$E_{\text{pair}} = 1.84e^{-\frac{n}{\lambda_0}} + 0.39$$  \hspace{1cm} (23)
FIG. 9. The spin current patterns in $|\Psi_-\rangle_{2h}$ with two holes projected to different locations on a $16 \times 16$ lattice (only the central part is shown). The dipolar configuration of the spin currents is clearly indicated with the increase of the hole-hole distance from (a) to (f), which illustrates the crucial role of the phase string effect in the hole pairing as opposed to the absence of both in $|\Psi_0\rangle_{2h}$. Note that an opposite chirality of the spin current patterns is also present in $|\Psi_-\rangle_{2h}$, which is not shown here for simplicity.

B. Pairing force and spin currents

A rather tight spatial pairing in Fig. 5 indicates a strong pairing force between two doped holes in an AF spin background. Here the phase shift factor $e^{\mp \hat{\Omega}_i}$ not only is essential in favoring the kinetic energy in a single hole case, but also plays a critical role in the pairing of two holes. As a matter of fact, without incorporating it, the variational wave function $|\Psi_0\rangle_{2h}$ in Eq. (14) cannot produce a sensible pairing even if the spin background $|\phi_0\rangle$ is artificially tuned from a long-range to short-range spin-spin correlations. In other words, the pairing mechanism here cannot be attributed to the purely RVB pairing in $|\phi_0\rangle$. Rather it is due to the phase shift $e^{\mp \hat{\Omega}_i}$ in $|\Psi_-\rangle_{2h}$ [Eq. (13)] that represents the phase string effect associated with the hopping term.

It has been previously shown that physically $e^{\mp \hat{\Omega}_i}$ can be visualized by a spin current vortex around a hole in the single hole ground state (cf. Fig. 1 and Ref. [36]). Similarly we may measure the spin current pattern for a fixed configuration of two holes in $|\Psi_-\rangle_{2h}$. For each term with a given chirality on the right hand of Eq. (13), one may compute the corresponding spin current based on $J_s^{\pm}$ defined in Eq. (12).

Figures 9(a)-(f) show the patterns of the neutral spin current $\langle J_s^{\pm}\rangle$ at different hole locations, contributed only by one of the terms with a given chirality of spin currents in Eq. (13). The patterns with exactly an opposite chirality of spin currents in Eq. (13) are not shown for simplicity. It can be seen that the spin currents surrounding the two doped holes form “roton-like” configurations with two holes sitting at the cores of the “roton”. The spin currents get strongly canceled as the two holes approach to each other, while the spin-current vortices (antivortices) become stronger as the two holes are separated in a farther distance, approaching to the single-hole limit.

Such a non-RVB-mechanism of the hole pairing has been first found [35] in the two-hole ground state of the two-leg $t$-$J$ ladder by the DMRG calculation, in which the strong binding between the holes is shown to disappear once the phase string effect is precisely turned off without altering the short-range antiferromagnetic correlation of the spin background in the so-called $\sigma \cdot t$-$J$ model. Furthermore, in a simplified two-leg $t$-$J$ ladder with $t_\perp = 0$, a stringlike pairing potential due to the
phase string effect can be explicitly identified [38] in an analytical form, which results in the strong binding consistent with the DMRG result. In the present 2D square lattice case, the ED and DMRG calculations have also shown [37] that once the phase string is removed in the $\sigma \cdot t$-$J$ model, the angular momentum of the two-hole ground state changes from $L_z = 2$ to a trivial $L_z = 0$ consistently with the description of $|\Psi_0\rangle_{2h}$ with diminished hole pairing.

Therefore, we have self-consistently established a novel pairing mechanism for two holes injected into the Mott insulator as described by the $t$-$J$ model. The starting point is that a single doped hole does not propagate like a translational invariant Bloch wave and its wave function in Eq. (10) must involve a spin-current vortex produced by the irreparable phase string effect via the phase shift factor $e^{\mp i\Omega_i}$, which is essential to facilitate the hopping in an AF spin background. Although the kinetic energy can be significantly lowered by such a phase shift field, the single hole also becomes highly incoherent in sharp contrast to a coherent Landau quasiparticle. As such, it is shown by the VMC calculation that two doped holes show a strong incentive to form a tightly bound pair, which can further reduce the kinetic energy cost by eliminating the residual spin currents due to $e^{\mp i\Omega_i}$ via the above “roton” pattern in the wave function $|\Psi_-\rangle_{2h}$.

V. DISCUSSION

Given the above understanding of the hole pairing mechanism in the two hole limit of a doped Mott insulator, in the following we shall discuss several remaining issues that is beyond the scope of the present VMC approach.

A. Single-particle coherence vs. incoherence: A dual picture of AF correlations

So far a good agreement between the VMC results and the exact numerics of ED and DMRG has been reached in a finite-size calculation. An important remaining issue is about the long-distance behavior of a hole or a pair of holes in the AFLRO phase. We shall point out below that the coherence/incoherence of the hole propagation will be determined by the AF correlations in the spin background in the long-wavelength limit.

The phase shift operator $e^{\mp i\Omega_i}$ plays an essential role in the construction of the ground states for both the single-hole and two-hole problems [cf. Eq. (4) and Eq. (13)]. For example, the single-hole propagator in the ground state of Eq. (4)

$$ G_{j'j} \equiv 1_{h}\langle \Psi_{G}|c_{j\sigma}c_{j'\sigma}^{\dagger}|\Psi_{G}\rangle_{1h} $$ (24)

is proportional to

$$ f_{j'j} \equiv e^{\mp \sum_{j'\rightarrow j} \phi_{k_{||}}(\phi_{0})n_{j\sigma}e^{\pm i(\Omega_{j'}-\Omega_{j})}n_{j'\sigma}|\phi_{0}\rangle , $$ (25)

