CURVE GRAPHS OF SURFACES WITH FINITE-INVARIENCE INDEX 1

JUSTIN LANIER AND MARISSA LOVING

ABSTRACT. In this note we prove a conjecture of Durham–Fanoni–Vlamis, showing that every infinite-type surface with finite-invariance index 1 fails to have a good curve graph, that is, a connected graph where vertices represent homotopy classes of essential simple closed curves and where the natural mapping class group action has infinite diameter orbits. Our arguments use tools developed by Mann–Rafi in their study of the coarse geometry of big mapping class groups.

1. INTRODUCTION

For the purposes of this note, surfaces are connected orientable 2-manifolds and curves are homotopy classes of essential simple closed curves. A surface $S$ is of finite or infinite type according to whether or not $\pi_1(S)$ is finitely generated. The mapping class group $\text{Map}(S)$ is the group of homotopy classes of orientation-preserving homeomorphisms of $S$.

A central object in the study of finite-type surfaces and their mapping class groups is the curve complex $\mathcal{C}(S)$, which was introduced by Harvey [8]. The vertices of $\mathcal{C}(S)$ represent curves on $S$ and sets of vertices that have disjoint representatives bound simplices. The curve complex is flag and it is also referred to as the curve graph. Many variants of $\mathcal{C}(S)$ have also been considered—for example, by replacing curves with subsurfaces or by considering only separating or nonseparating curves. When $S$ is of finite type, $\mathcal{C}(S)$ has infinite diameter when equipped with the path metric, and its geometry is Gromov hyperbolic, as shown by Masur–Minsky [12]. Further, the orbits of the natural action of $\text{Map}(S)$ on $\mathcal{C}(S)$ have infinite diameter, and analyzing these orbits gives information about the Nielsen–Thurston type of a mapping class.

For any infinite-type surface $S$, it is not hard to see that $\mathcal{C}(S)$ has diameter 2. If we have any hope of recovering the interesting mapping class group actions found in the finite-type setting, it is necessary to build alternatives to $\mathcal{C}(S)$. One option is to replace curves with other objects; in this direction, Calegari and Bavard initiated the study of ray graphs [5, 4]. In this note, following Durham–Fanoni–Vlamis, we consider alternatives where vertices correspond to curves on $S$, but where perhaps only a proper subset of curves are included, and where edges need not correspond to disjointness [6]. We will say that a graph $\Gamma$ is a curve graph for $S$ if the vertices of $\Gamma$ represent some (not necessarily proper) subset of curves on $S$ and $\Gamma$ admits an action that restricts to the natural action of $\text{Map}(S)$ on vertices. When a curve graph $\Gamma$ for $S$ is connected and has an infinite diameter orbit under the natural action of $\text{Map}(S)$, we will call $\Gamma$ a good curve graph for $S$.

The second author acknowledges support from NSF Grants DGE-1144245 and DMS-1902729, as well as from NSF Grants DMS 1107452, 1107263, 1107367 “RNMS: GEometric structures And Representation varieties”, which allowed the author to work on this project during the 2017-2018 Warwick EPSRC Symposium on Geometry, Topology and Dynamics in Low Dimensions.
Durham–Fanoni–Vlamis defined an invariant of infinite-type surfaces that in most cases determines whether or not $S$ has a good curve graph [6]. The finite-invariance index $f(S)$ of a surface is the size of the largest finite $\text{Map}(S)$-invariant collection of disjoint closed proper subsets of ends of $S$; see Section 2 for more details. Using this invariant, Durham–Fanoni–Vlamis characterized in most cases whether $S$ has a good curve graph.

**Theorem 1.1.** [6, Main Theorem] If $f(S) \geq 4$, then $\text{Map}(S)$ admits an unbounded action on a graph consisting of curves. If $f(S) = 0$, then $\text{Map}(S)$ admits no such unbounded action.

