(Dated: June 30, 2021)

A single ferromagnetic kagomé layer is predicted to realize a Chern insulator with accompanying quantized Hall conductance, which upon stacking can become a Weyl-semimetal possessing large anomalous Hall effect (AHE) and magneto-optical activity. Indeed, in the kagomé bilayer material \( \text{Fe}_3\text{Sn}_2 \), a large AHE was detected, however it still awaits the direct probing of the responsible band structure features by bulk sensitive methods. By measuring the optical diagonal and Hall conductivity spectra, we identified their origin and determine the intrinsic contribution to the AHE. Facilitated by momentum and band decomposed first principles calculations, we found that transitions around the K-point are responsible for a step edge at 0.25 eV in \( \sigma_{xy} \), while they strongly modify \( \sigma_{xy} \) even towards the DC limit. Together with a broad hump detected around 0.9 eV originating from multiple transitions, these excitations produce the static AHE.

Recently, much effort has been focused on the study of materials derived from the kagomé lattice – the triangular lattice of corner-sharing triangles – as they realize topologically non-trivial band structure features such as flat bands [1–4] and Dirac fermions [4–6]. Symmetry breaking phase transitions give rise to non-trivial electronic states in these compounds: magnetic Weyl-semimetals [7, 8], magnetic skyrmions [9, 10] and unconventional superconductivity [3, 11–13].

One of the most profound manifestations of the interplay between magnetism and the topology of the itinerant electrons is the intrinsic anomalous Hall effect (AHE) [14]. If the spin degeneracy of the electronic bands is lifted by breaking the time-reversal symmetry, their spin-orbit mixing leads to a finite Berry curvature, which, as a fictitious magnetic field, deflects electric currents. Remarkably, the AHE can become quantized in 2D by tuning the Fermi energy into the exchange gap between topologically non-trivial bands, as suggested for the case of a single kagomé layer [15]. When such layers are stacked in 3D, a magnetic Weyl-semimetal showing enhanced AHE response can be realised. Recently, a large AHE was observed in the kagomé bilayer compound \( \text{Fe}_3\text{Sn}_2 \) (see Fig. 1a) [5]. The temperature independent response, assumed to represent the intrinsic AHE, was attributed to the Dirac(-like) quasiparticles existing in the vicinity of the K-point. However, optical spectroscopy and STM studies also indicate the presence of flat bands close to the Fermi energy [16, 17]. Therefore, the direct assignment of the band structure features responsible for the large intrinsic AHE is still a crucial question yet to be answered.

\( \text{Fe}_3\text{Sn}_2 \) (space group \( \overline{R} \bar{3}m \)) consists of an alternating stack of \( \text{Fe}_3\text{Sn} \) kagomé bilayers and honeycomb layers of Sn as shown in Fig. 1 [18]. A magnetic order with dominantly ferromagnetic character develops below \( T_c = 657 \) K. The moments are aligned along the c axis at high temperature and they gradually rotate toward the \( ab \) plane as the temperature is lowered [9, 18, 19]. Whether the ferromagnetic order in \( \text{Fe}_3\text{Sn}_2 \) is a completely collinear one is under debate, while in thin samples the combination of the ferromagnetic exchange, the crystalline anisotropy and the dipolar interactions lead to branched domains and even skyrmionic bubbles [9, 19, 20]. Owing to the kagomé structure, \( \text{Fe}_3\text{Sn}_2 \) shows non-trivial electronic topology. The presence of flat electron bands [16, 21], Weyl nodes in the 10 meV vicinity of the Fermi-energy [22] as well as several Dirac nodes at the K-points [5, 16, 23, 24] have been proposed.

Identifying whether these features are the main source of the AHE is difficult based on magnetotransport experiments alone, since the response is a sum of the intrinsic and extrinsic contributions with sometimes identical dependence on the longitudinal conductivity [14]. Superior to its \( \omega \to 0 \) limit, the off-diagonal or optical Hall conductivity spectrum \( \sigma_{xy}(\omega) \) can provide the necessary information to identify the inter-band excitations determining the intrinsic Hall-conductivity. According to the Kubo formula this can be calculated by:

\[
\sigma_{xy}^{\text{Hall-int}}(\omega) = e^2 \hbar \sum_{n \neq n'} \int \frac{dk}{(2\pi)^d} \left[ f\left( \varepsilon_n^r(k) \right) - f\left( \varepsilon_{n'}^r(k) \right) \right] \times \text{Im} \left\langle \frac{\langle n, k | v_x(k) | n', k \rangle \langle n', k | v_y(k) | n, k \rangle}{\epsilon_n(k) - \epsilon_{n'}(k) - (\hbar \omega)^2} \right\rangle,
\]