which falls off exponentially as a function of $|i-j|$ if $|\phi_{0}\rangle$ is an AFLRO state, but becomes a power-law decay if $|\phi_{0}\rangle$ is artificially tuned into a short range RVB state, as to be seen in the VMC simulation below. Here the phase factor $\sum_{j'\rightarrow j} \phi_{k_{||}}^0$ is added to replace the variational parameters $\phi_{k_{||}}(j)(j')$ to make $f_{jj'}$ gauge invariant, which is a summation over the link variables $\phi_{k_{||}}^0$ (cf. Eq. (20)) connecting $i$ and $j$. For simplicity, one may consider $j = i + x$ along the $x$-axis and calculate the following Fourier transformation of Eq. (25) along the $k_x$-direction

$$ f_{k_x} \equiv \int \frac{dk_{||}}{2\pi} e^{-ik_{x}x}f_{j,j'+x} , $$ (26)

as shown in Fig. 10, where $f_{k_x}$ peaks at $\pm \pi/2$ are substantially broadened in the AFLRO state but become very sharp in a short-range RVB state of $|\phi_{0}\rangle$ in a dimer limit.

FIG. 10. The mutual duality shown by the Fourier transformations, $f_{k_x}$ and $S_{k_x}$, of the gauge invariant vortex correlations $f_{j,j'}$ in Eq. (25) (red) and the spin-spin correlation $\langle \phi_{0}|\hat{S}_{||} \cdot \hat{S}_{||i+x}|\phi_{0}\rangle$ (blue) along the $x$-direction, which are measured on (a): AFLRO state and (b): an RVB state in dimer limit.

Thus the single-hole behavior as controlled by the long-range behavior of $f_{j,j'}$, which is in turn decided by the spin-spin correlation in $|\phi_{0}\rangle$ via the phase shift factor $e^{\mp i\Omega_i}$, should be rather incoherent in an AFLRO background, while become coherent once the AFRLO disappears in a short-range RVB state of $|\phi_{0}\rangle$. 
B. Possible localization in the AFLRO state

Two holes have been shown to form a tightly bound pair in Fig. 5. It means that one may reasonably treat such a pairing entity as a building block with more holes doped into the antiferromagnet in the dilute limit so long as the spin-spin correlation length is much larger than the pair size. As emphasized before, $|\Psi_{-}\rangle_{2}$ involves two opposite vortices of spin currents that are cancelled out in a distance far away from the hole pair (cf. Fig. 9). Thus the long-range AF correlation should not be affected by the presence of such a tightly-bound hole pair. In other words, the AFLRO is expected to persist in the presence of such a pairing entity as a building block with more holes.

Naively, if a hole pair can propagate coherently, a finite density of them should be superconducting. However, in the AFLRO state, the incoherence of a single hole due to the leading frustration effect of $2\hbar \eta$ indicates the self-localization of the doped hole. Similarly the long-wavelength coherence/incoherence of the hole pair should be also sensitive to the spin-spin correlation in the background.

Nevertheless, the very mechanism of pairing is to remove the leading frustration effect of $e^{\mp \Omega_{i}}$ in the ground state of Eq. (13). The question is if there would be still a residual effect of the phase string effect not cancelled out by the pairing to further localize the hole pair in the AFLRO phase. Here we would like to point out that the conserved spin currents associated with the holes become dissipationless “supercurrents” in the AFLRO phase. On a general ground, the vortex-antivortex configuration of spin current or the “roton” in Fig. 9 is expected to be an immobile object [55], in contrast to a “polaron” of spin amplitude distortion tightly bound to the hole pair to form a rigid translational invariant object. In particular, $|\Psi_{-}\rangle_{2}$ also involves an opposite chirality of spin currents (not shown in Fig. 9) as the superposition state in Eq. (13). Thus, as a whole such a hole pair state is not translationally invariant, which indirectly implies a tendency for the self-trapping of the hole pair once the spin background becomes AF ordered.

Furthermore, locally the NN and NNN pairings in $|\Psi_{-}\rangle_{2}$ are closely connected by the hopping term, which even makes the NNN pairing stronger (cf. Fig. 5). But only the NN Cooper pair shows a longer range coherence in Fig. 4(a), whereas a quick exponential decay for the NNN Cooper pair in Fig. 4(c) clearly indicates the “incoherence/localization” of the NNN component caused by the phase shift field. It explains and reconciles the dichotomy in the pairing symmetries of the s-wave-like local pairing vs. the d-wave-like Cooper pairing in large distance. Then, as the superposition of both delocalized and localized components, the hole pair as a whole quantum entity is generally expected to be localized too in a long-distance, although a more careful study beyond the present VMC approach will be further needed to resolve this important issue.

C. The ground state with more doped holes

How the present approach to the two-hole problem can provide an understanding of the SC state ansatz in Eq. (1) at finite doping?

Note that in the hole pair creation operator $\hat{D}$ defined in Eq. (2) for the SC state, $\hat{c}_{\sigma}$ is defined in Eq. (3) in terms of the same phase shift factor $e^{\mp \Omega_{i}}$ such that the translational symmetry is formally retained in the ground state (1) if the short-range AF vacuum state $|RVB\rangle$ is translationally invariant. However, such a state in the two-hole limit reduces to $\hat{D}|RVB\rangle$, which would look more like $|\Psi_{+}\rangle_{2}$ than the true ground state $|\Psi_{-}\rangle_{2}$ studied in the present work. But we point out below that the distinction between $|RVB\rangle$ and $|\phi_{0}\rangle$ can reconcile this difference, which also means that there must be a phase transition to separate two phases.