In earlier work, Aramayona–Valdez proved whether or not $\text{Map}(S)$-invariant subgraphs of $\mathcal{C}(S)$ are good for certain classes of infinite-type surfaces [2]. Their results break into two cases, depending on whether $S$ has finite or infinite genus. We summarize their relevant results as follows.

**Theorem 1.2.** [2, Theorems 1.4 and 1.7] Let $S$ be an infinite-type surface.

1. If $S$ has finite genus and no isolated punctures, then a $\text{Map}(S)$-invariant subgraph $\mathcal{G}(S)$ has infinite diameter if and only if it contains no separating curves that cut off a disk containing some, but not all, of the punctures.

2. If $S$ is a blooming Cantor tree and $\mathcal{G}(S)$ is a $\text{Map}(S)$-invariant subgraph of $\mathcal{C}(S)$, then $\text{diam}(\mathcal{G}(S)) = 2$.

The statement given in (2) is a correction of the statement given by Aramayona–Valdez [2, Theorem 1.7]; their original statement contradicts Theorem 1.1. The proof that they give assumes not only that $S$ has infinite genus, but that every end is accumulated by genus [1]; this further hypothesis implies that $S$ is a blooming Cantor tree. The surfaces treated in Theorem 1.2 are also treated in Theorem 1.1 since they all have finite-invariance index either 0 or $\infty$.

In their paper, Durham–Fanoni–Vlamis make some observations about the cases of finite-invariance index 1, 2, and 3. For $f(S) = 2$ and $f(S) = 3$, they give examples showing that finite-invariance index is too coarse an invariant to determine whether $S$ has a good curve graph. On the other hand, they conjecture that $f(S) = 1$ implies that $S$ has no good curve graph [6, Conjecture 9.1].

The statement given in (2) is a correction of the statement given by Aramayona–Valdez [2, Theorem 1.7]; their original statement contradicts Theorem 1.1. The proof that they give assumes not only that $S$ has infinite genus, but that every end is accumulated by genus [1]; this further hypothesis implies that $S$ is a blooming Cantor tree. The surfaces treated in Theorem 1.2 are also treated in Theorem 1.1 since they all have finite-invariance index either 0 or $\infty$.

The main result of this note confirms their conjecture.

**Theorem 1.3.** Let $S$ be a surface of infinite type with $f(S) = 1$. Then $S$ does not have a good curve graph.

We give two proofs of this theorem. After reviewing some background in Section 2, we begin Section 3 by proving two preliminary lemmas that square up several definitions introduced by Durham–Fanoni–Vlamis and Mann–Rafi. Theorem 1.3 then follows directly from a strictly stronger result of Mann–Rafi [11, Proposition 3.1]. Our second proof of Theorem 1.3 is given in Section 4. This proof uses the same preliminary lemmas but then follows the style of the arguments of Durham–Fanoni–Vlamis.

**Acknowledgements.** The authors thank Javier Aramayona, Federica Fanoni, Katie Mann, Hugo Parlier, Ferrán Valdez, and Nick Vlamis for a number of helpful conversations.

2. Background

The goal of this section is to overview the aspects of infinite-type surfaces relevant to our work. We review the classification of infinite type surfaces as well as notions related to the
finite-invariance index, the Mann–Rafi partial order, self-similarity, and coarse boundedness of a group. For more comprehensive treatments of these topics, we refer the reader to [3], [13], [6], and [11].

Classifying infinite-type surfaces. The classification of infinite-type surfaces was first given by Kerékjáró and was clarified and extended by Richards [9, 13].

The classification implies that every connected orientable 2-manifold may be constructed as follows. Begin with a sphere. Puncture it, without loss of generality, along some closed subset of a Cantor set. This set of punctures is denoted $E(S)$, and punctures are called ends. Finally, add handles to the surface so that the only accumulation points of sequences of handles are in $E(S)$. This marks some closed subset of $E(S)$ as being accumulated by genus. This space of genus ends is denoted $E^g(S)$ and is recorded as a subspace of $E(S)$.