By a reorganization in Eq. (19), the ground state $|\Psi_{-}\rangle_{2}$ may be rewritten as

$$|\Psi_{-}\rangle_{2} = \sum_{ij} g_{-}(i,j) \hat{c}_{i\sigma} \hat{c}_{j\sigma} [e^{\mp 2\Omega_{i}}|\phi_{0}\rangle] + \cdots$$

(27)

with introducing $\hat{c}_{i\sigma} = c_{i\sigma} e^{\mp \Omega_{i}}$, which may be further expressed as

$$|\Psi_{-}\rangle_{2} = \sum_{ij} g_{-}(i,j) \hat{c}_{i\sigma} \hat{c}_{j\sigma} |RVB\rangle + \cdots$$

(28)

by denoting $e^{\mp 2\Omega_{i}}|\phi_{0}\rangle \rightarrow |RVB\rangle$. Note that Eq. (28) would also resemble $|\Psi_{+}\rangle_{2}$ defined in Eq. (13) ($\eta = +1$) if $|\phi_{0}\rangle$ is replaced by $|RVB\rangle \sim e^{\mp 2\Omega_{i}}|\phi_{0}\rangle$ there. Although the original $|\Psi_{+}\rangle_{2}$ has a higher VMC energy and a distinct quantum number $L_{z} = \pm 1$ than that of $|\Psi_{-}\rangle_{2}$ with $|\phi_{0}\rangle$ as an AFLRO state, now with $|\phi_{0}\rangle \rightarrow |RVB\rangle$, one may repeat a VMC procedure for such a new state given in Eq. (28). Here both $|RVB\rangle$ and parameter $g_{-}(i,j)$ are treated variationally, and in particular, $|RVB\rangle$ satisfying an eigen equation in the variational procedure that can be diagonalized by ED with each given $g_{-}(i,j)$ in an iteration procedure of the VMC (The detail is given in Appendix C).

As a result, a non-degenerate $|\Psi_{+}\rangle_{2}$ can be found with the correct angular momentum $L_{z} = 2$ mod 4, consistent with $|RVB\rangle \sim e^{\pm 2\Omega_{i}}|\phi_{0}\rangle$ in Eq. (28). The variational kinetic energy $\sim -11.94 J$, is even slightly lower than that of the ground state $|\Psi_{-}\rangle_{2}$ shown in Table II, with a slightly higher superexchange energy $\sim -10.35 J$. Furthermore, it is easy to find the overlap $\langle RVB|\phi_{0}\rangle \sim 10^{-13}$, i.e., almost orthogonal, and on the other hand, $\langle RVB|e^{\pm 2\Omega_{i}}|\phi_{0}\rangle \sim 0.2$, which is of order of one to validate Eq. (28).

With the pairing creation operator in Eq. (2), a generalization of Eq. (28) implies a ground ansatz for $N_{h}$ hole case,

$$|\Psi_{G}\rangle \propto \hat{D}^{N_{h}}|RVB\rangle$$

(29)
which is essentially the same as Eq. (1) with the total hole number fixed at a finite doping concentration, where
\[
|\text{RVB}| \sim e^{i \sum_{ij} \bar{n}_i \phi_j} |\phi_0\rangle.
\] (30)

At finite dopings, $|\text{RVB}\rangle$ can be shown to become short-ranged by a mean-field theory [32]. This is the reason why the vacuum state in Eq. (29) is denoted by $|\text{RVB}\rangle$ to distinguish it from $|\phi_0\rangle$ of the AFLRO state of the Heisenberg model at no doping.

An ODLRO of the pairing amplitude can be achieved by $\langle \mathcal{D} \rangle \neq 0$ in Eq. (29) at finite doping [31]. According to Eq. (28), the local pairing symmetry should resemble that of $|\Psi_{-\text{2h}}\rangle$ for two holes discussed in the present work so long as the short-range AF correlations persist in $|\text{RVB}\rangle$. Indeed, a dichotomy of an s-wave symmetry of the pairing amplitude $g(i,j)$ for the twisted quasiholes created by $\mathcal{D}$ in Eq. (30) and a d-wave symmetry of the Cooper pairing order parameter have been previously found in a generalized mean-field theory [33] leading to Eq. (29).

Therefore, by properly incorporating the hole-induced phase shift field $e^{\mp \hat{\Omega}_i}$, an evolution of the ground state from the AFLRO to the SC as a function of doping may be mathematically realizable, although a phase transition should occur from long-range AF ordered $|\phi_0\rangle$ to an emergent RVB state $|\text{RVB}\rangle$. It leads to a non-BCS-like SC wave function (29) at finite doping, in which the local pairing structure should be similar to that of $|\Psi_{-\text{2h}}\rangle$ studied in the AFLRO phase in the present work, but it is in a translational invariant form in contrast to the latter. In particular, the AFLRO must be replaced by an emergent RVB state self-consistently to establish the transition of the charge pairing from localized state to superconducting.

A possible non-Landau-type phase transition has been studied before in a topological gauge theory formulation [56, 57]. The hole pairing in the AFLRO phase with a phase transition to the SC phase have been also discussed in the semiclassical form of vortex-antivortex pairing [58, 59]. Such long-wavelength physics in the dilute concentration of holes is beyond the scope of the present two-hole VMC work. Nevertheless, the short-distance pairing structure is expected to remain similar as characterized by Eq. (13). A further exploration of the phases and the phase transition in the dilute doping regime should first incorporate this short-range physics correctly.

D. Comparison with other approaches

As the building block of superconductivity, the pairing mechanism of doped holes has been under intensive study. Numerical methods, including ED [52, 53, 60, 61], DMRG [40, 51, 62, 63], and VMC [20, 54, 64, 65], are employed to analyze the pairing structure of the two hole ground state and excitations. Consistent results, including a strong pairing of d-wave symmetry and a maximal hole density correlator at distance $\sqrt{2}$, have been obtained. In comparison with these numerical results, the variational wave function Eq. (5) proposed in this work has captured essentially all the important features with using only a few number of variational parameters ($\sim N^2$ where $N = N_x \times N_y$ is the lattice site number).