Note that $E^g(S)$ is also a closed subset of a Cantor set. Observe that closed surfaces and punctured surfaces of finite type are special cases of this construction.

Let $g(S) \in \mathbb{N} \cup \{\infty\}$ equal the genus of $S$. The classification states that the triple $(g(S), E(S), E^g(S))$ uniquely determines $S$ up to homeomorphism. For more details on the classification and on the definition of the spaces of ends, see [6].

The finite-invariance index. Following Durham–Fanoni–Vlamis, we make the following definitions. We say that a collection $\mathcal{P}$ of disjoint subsets of the space of ends is Map($S$)-invariant if for every $P \in \mathcal{P}$ and for every $\varphi \in \text{Map}(S)$ there exists $Q \in \mathcal{P}$ such that $\varphi(P) = Q$. The finite-invariance index of $S$, denoted $f(S)$, is defined as follows:

- $f(S) \geq n$ if there is a Map($S$)-invariant collection $\mathcal{P}$ of disjoint closed proper subsets of $E(S)$ satisfying $|\mathcal{P}| = n$;
- $f(S) = \infty$ if $g(S)$ is finite and positive;
- $f(S) = 0$ otherwise.

We say that $f(S) = n$ if $f(S) \geq n$ but $f(S) \notin n + 1$.

For any Map($S$)-invariant collection $\mathcal{P}$ of disjoint closed proper subsets of $E(S)$, call the elements of $\mathcal{P}$ finite-invariance sets. When $\mathcal{P}$ contains only one set, we also call $\mathcal{P}$ a finite-invariance set.

A partial order and self-similarity. Following Mann–Rafi, we make the following definitions. For $x, y \in E(S)$, we say $x \preceq y$ if every clopen neighborhood of $y$ contains a homeomorphic copy of some clopen neighborhood of $x$. We say $x$ and $y$ are equivalent if $x \preceq y$ and $y \preceq x$. We will make use of the following result concerning this partial order on equivalence classes of ends.

Proposition 2.1 ([11], Proposition 4.7). The partial order $\preceq$ has maximal elements. Furthermore, the equivalence class of every maximal element is either finite or a Cantor set.

We let $\mathcal{M}(E)$ denote the set of equivalence classes of maximal ends of $E(S)$.

Continuing to follow Mann–Rafi, a pair $(E, E^g)$ is self-similar if for any decomposition $E = E_1 \sqcup E_2 \sqcup \cdots \sqcup E_n$ of $E$ into pairwise disjoint clopen sets, there exists a clopen set $D$ contained in some $E_i$ such that the pair $(D, D \cap E^g)$ is homeomorphic to $(E, E^g)$.

A Polish group $G$ is (globally) coarsely bounded, or CB, if every compatible left-invariant metric on $G$ gives $G$ finite diameter. Mann–Rafi show that self-similarity of the space of ends of a surface $S$ is a sufficient condition for Map($S$) to be CB.
Proposition 2.2 ([11], Proposition 3.1). Let $S$ be a surface of infinite or zero genus. If the space of ends of $S$ is self-similar, then $\text{Map}(S)$ is CB.

Good curve graphs vs. coarse boundedness. If a surface $S$ has a good curve graph, then $\text{Map}(S)$ is not CB. However, the converse is not true. There are surfaces whose mapping class groups are not CB, and so admit an action with an unbounded orbit on some metric space, yet do not admit such an action in a natural way on any metric space arising as a connected curve graph for the surface.

Examples of such surfaces include the plane minus a Cantor set and the tripod surface, which has exactly three ends, all accumulated by genus. These surfaces have finite-invariance index 2 and 3, respectively. Since these surfaces have nondisplaceable subsurfaces, their mapping class groups are not CB by the work of Mann–Rafi [11, Theorem 1.9]. However, Durham–Fanoni-Vlamis showed that neither surface has a good curve graph [6, Proposition 9.2].