The structure of the two-hole ground state in Eq. (13) ($\eta = -1$) is basically fixed with the fitted form of the variation parameter $g_{-\text{2h}}(i,j)$ given in Eq. (19). Introducing more variational parameters including considering the “spin polaron” effect in $|\phi_0\rangle$ may lead to a better variational ground state. However, the most essential features, i.e., the dichotomy in pairing structure, with a d-wave-like pairing symmetry in terms of the bare electron operators and the s-wave-like real space pairing of the holes, is already well captured in the simplest variational ansatz. The phase shift field $\hat{\Omega}_i$ in Eq. (13) plays a fundamental role here, which keeps track of the singular phase string effect.

It has been long believed that the superexchange interaction plays the role of the driven force for the pairing in the cuprate in place of the electron-phonon interaction in conventional BCS theory. The pairing mechanisms due to the RVB spin pairing [2, 12, 13], the semiclassical long-range spin texture [66, 67], or the “spin bag” [68, 69], were proposed and extensively explored. However, the recent DMRG calculation for the two-leg ladder has revealed [40] that the superexchange interaction is only a necessary condition. By comparing the $t$-$J$ model and the so-called $\sigma$-$t$-$J$ model, in which the superexchange term is the same, it shows that the phase string sign structure induced by the hopping term in the former is sufficient to lead to the formation of strong hole pairing, whereas both are absent in the latter. The present results clearly support this opinion, in which the phase string as encoded in the phase shift factor $e^{\pm \hat{\Omega}_i}$ is crucial in the variational two-hole wave function $|\Psi_{-\text{2h}}\rangle$, for the $t$-$J$ model, including the strong binding of two holes. But due to the absence of $e^{\mp \hat{\Omega}_i}$ in $|\Psi_0\rangle_{\text{2h}}$, which works for the $\sigma$-$t$-$J$ model, the pairing is diminished even if the superexchange term may be optimized via the vacuum $|\phi_0\rangle$.

VI. CONCLUSION

In this paper, we have studied a two-hole ground state wave function in both the 2D lattice and two-leg ladder $t$-$J$ models. The VMC results are in good agreement with the ED and DMRG numerics. Here the key feature in the wave function is the presence of a many-body nonlocal phase shift associated with each doped hole, which keeps track of the precise phase string sign structure of the $t$-$J$ model. For one-hole ground state in a 2D square lattice with $C_4$ symmetry (OBC), an emergent novel quantum number, i.e., an angular momentum $L_z = \pm 1$, is a manifestation of such an effect. In the present two-hole case, the same effect leads to $L_z = 2 \mod 4$, which character-
izes a non-degenerate ground state as precisely predicted by the exact numerical calculations. Therefore, the spin transverse distortion or spin current generated by the motion of a doped hole is essential in the construction of the ground state with the correct new quantum number. This is in sharp contrast to the previous approaches in the literature, in which the spin longitudinal/magnetization distortion or the “spin bag” effect have been emphasized instead.

Here we have found that two doped holes in the ground state do form a tightly bound pair in both 2D and two-leg ladder, indicating the existence of a strong binding force in such doped Mott insulators. The hole binding diminishes once the phase shift field in the wave function is turned off, even if the spin background remains in the AFLRO or RVB state. This strongly suggests that the pairing glue originates from the phase string effect, which is explicitly illustrated by a roton-like pattern of spin currents surrounding two holes. In particular, the pairing is kinetic-energy-driven to facilitate the hole hopping, which is kind of counterintuitive. It is distinct from the usual pairing mechanism of potential energy driven like exchanging AF spin fluctuations or the RVB pairing.

Such an unconventional pairing structure results in a dichotomy in the pairing symmetry. Namely, although a d-wave symmetry is clearly exhibited in the Cooper channel of bare electronic holes, a stronger s-wave-like pairing will manifest if probed in terms of the “twisted holes”. Here the “twisted hole” has been shown to replace the usual Landau quasiparticle as a new quasiparticle in the two-hole ground state, which is thus more “robust” as compared to the d-wave symmetry in the Cooper pair channel.

The important lesson that we have learned in the present approach is that doping a quantum spin antiferromagnet is very singular and non-perturbative at short distance. Before to correctly tackle the long-wavelength physics at dilute but finite doping, one has to first handle the short-range physics carefully since a conventional perturbative renormalization group approach may well be failed as clearly demonstrated in this work. In the last subsection we have briefly discussed the possible long-wavelength physics including the self-localization of the hole pair in the AFLRO phase as well as the phase transition to a true superconducting phase beyond a critical doping. A future theoretical effort beyond the present VMC method will be needed to further deal with these important issues of long distance including the phase transition.

Appendix A: Symmetries of the ansatz wave function

For a system with non-degenerate ground state, a good ansatz wave function is expected to conserve the symmetries of its Hamiltonian. In the following, we show that for the symmetry to be maintained in the ground state wave function, the opposite chirality counterpart (the ⋅⋅⋅ term) of Eq. (13), i.e.,

\[
|\Psi_{\eta}\rangle_{2h} = \sum_{ij} g_{\eta}(i,j) c_{\eta}^{i\uparrow} c_{\eta}^{j\downarrow} e^{-i(\Omega_{i}+\Omega_{j})} |\phi_{0}\rangle + \cdots
\]

\[
= \sum_{i,j,m=\pm} g_{\eta,m}(i,j) c_{\eta}^{i\uparrow} c_{\eta}^{j\downarrow} e^{-im(\Omega_{i}+\Omega_{j})} |\phi_{0}\rangle ,
\]

has to be present. Here we introduce \( m = \pm \) as an explicit index of the chirality and \( g_{\eta,\pm}(i,j) \) as variational parameters corresponding to \( m = \pm \), respectively.

First let us examine the Time Reversal Symmetry. Under the Time Reversal transformation \( \hat{T} \), one has

\[
\hat{T} c_{i \sigma} \hat{T}^{-1} = \sigma c_{i \bar{\sigma}} ,
\]

\[
\hat{T} e^{-im\Omega_{i}} \hat{T}^{-1} = e^{i+im\hat{\Omega}_{i}} \hat{T}^{-1} = e^{i\sum_{l}(\theta_{l} + \eta_{l})} e^{-im\hat{\Omega}_{i}} ,
\] (A3)

with using the constraint \( n_{\uparrow} + n_{\downarrow} = 1 \). A time reversal invariant wave function is expected to transform as

\[
\hat{T} |\Psi_{\eta}\rangle = \sum_{i,j,m} e^{i\sum_{l}(\theta_{l} + \eta_{l})} |\Psi_{\eta}\rangle = \sum_{i,j,m} e^{i\sum_{l}(\theta_{l} + \eta_{l})} |\Psi_{\eta}\rangle = \hat{T} |\Psi_{\eta}\rangle ,
\]

\[
= \alpha_{T} |\Psi_{\eta}\rangle ,
\]

\[
\alpha_{T} = \frac{1}{\sqrt{2}} e^{i(\sum_{l}(\theta_{l} + \eta_{l}))} .
\]
which requires
\[ g_{n,m}(i, j) = \alpha_T g_{n,m}(i, j) e^{-im\left(\sum_{l} \varphi_l + \eta \sum_{l} \varphi_l\right)}, \]  
(A5)

where \( \alpha_T \) is an arbitrary global phase factor with \( |\alpha_T| = 1 \).

Next consider a discrete \( Z_2 \) symmetry of spin flip \( \hat{F} \), which is defined as:
\[ \hat{F} c_{i\sigma} \hat{F}^{-1} = c_{\sigma}, \]
\[ \hat{F} e^{-im\hat{\Omega}_i} \hat{F}^{-1} = e^{-im\sum_{l} \varphi_l} e^{im\hat{\Omega}_i}. \]

It is expected that the ground state would remain the same under this transformation up to a global phase
\[ \hat{F} |\Psi_g\rangle = \sum_{i,j,m} e^{-im\left(\sum_{l} \varphi_l + \eta \sum_{l} \varphi_l\right)} g_{n,m}(i, j) c_{i\uparrow} c_{j\uparrow} e^{im\left(\hat{\Omega}_i + \eta \hat{\Omega}_j\right)} |\phi_0\rangle \]
\[ = \alpha_F |\Psi_g\rangle. \]

We have swapped the summation indexes \( i, j \) and replace \( m \) by \(-\eta m\) in the second line of derivation above. Again \( \alpha_F \) is an arbitrary global phase factor with \( |\alpha_F| = 1 \).

Actually, by doing the spin flip transformation twice, we further get \( \alpha_F^2 = 1 \), which leads to \( \alpha_F = \pm 1 \). The last equality gives rise to the following constraint on a spin-flip invariant wave function
\[ g_{n,-\eta m}(i, j) = -\alpha_F g_{n,m}(i, j) e^{-im\left(\sum_{l} \varphi_l + \eta \sum_{l} \varphi_l\right)}. \]
(A9)

For a wave function satisfying both of the above symmetries, we can fix the arbitrary phase factor \( \alpha_T = -\alpha_F \) and combine the two constraints into one:
\[ g_{n,m}(i, j) = g_{n,-m}(i, j), \]
(A10)

which is equivalent to say that a non-degenerate ground state should be a real one, and no net currents are expected to exist. This constraint has been verified numerically for the variational ground state \( |\Psi_g\rangle \) studied in the main text, which is non-degenerate with \( L_z = 2 \) mod 4 under the \( C_4 \) symmetry.

### Appendix B: Variational Monte Carlo procedure

The Monte Carlo procedure used to optimize the variational energy and to measure other observables of the two-hole doped wave function ansatz (13) will be outlined in this appendix. Similar procedures have been previously utilized first in the single-hole doped \( t-J \) model for both two-leg ladder and 2D lattice cases [34, 36], and then in the two-hole doped problem in the \( t_\perp = 0 \) two-leg ladder [38].

At half filling, the \( t-J \) model reduces to the Heisenberg model, whose ground state \( |\phi_0\rangle \) for a bipartite lattice can be well simulated variationally by the Liang-Doucet-Anderson type (bosonic RVB) wave function [9]. Namely,
\[ |\phi_0\rangle = \sum_v \omega_v |v\rangle, \]
(B1)

where the valence bond (VB) state
\[ |v\rangle = |(a_1, b_1) \cdots (a_n, b_n)\rangle \]
(B2)

consist of singlet pairs \( |(a, b)\rangle = |\uparrow \downarrow - \downarrow \uparrow\rangle \), with \( a \) and \( b \) from different sublattices, \( A \) and \( B \), respectively. Here VB states are not orthogonal to each other, and the overlap between two different VB states are given by
\[ \langle v' | v \rangle = 2^{N_{\text{loop}}} v', v \]
(B3)

where \( N_{\text{loop}} \) is the number of loops in the transposition-graph covers \( (v', v) \) [9].

The variational parameter \( \omega_v \) of each valence bond state \(|v\rangle\), which is always positive according to the Marshall sign rule, can be further fractionalized as \( \omega_v = \prod_{(a, b) \in v} h(a_i - b_i) \), where \( h(|a_i - b_i|) > 0 \) is a positive function dependent on the distance \(|a_i - b_i|\) between sites \( a_i \) and \( b_i \). By tuning the long range behavior of \( h(a-b) \), different spin background can be obtained. For a power law \( h(l) \sim l^{-p} \) and \( p < 5 \), \(|\phi_0\rangle \) is an AFLRO state; while for \( h(l) \sim l^{-p} \) and \( p \geq 5 \) or when the maximum bond length is finite, a short ranged state can be obtained. Specifically, a dimer limit state is obtained when the maximum bond length is chosen as 1.