In cases where such a “gap” exists, we can hope to find a substitute for graphs of curves by constructing graphs of other objects naturally associated to a surface. For instance, in the case of the plane minus a Cantor set, Bavard showed that the ray graph is connected and $\delta$-hyperbolic and has infinite diameter orbits under the natural action of the mapping class group [4]. In the case of the tripod, it follows from a recent result of Fanoni–Ghaswala–McLeay that its mapping class group acts with infinite diameter orbits on its omnipresent arc graph; this is a connected, $\delta$-hyperbolic graph where vertices correspond to certain (possibly bi-infinite) arcs between distinct ends of the surface and where edges correspond to disjointness [7, Theorem C].

3. Main theorem: first approach

In this section we begin by relating the finite-invariance index, the partial order on equivalence classes of ends, and self-similarity in the case $\mathfrak{f}(S) = 1$. We then give our first proof of Theorem 1.3.

Lemma 3.1. Let $S$ be a surface of infinite type with $\mathfrak{f}(S) = 1$. Then $\mathcal{M}(E)$ consists of a unique equivalence class that is either a point or a Cantor set.

Proof. Let $S$ be a surface with $\mathfrak{f}(S) = 1$ and with end space $E$. It follows that $\mathcal{M}(E)$ consists of a unique equivalence class, for otherwise two of the equivalence classes could be taken as a collection of finite-invariance sets for $S$, as these would be closed, $\text{Map}(S)$-invariant, proper, and disjoint, contradicting $\mathfrak{f}(S) = 1$.

By Proposition 2.1 an individual maximal equivalence class is either finite or a Cantor set. If $\mathcal{M}(E)$ is finite, then it must consist of a single point because $\mathfrak{f}(S) = 1$, just as before. Therefore $\mathcal{M}(E)$ is either a point or a Cantor set. 

Lemma 3.2. Let $S$ be a surface of infinite type with $\mathfrak{f}(S) = 1$. Then the space of ends $E(S)$ is self-similar.

Proof. By Lemma 3.1, $\mathcal{M}(E)$ consists of a unique equivalence class that is either a point or a Cantor set. In their Lemmas 4.12 and 4.13, Mann–Rafi show that either of these conditions implies that $E(S)$ is self-similar under the additional hypothesis that $S$ has no connected finite-type nondisplaceable subsurfaces.
Since \( f(S) = 1 \), then \( g(S) = 0 \) or \( \infty \). In their Lemma 6.2, the first author and Vlamis show that if \( S \) has a unique maximal end and \( g(S) = 0 \) or \( \infty \), every compact subsurface of \( S \) is displaceable and the end space of \( S \) is self-similar [10]. It remains, then, to prove the corresponding result in the case where \( \mathcal{M}(E) \) is a Cantor set.

Let \( S \) be such a surface and let \( \Sigma \) be a compact subsurface of \( S \). By possibly enlarging \( \Sigma \), we may assume that each component of \( \partial \Sigma \) is separating and the closure of each component of \( S \setminus \Sigma \) is non-compact.

Let \( \Omega_0, \Omega_1, \ldots, \Omega_n \) denote the components of \( S \setminus \Sigma \), labelled such that \( E(\Omega_0) \) is a neighborhood of \( \mu_0 \), a maximal end of \( S \). Fix a small open neighborhood \( \mathcal{W}_0 \) of \( \mu_0 \), so that \( E(\Omega_0) \setminus \mathcal{W}_0 \) contains infinitely many ends in the \( \text{Map}(\Omega) \)-orbit of \( \mu_0 \).