Here we follow Ref. [9] to express all the observables we need in the form of expectation values on the spin background \(|\phi_0\rangle\). As a simple example, the spin-spin correlation \( S_i \cdot S_j \) of the spin background \(|\phi_0\rangle\) can be calculated as
\[ \frac{\langle \phi_0 | S_i \cdot S_j | \phi_0 \rangle}{\langle \phi_0 | \phi_0 \rangle} = \sum_{v', v} P(v', v) \frac{|\langle v'| S_i \cdot S_j | v \rangle|}{\langle v' | v \rangle}, \]
(B4)
where

\[ P(v', v) = \frac{w_{v'} w_{v} \langle v' | v \rangle}{\langle \phi_0 | \phi_0 \rangle} \quad (B5) \]

is a probability distribution satisfying \( \sum_{v', v} P(v', v) = 1 \). Eq. (B4) can then be evaluated using the standard Monte Carlo method as long as one know how to calculate \( \langle v' | S_i, S_j | v \rangle \), which is

\[
\frac{\langle v' | S_i, S_j | v \rangle}{\langle v' | v \rangle} = \begin{cases} (-1)^{i+j} \frac{3}{4}, & i, j \in \text{s.l.} \\ 0, & i, j \notin \text{s.l.} \end{cases}
\]

where \( i, j \in \text{s.l.} \) means that \( i \) and \( j \) belong to the same loop in the transposition-graph.

Similar Monte Carlo procedure can also be done for the two-hole wave function \( |\Phi_{\eta}^{2h} \rangle \) with minor adjustment. For an arbitrary observable \( \hat{O} \), its expectation value over \( |\Psi_{\eta}^{2h} \rangle \) is

\[
\langle \hat{O} \rangle = \frac{2h \langle \Psi_{\eta}^{2h} | \hat{O} | \Psi_{\eta}^{2h} \rangle_{2h}}{2h \langle \Psi_{\eta}^{2h} | \Psi_{\eta}^{2h} \rangle_{2h}} = \frac{2h \langle \Psi_{\eta} | \hat{O} | \Psi_{\eta} \rangle_{2h}}{2h \langle \psi_0 | \psi_0 \rangle} \quad (B6)
\]

By fixing the normalization condition of \( |\Psi_{\eta}^{2h} \rangle \) as

\[
\frac{2h \langle \Psi_{\eta} | \Psi_{\eta}^{2h} \rangle_{2h}}{\langle \phi_0 | \phi_0 \rangle} = 1 , \quad (B7)
\]

we further get

\[
\langle \hat{O} \rangle = \frac{2h \langle \Psi_{\eta} | \hat{O} | \Psi_{\eta} \rangle_{2h}}{\langle \phi_0 | \phi_0 \rangle} = \sum_{i', j', m'} g_{\eta, m'} (i', j') g_{\eta, m}(i, j) \frac{\langle \phi_0 | \hat{\Lambda}_m^{ij} c_{i'}^{\dagger} c_{j'}^{\dagger} \hat{O} c_{i} c_{j} \hat{\Lambda}_m | \phi_0 \rangle}{\langle \phi_0 | \phi_0 \rangle} \quad (B8)
\]

where for simplicity the phase operator is written as \( \hat{\Lambda}_m^{ij} = e^{-im(\sum_{i, j} \theta_i \eta_{ij} + \sum_{i, j} \eta_{ij} \theta_j)} \). Eq. (B8) is a quadratic form of the variational parameters \( g_{\eta, m}(i, j) \), which are written as a vector \( g \) in the last line. \( \hat{O} \) is a Hermitian matrix, whose matrix elements are

\[
O_{i'j'm'}^{ijm} = \sum_{v', v} P(v', v) \frac{\langle v' | \hat{\Lambda}_m^{ij} c_{i'}^{\dagger} c_{j'}^{\dagger} \hat{O} c_{i} c_{j} \hat{\Lambda}_m | v \rangle}{\langle v' | v \rangle} \quad (B9)
\]

which have the same form as that of Eqs. (B4) and (B5). Therefore, the same Monte Carlo procedure in Ref. [9] can be directly used here as long as one gets the formulas of \( \langle v' | \hat{\Lambda}_m^{ij} c_{i'}^{\dagger} c_{j'}^{\dagger} c_{i} c_{j} \hat{\Lambda}_m | v \rangle \). Loop update procedure introduced in Ref. [70] is used in the Monte Carlo sampling procedure to accelerate calculation.

Specifically, the normalization condition (B7) can also be written as the form of Eq. (B8), with \( \hat{O} \) taken as the identity operator \( \hat{1} \),

\[
1 = \langle \hat{1} \rangle = g^{\dagger} A g , \quad (B10)
\]

which is also a quadratic form serving as the normalization condition for the variational parameters \( g_{\eta, m}(i, j) \). The corresponding matrix of the identity operator \( \hat{1} \) is denoted as \( A \) here (cf. Eq. (B13) below), whose matrix elements can also be obtained by Eq. (B9). Note that \( A \) is not an identity matrix as a result of indistinguishability of identical holes created by \( c_{i} c_{j} \) and \( c_{i'} c_{j'} \).

1. Explicit expressions for some observables

In calculating the matrix elements in (B9), one may find that all the calculations can be transformed to evaluating expressions of the following form:

\[
\langle v' | \hat{\Lambda}_m^{ij} n_{k_1, \sigma_1} n_{k_2, \sigma_2} \cdots n_{k_n, \sigma_n} S_{l_1}^{\sigma_1} S_{l_2}^{\sigma_2} \cdots S_{l_s}^{\sigma_s} \hat{\Lambda}_m | v \rangle , \quad (B11)
\]

Making use of this expression, we can again take advantage of the loop configurations in the transposition-graph covers \((v', v)\), by dividing the loops into relevant loops who contain sites \( k_1 \cdots k_n \) or \( l_1 \cdots l_s \) and irrelevant loops who
do not. When the phase factor $\hat{\Lambda}_{ij}^m$ is not considered, the irrelevant loops are just unity while the relevant loops will determine whether the term is nonzero or zero. After the phase factor $\hat{\Lambda}_{ij}^m$ is added back, the irrelevant loops will contribute a factor $\frac{1}{2}(e^{i\theta_\alpha} + e^{i\theta_\alpha'})$ now, while the relevant loops will give a phase factor $\frac{1}{2}e^{i\theta_\alpha}$ besides the duty of checking compatibility, where

$$\theta_{\alpha} = \sum_{l \in \text{loop } \alpha} m'(\theta_i(l) + \eta\theta_j(l)) - m(\theta_i(l) + \eta\theta_j(l))$$

is the summation of all the phases along a loop $\alpha$ and $\theta_{\alpha}^0$ depends on the spin configuration on the relevant loops. Therefore, as long as we expand the matrix elements of Eq. (B9) in the form of Eq. (B11), the programming progress will be straightforward. In the following we will give this expansion explicitly for some important operators.

1. First for the normalization condition $\hat{O} = \hat{1}$, the corresponding matrix $\mathbf{A}$ has matrix elements

$$A_{ijm} = \sum_{v',v} P(v', v) \frac{1}{\langle v'|v \rangle} \left[ \delta_{ii'} \delta_{jj'} \langle v'|\hat{\Lambda}_{ij}^{-m'} n_{i\uparrow} n_{j\downarrow} \hat{\Lambda}_{ij}^m|v \rangle - \delta_{ji'} \delta_{jj'} \langle v'|\hat{\Lambda}_{ij}^{-m'} S_i^- S_j^+ \hat{\Lambda}_{ij}^m|v \rangle \right].$$

2. The hopping Hamiltonian $\hat{H}_t$ defined in Eq. (6) connects pairs of sites with only one site different, resulting in the corresponding matrix $\mathbf{H}_t$ with elements

$$(H_t)_{ijm}^{i'j'm'} = \sum_{v',v} P(v', v) \frac{1}{\langle v'|v \rangle} \sum_{\alpha=x,y} \left[ \delta_{ii'} \delta_{jj'} \langle v'|\hat{\Lambda}_{ij}^{-m'} n_{i\uparrow} n_{j\downarrow} + S_i^+ S_j^- \hat{\Lambda}_{ij}^m|v \rangle \right. $$

$$+ \delta_{ji'} \delta_{jj'} \langle v'|\hat{\Lambda}_{ij}^{-m'} n_{i\uparrow} n_{j\downarrow} + S_i^- S_j^+ \hat{\Lambda}_{ij}^m|v \rangle $$

$$\left. - \delta_{ji'} \delta_{ji'} \langle v'|\hat{\Lambda}_{ij}^{-m'} S_i^- S_j^- \hat{\Lambda}_{ij}^m|v \rangle \right]$$

$$- \delta_{ji'} \delta_{ji'} \langle v'|\hat{\Lambda}_{ij}^{-m'} S_i^+ S_j^+ \hat{\Lambda}_{ij}^m|v \rangle,$$

where $e_{x,y}$ are the $x$ and $y$ direction unit vectors.

3. For the superexchange Hamiltonian $\hat{H}_s$ defined in Eq. (7), the corresponding matrix $\mathbf{H}_s$ is

$$(H_s)_{ijm}^{i'j'm'} = \frac{1}{2} \sum_{v',v} P(v', v) \frac{1}{\langle v'|v \rangle} \sum_{\alpha=x,y} \left[ \delta_{ii'} \delta_{jj'} \langle v'|\hat{\Lambda}_{ij}^{-m'} S_i^+ S_j^- + S_i^- S_j^+ \hat{\Lambda}_{ij}^m|v \rangle \right. $$

$$+ \delta_{ji'} \delta_{ji'} \langle v'|\hat{\Lambda}_{ij}^{-m'} S_i^- S_j^- \hat{\Lambda}_{ij}^m|v \rangle \right].$$

4. Calculation of the overlap Eq. (16) is a bit different with other variables. We first normalize Eq. (16) as

$$\Delta_{k} = \frac{1}{\sqrt{2h}} \langle \Psi_n | \hat{\Lambda}_{k}^+ | \phi_0 \rangle = \sum_{i'j'm'} g_{n,m}(i', j') \frac{\langle \phi_0 | \hat{\Lambda}_{ij}^{-m'} c_{i'j'}^\dagger \hat{\Lambda}_{k}^+ | \phi_0 \rangle}{\langle \phi_0 | \phi_0 \rangle},$$

$$\Delta_{k} = \sum_{i'j'm',i,j} g_{n,m}(i', j') \frac{1}{N} e^{i k (r_i - r_j)} \sum_{v',v} P(v', v) \frac{\langle v'|\hat{\Lambda}_{ij}^{-m'} c_{i'j'}^\dagger c_{i'j'} \hat{\Lambda}_{ij}^m \hat{\Lambda}_{ij}^+|v \rangle}{\langle v'|v \rangle}.$$
5. For the singlet pair-pair correlators defined in Eq. (18), written together as $C_{k'kl}^{s} = \hat{\Delta}_{k'l}(\Delta_{kl}^{s})^\dagger$ here with $k' \neq k,l$ and $l' \neq k,l$, the matrix elements are as the following

$$\langle C_{k'kl}^{s}\rangle_{ijm} = \sum_{v',v} P(v', v) \frac{1}{\langle v'|v\rangle} \left[ \delta_{v'k} \delta_{v'I} \delta_{vjkl}(v'\hat{\Delta}^{-m'}(n_{k\uparrow}n_{l\downarrow} - S_{k}^{+}S_{l}^{-})|v\rangle \right]$$

$$\delta_{v'k} \delta_{v'I} \delta_{vjkl}(v'\hat{\Delta}^{-m'}(n_{k\uparrow}n_{l\downarrow} - S_{k}^{+}S_{l}^{-})|v\rangle \right]$$

$$\delta_{v'k} \delta_{v'I} \delta_{vjkl}(v'\hat{\Delta}^{-m'}(n_{k\uparrow}n_{l\downarrow} - S_{k}^{+}S_{l}^{-})\hat{\Delta}_{kl}^{m}|v\rangle \right] .$$