By the maximality of \( \mu_0 \), for all \( 0 < i \leq n \) and each \( e \in E(\Omega_i) \) there exists a clopen neighborhood \( \mathcal{V}_e \) of \( e \) contained in \( E(\Omega_i) \) such that \( \mathcal{W}_0 \cap \mathcal{V}_e \) is an open subset homeomorphic to \( \mathcal{V}_e \). The sets \( \mathcal{V}_e \) in \( E(\Omega_i) \) form an open cover for \( E(\Omega_i), i > 0 \). The compactness of each \( E(\Omega_i) \) guarantees a finite open cover of each \( E(\Omega_i) \) consisting of sets taken among the \( \mathcal{V}_e \). After taking all of these finitely many \( \mathcal{V}_e \) from the open covers of the \( E(\Omega_i) \) and indexing them \( 1 \) to \( m \), we may replace \( \mathcal{V}_{e_2} \) with \( \mathcal{V}_{e_2} \setminus \mathcal{V}_{e_1}, \mathcal{V}_{e_3} \setminus \mathcal{V}_{e_1} \setminus \mathcal{V}_{e_2} \), and so on, and so may assume that the \( \mathcal{V}_{e_j} \) are pairwise disjoint, \( 1 \leq j \leq m \).

Take a sequence \( \{\mu_j\}_{0 < j \leq m} \) of distinct ends in \( E(\Omega_0) \setminus \mathcal{W}_0 \) that are in the \( \text{Map}(S) \)-orbit of \( \mu_0 \). For each \( \mu_j \) take a small open neighborhood \( \mathcal{W}_j \) so that \( \mathcal{W}_j \subset E(\Omega_0) \) and so that all of the \( \mathcal{W}_j \) are pairwise disjoint, \( 0 \leq j \leq m \). For each \( \mathcal{V}_{e_j} \), let \( \mathcal{V}_j \) be an open copy of \( \mathcal{V}_{e_j} \) in \( \mathcal{W}_j \). By construction the \( \mathcal{V}_j \) are disjoint. The \( \mathcal{V}_j \) can be collected into sets \( \mathcal{X}_i \), so that \( \mathcal{V}_j \) belongs to \( \mathcal{X}_i \) exactly when \( \mathcal{V}_{e_j} \subset E(\Omega_i) \). We therefore have that \( \mathcal{X}_i \) is homeomorphic to \( E(\Omega_i) \).

Choose pairwise-disjoint separating simple closed curves \( c_1, \ldots, c_n \) contained in \( \Omega_0 \) such that there is a component of \( S \setminus c_i \) inducing the set \( \mathcal{X}_i \) in the end space of \( S \). Take a simple closed curve \( c_0 \) in \( \Omega_0 \) co-bounding a surface \( \Sigma' \) with \( c_1, \ldots, c_n \) whose genus is the same as the genus of \( \Sigma \). By the classification of surfaces, there exists a homeomorphism \( S \to S \) mapping \( \Sigma \) to \( \Sigma' \), and hence \( \Sigma \) is displaceable since \( \Sigma \cap \Sigma' = \emptyset \) by construction. The self-similarity of \( E(S) \) then follows by Lemma 4.13 of Mann–Rafi.

We restate one of the conclusions of the above proof as its own lemma, to parallel the statement of [10] Lemma 6.2.

**Lemma 3.3.** Let \( S \) be a surface where \( \mathcal{M}(E) \) consists of a unique equivalence class that is a Cantor set and where \( g(S) = 0 \) or \( \infty \). Then every compact subsurface of \( S \) is displaceable and the end space of \( S \) is self-similar.

**Proof #1 of Theorem 1.3.** By Lemma 3.2 the space of ends of \( S \) is self-similar. By Proposition 2.2 this implies that \( \text{Map}(S) \) is CB, and so it has no unbounded length function. In particular, it cannot act with infinite diameter orbits on a connected curve graph. We conclude that \( S \) has no good curve graph.

**4. Main theorem: second approach**

In this section we will first review the approach introduced by Durham–Fanoni–Vlamis to show that a surface has no good curve graph. We then extend their approach under the hypothesis \( f(S) = 1 \). We conclude with our second proof of Theorem 1.3.

Durham–Fanoni–Vlamis introduced the following tool for showing that a curve graph is not good.
Proposition 4.1 ([6], Proposition 4.1). Let $S$ be an oriented surface and $\Gamma = \Gamma(S)$ be a connected graph consisting of curves on which the mapping class group acts. Let $V \subseteq \Gamma \times \Gamma$ satisfying:

1. there exists a vertex $c \in \Gamma$ such that, up to the action of $\text{Map}(S)$, there is a finite number of pairs $(a, b) \in V$ with $a, b \in \text{Map}(S) \cdot c$, and
2. for every $a, b \in \text{Map}(S) \cdot c$ with $(a, b) \notin V$, there exists $d \in \text{Map}(S) \cdot c$ such that $(a, d)$ and $(b, d)$ belong to $V$.

Then every $\text{Map}(S)$-orbit in $\Gamma$ has finite diameter.

Durham–Fanoni–Vlamis use this tool to derive three easily-applied criteria for showing that a curve graph is not good. They use these criteria to show that surfaces with finite-invariance index 0 do not have good curve graphs. These three criteria are given in the following proposition.

Proposition 4.2 ([6], Proposition 4.2). Suppose that $\Gamma = \Gamma(S)$ is a connected graph consisting of curves with an action of $\text{Map}(S)$ and:

1. $S$ has infinitely many isolated punctures and $\Gamma$ contains a vertex bounding a finite-type genus-0 surface, or
2. $\text{genus}(S) = \infty$, $S$ has either no punctures or infinitely many isolated punctures (and in the latter case $S$ has an end accumulated by both genus and punctures), and $\Gamma$ contains a curve bounding a finite-type surface, or
3. $\text{genus}(S) = \infty$ and $\Gamma$ contains a nonseparating curve,

then $\text{Map}(S)$ acts on $\Gamma(S)$ with finite-diameter orbits.

The statement given in (2) adds a parenthetical hypothesis to the statement given by Durham–Fanoni–Vlamis. Without some hypothesis on the positioning of the genus and punctures in the case that $S$ has infinite genus and infinitely many punctures, their proof of their Proposition 4.2(2) does not go through. For instance, take $S$ to be a surface with end space consisting of one end accumulated by genus and a second end accumulated by isolated punctures. Let $c$ be a separating curve that bounds a subsurface of genus 1 with one puncture. Then there are curves $a, b \in \text{Map}(S) \cdot c$ such that $a$ and $b$ fill a separating finite-type subsurface $F$ where one component of $S \setminus F$ has no punctures and the other component has no genus. Because of this there is no curve $d \in \text{Map}(S) \cdot c$ that is disjoint from both $a$ and $b$, and so Proposition 4.1 does not apply directly. The additional hypothesis we introduce avoids this situation.

In all of the cases where Durham–Fanoni–Vlamis apply their Proposition 4.2(2), the further hypothesis in fact holds, and so the further results they prove that rely on the proposition remain true. The further hypothesis also holds in all of the cases we consider in the present note.

The upshot of Proposition 4.2 is that certain curves in $S$ are “bad”, in the sense that no good curve graph for $S$ can contain such a curve. For instance, under certain hypotheses, separating curves are bad when they cut off a finite-type surface from an “infinite pool” of genus and/or isolated punctures. In the course of proving Propositions 4.3 and 4.4 we show that, under the hypothesis of $f(S) = 1$, separating curves are also bad when they cut off an infinite-type surface and leave behind an “infinite pool” of what has been cut off. As this exhausts all possible curve types in the case that $f(S) = 1$, we conclude that $S$ has no good curve graph.
For two distinct disjoint separating curves $a$ and $b$, we say that $a$ is nested in $b$ with respect to $E' \subset E(S)$ if $b$ separates $a$ from $E'$. If $a$ and $b$ are two distinct disjoint separating curves and neither is nested in the other with respect to $E'$, then $a$ and $b$ are unnested with respect to $E'$.