(B18)

6. The hole-hole density correlator $\hat{N}_{kl}^{h}$ defined in Eq. (21) is essentially the same with the unit operator

$$\langle \hat{n}_{i}^{h} \rangle = \sum_{j \neq i} N_{ij}^{h} .$$

(B20)

7. And the hole density can be obtained by a simple summation of $N_{ij}^{h}$

8. The neutral spin current $\hat{J}_{kl}^{s}$ defined in Eq. (12) has similar matrix elements with the superexchange term:

$$\langle J_{kl}^{s}\rangle_{ijm} = -i\frac{J}{2} (1 - \delta_{(ij)l(kl)}) P(v', v) \frac{1}{\langle v'|v\rangle} \left[ \delta_{v'k} \delta_{v'I} \delta_{vjkl}(v'\hat{\Delta}^{-m'}(n_{i\uparrow}n_{j\downarrow}\hat{\Delta}_{ij}^{m}|v\rangle \right]$$

$$\delta_{v'k} \delta_{v'I} \delta_{vjkl}(v'\hat{\Delta}^{-m'}n_{i\uparrow}n_{j\downarrow}(S_{k}^{+}S_{l}^{-} - S_{k}^{-}S_{l}^{+})\hat{\Delta}_{ij}^{m}|v\rangle \right] .$$

(B21)

where $\delta_{(ij)l(kl)} = 0$ when $i \neq k,l$ and $j \neq k,l$, and $\delta_{(ij)(kl)} = 1$ otherwise. The above expressions can also be used to calculate $J_{kl}^{s}$ with the two doped holes projected at $i$ and $j$.

2. Variational procedure for optimizing $g_{ij}(i,j)$

In the variational procedure, we take the operator $\hat{O}$ in Eq. (B8) as the kinetic Hamiltonian $\hat{H}_{t}$

$$E_{t} \equiv \langle \hat{H}_{t} \rangle = g^\dagger H_{t} g .$$

(B22)

Combined with the normalization condition Eq. (B10), the procedure to optimize $E_{t}$ turns out to be a generalized eigenvalue problem

$$H_{t} g = E_{t} A g .$$

(B23)

Besides the ground state energy, Eq. (B23) can also give excited energies and corresponding variational parameters $\mathbf{g}$, which are used in Section IV in obtaining binding energy. Here only the kinetic energy $E_{t}$ is taken into account in variational procedure following [36]. The superexchange energy $E_{J}$ is omitted as inclusion of $E_{J}$ will cause severe boundary effect and make the calculation time unacceptable for large lattice. However, calculation on $10 \times 10$ lattice with the holes constrained on the central $8 \times 8$ sites shows that the $E_{J}$ term seldom changes the physics, which validates our omission of $E_{J}$ on larger lattice.

Appendix C: Feedback effect on the spin background

In the basic variational procedure in the main text, the spin background $|\psi_{0}\rangle$ in Eq. (13) has been taken to be the half filling ground state of $H_{J}$ by ignoring the feedback effect from motion of holes. The main doping effect is explicitly incorporated as the phase string sign structure in the two-hole ground state anstaz $|\Psi_{-2n}\rangle$ in the VMC simulation. However, this assumption may no longer hold true at finite doping as the spin background...

TABLE IV. The energies of the generalized two-hole ground states [Eq. (C1) and Eq. (C3)] on a 4 × 4 lattice: $E_G$ is the total energy; $E_t$ and $E_J$ are the kinetic and the superexchange energies, respectively; $L_z$ denotes the corresponding orbital angular momentum.

Iterate calculations are done to get the best variational energy, i.e. first choose $w^0(\{\sigma\})$ as the ground state of $H_J$, and find variational parameters $g_j^0(i,j)$ to optimize the kinetic energy, then fix the variational parameters $g_j^0(i,j)$, and find new $w^1(\{\sigma\})$ to optimize the ground state energy, and then fix the spin background as $w^1(\{\sigma\})$ to find new variational parameters $g_j^1(i,j)$ to optimize the kinetic energy and so on, until a convergent ground state energy is obtained.

Variational energies and the quantum numbers calculated via the generalized wave function ansatz Eq. (C1) on a 4 × 4 lattice are shown in Table IV, with the results of original Eq. (13) also shown here for comparison. It can be seen that the energy of $|\Psi_+\rangle_{2h}$ is improved significantly, while the energy of $|\Psi_-\rangle_{2h}$ is improved less. These results confirm that the feedback effect indeed is insignificant for $|\Psi_-\rangle_{2h}$, but plays essential role for the same chirality state $|\Psi_+\rangle_{2h}$, with its ground state angular momentum changed from $L_z = \pm 1$ to $L_z = 2$ the same as that of $|\Psi_-\rangle_{2h}$.

In other words, now both $|\Psi_\pm\rangle_{2h}$ converge to the same non-degenerate ground state in the VMC procedure. The overlap $|\langle \Psi_\pm | \Psi_\mp \rangle_{2h}|^2 = 0.50$ also confirms this. Therefore, at least for the short range physics, the above two kinds of wave function ansatz can lead to the same ground state. Actually, as stated in Eq. (28) and Eq. (30) in the main text, a vortex $e^{2i\Omega_\sigma}$ is expected to be generated automatically in the $|\Psi_\mp\rangle_{2h}$ due to the feedback effect, which reconciles with the anti-phase factor in $|\Psi_-\rangle_{2h}$. Inspired by the similarity of $|\Psi_+\rangle_{2h}$ and $|\Psi_-\rangle_{2h}$, we can further mix these two states

$|\Psi_{\text{mix}}\rangle_{2h} = c_1 |\Psi_+\rangle_{2h} + c_2 |\Psi_-\rangle_{2h}$

and optimize the variational parameters $g_{\pm}(i,j)$ to get an improved ground state energy, which is also shown in Table IV.