Proposition 3.1 states that the condition $f(S) = 1$ implies that $\mathcal{M}(E)$ contains a unique equivalence class that is either a point or a Cantor set. We treat these two cases in the following two propositions.

**Proposition 4.3.** Suppose $S$ is of infinite type with $f(S) = 1$ and that $\Gamma$ is a connected curve graph for $S$. Suppose further that the unique equivalence class in $\mathcal{M}(E)$ is a point. Then $\text{Map}(S)$ acts on $\Gamma$ with finite-diameter orbits.

**Proof.** Let $S$ and $\Gamma$ be as in the statement and let $e$ be the point in the unique equivalence class in $\mathcal{M}(E)$. Let $c$ be a curve in $\Gamma$. Since $f(S) = 1$, we have $g(S) = 0$ or $\infty$. If $c$ is a nonseparating curve, then $g(S) = \infty$, Proposition 1.2(3) applies, and $\Gamma$ is not good.

If $c$ is separating and cuts off a finite-type surface, then $\Gamma$ is not good since either Proposition 1.2(1) or (2) applies, as follows. Since we already have that $g(S) = 0$ or $\infty$, we next show that $S$ has either 0 or infinitely many isolated punctures. The surface $S$ cannot have two or more (but finitely-many) isolated punctures, since these would be maximal, contrary to the hypothesis on $\mathcal{M}(E)$. If there is a single isolated puncture, then it must be maximal and so equal to $e$. But then $S$ is the plane and so not of infinite type. Finally, if $S$ has infinite genus and infinitely many isolated punctures, then $e$ is accumulated both by genus and by isolated punctures, and so we conclude that the proposition applies.

Otherwise, $c$ is separating but does not cut off a finite-type subsurface. Set
\[ V = \{(a, b) \mid i(a, b) = 0, \text{ } a \text{ and } b \text{ are unnested with respect to } e\}. \]

By the classification of surfaces and the self-similarity of $E(S)$, there is a unique pair of separating curves $(a, b) \in V$ with $a, b \in \text{Map}(S) \cdot c$, up to the action of $\text{Map}(S)$. Therefore condition (1) of Proposition 1.1 is satisfied.

Next, consider $a, b \in \text{Map}(S) \cdot c$ such that $(a, b) \notin V$. This means that either $a$ and $b$ intersect, or one is nested in the other with respect to $e$, or they are not distinct. In each case we will find $d \in \text{Map}(S) \cdot c$ such that $(a, d)$ and $(b, d)$ belong to $V$. If $a$ and $b$ intersect, then together they fill a finite-type subsurface $F$. By Lemma 3.2, one of the components of $S \setminus \partial F$ has end space homeomorphic to $S$. Then there exists a separating curve $d$ in this component that is in $\text{Map}(S) \cdot c$ and is disjoint from and unnested with each of $a$ and $b$ with respect to $e$. Therefore, $(a, d), (b, d) \in V$. Similarly, if $a$ and $b$ are nested with respect to $e$, there is again a component of $S \setminus \{a \cup b\}$ with end space homeomorphic to $S$ where there exists the desired curve $d$ that is disjoint from and unnested with each of $a$ and $b$. A similar argument applies if $a$ and $b$ are not distinct. Condition (2) of Proposition 1.1 is therefore satisfied, and $\Gamma$ is not good.

Since this exhausts the possibilities for $c$, we conclude that $S$ has no good curve graph. □

We now prove the analogous result to Proposition 4.3 for surfaces with $f(S) = 1$ where the unique equivalence class in $\mathcal{M}(E)$ is a Cantor set.

**Proposition 4.4.** Suppose $S$ is of infinite type with $f(S) = 1$ and that $\Gamma$ is a connected curve graph for $S$. Suppose further that the unique equivalence class in $\mathcal{M}(E)$ is a Cantor set. Then $\text{Map}(S)$ acts on $\Gamma$ with finite-diameter orbits.
Proof. Let $S$ and $\Gamma$ be as in the statement, and let $\mathcal{C}$ be the Cantor set that is the unique equivalence class in $\mathcal{M}(E)$. Let $c$ be a curve in $\Gamma$. Since $f(S) = 1$, we have $g(S) = 0$ or $\infty$. If $c$ is a nonseparating curve, then $g(S) = \infty$, Proposition 4.2(3) applies, and $\Gamma$ is not good.

If $c$ is separating and cuts off a finite-type surface, then $\Gamma$ is not good since either Proposition 4.2(1) or (2) applies, as follows. Since we already have that $g(S) = 0$ or $\infty$, we next show that $S$ has either 0 or infinitely many isolated punctures. The surface $S$ cannot have one or more (but finitely-many) isolated punctures, since these would be maximal, contrary to the hypothesis on $\mathcal{M}(E)$. Finally, if $S$ has infinite genus and infinitely many isolated punctures, then each end in $\mathcal{M}(E)$ is accumulated both by genus and by isolated punctures, and so we conclude that the proposition applies.

Otherwise, $c$ is separating but does not cut off a finite-type subsurface. In Proposition 4.3 there was only one case to consider, but here there are two: either only one component of $S \setminus c$ has end space with nontrivial intersection with $\mathcal{C}$, or instead both do. The former case is analogous to the only case in Proposition 4.3 and the same argument holds here as in that proposition, substituting $\mathcal{C}$ for $c$. In this case, then, $\Gamma$ is not good.

The remaining case where both components of $S \setminus c$ have end spaces with nontrivial intersection with $\mathcal{C}$ follows similarly to the treatment of the Cantor tree surface by Durham–Fanoni–Vlamis [6, Theorem 1.7]. Since $S$ has a unique maximal equivalence class of ends, any clopen neighborhood in $E(S)$ of any maximal end is homeomorphic to $E(S)$. In particular, the end spaces of the two components of $S \setminus c$ are each homeomorphic to $E(S)$. Set

$$\mathcal{V} = \{(a, b) \mid i(a, b) = 0, \text{ } a \text{ and } b \text{ are distinct.}\}$$

By the classification of surfaces and the self-similarity of $E(S)$, there is a unique pair of distinct disjoint separating curves $(a, b) \in \mathcal{V}$ with $a, b \in \text{Map}(S) \cdot c$, up to the action of $\text{Map}(S)$. Therefore condition (1) of Proposition 4.1 is satisfied.

Next, consider $a, b \in \text{Map}(S) \cdot c$ such that $(a, b) \notin \mathcal{V}$. Then either $a$ and $b$ intersect or else they are not distinct. In the former case, $a$ and $b$ together they fill a finite-type subsurface $F$. At least one component of $S \setminus \partial F$ has end space homeomorphic to $E(S)$ by Lemma 3.2. Then there exists a separating curve $d$ in this complementary component that is in $\text{Map}(S) \cdot c$ and that is distinct from and disjoint from each of $a$ and $b$. We then have $(a, d), (b, d) \in \mathcal{V}$. A similar argument applies if $a$ and $b$ are not distinct. Condition (2) of Proposition 4.1 is therefore satisfied, and $\Gamma$ is not good.

Since this exhausts the possibilities for $c$, we conclude that $S$ has no good curve graph. □

Proof #2 of Theorem 1.3. By Lemma 3.1 $\mathcal{M}(E)$ is either a point or a Cantor set. If $\mathcal{M}(E)$ is a point, we apply Proposition 4.3. If it is a Cantor set, we apply Proposition 4.4. We conclude that $S$ has no good curve graph. □