where \( | n, k \rangle \) and \( \epsilon_n(k) \) are the Bloch-type eigenstates and eigenvalues, respectively, \( f(\epsilon) \) is the Fermi function and \( \omega \)
ARPES, this serves as a direct probe for the bulk electronic contributions to the static Hall effect. Ab initio calculations around 0.25 eV and a positive hump at 0.9 eV yielding the main $\sigma_{xy}$ excitation continua in the imaginary part of transitions contributing to the intrinsic AHE. We identified two for the dc AHE, implying that our study covers all the interband measurements, the real part of it exhibits distinct features. At the low energy cutoff of our temperature dependence, especially towards lower energies, and range, where the magnitude of the effect shows a strong temperature dependence. Above 0.8 eV, the rotation exhibits a broad minimum and the ellipticity shows a zero-crossing. At higher energies, both Kerr parameters remain negative with a monotonic temperature dependence. Above 0.8 eV, the overlapping interband transitions form a rather featureless optical response, thus appearing in the denominator in Eq. 2 is strongly suppressed at the plasma frequency and correspondingly enhances the MOKE [29]. Around 0.5 eV, the rotation exhibits a broad minimum and the ellipticity shows a zero-crossing. At higher energies, both Kerr parameters remain negative with a monotonic temperature dependence. Above 0.8 eV, the overlapping interband transitions form a rather featureless optical response, thus we expect that MOKE is proportional to the magnetisation. Since the measured normal incidence Kerr effect, the so-called polar MOKE, is sensitive to the out-of-plane component of the magnetisation, the tilting of the magnetisation axis towards the $ab$-plane [9, 19] can lead to the decrease in the magnitude of the Kerr effect, although the magnetic moment per Fe-atom increases for lower temperatures [30].

The spectra of both the diagonal and the off-diagonal elements of the conductivity tensor are shown in Fig. 3. The low energy extrapolation of the optical conductivity coincides with the static values which were determined from a dc resistivity measurement (compare Fig. S2), as shown in Fig. 3. Since we measured MOKE in 0.3 T, i.e. in a magnetic field smaller

\[
\theta + i\eta = -\frac{\sigma_{xy}}{\sigma_{xx} \sqrt{1 + i\frac{\sigma_{xx}}{\epsilon_0}}}.
\]

where $\sigma_{xx}$ is the optical conductivity spectrum, $\epsilon_0$ is the vacuum permittivity, $\theta$ and $\eta$ are the Kerr rotation and ellipticity, respectively.

We present the measured reflectivity and MOKE spectra in Fig. 2. The reflectivity shows metallic behaviour towards zero frequency approaching unity (For log-lin scale compare Fig. S1). Around 0.2 eV, a dip develops with lowering temperature, in agreement with former results [16]. Since the magnetic order in Fe$_3$Sn$_2$ develops well above the studied temperature range, we detected a finite Kerr effect already at room temperature. The simultaneously measured rotation and ellipticity spectra can be closely mapped on each other by Kramers-Kronig-transformation, validating the correctness of the measurement procedure. Accompanying the plasma edge at 0.125 eV, the rotation spectra show a steep increase whereas the ellipticity has a peak which becomes more pronounced toward low temperatures. The dielectric response appearing in the denominator in Eq. 2 is strongly suppressed at the plasma frequency and correspondingly enhances the MOKE [29]. Around 0.5 eV, the rotation exhibits a broad minimum and the ellipticity shows a zero-crossing. At higher energies, both Kerr parameters remain negative with a monotonic temperature dependence. Above 0.8 eV, the overlapping interband transitions form a rather featureless optical response, thus we expect that MOKE is proportional to the magnetisation. Since the measured normal incidence Kerr effect, the so-called polar MOKE, is sensitive to the out-of-plane component of the magnetisation, the tilting of the magnetisation axis towards the $ab$-plane [9, 19] can lead to the decrease in the magnitude of the Kerr effect, although the magnetic moment per Fe-atom increases for lower temperatures [30].

The spectra of both the diagonal and the off-diagonal elements of the conductivity tensor are shown in Fig. 3. The low energy extrapolation of the optical conductivity coincides with the static values which were determined from a dc resistivity measurement (compare Fig. S2), as shown in Fig. 3. Since we measured MOKE in 0.3 T, i.e. in a magnetic field smaller
FIG. 2. Temperature dependence of the reflectivity, Kerr-rotation and ellipticity spectra in the energy range up to 3 eV.

than the saturation of the magnetisation and the Hall effect, we scaled the non-diagonal conductivity spectra in order to compare them with the dc results. As the Hall resistivity scales linearly up to the saturation, we use the ratio of the remanent value and the measurement field as a scaling factor for the off-diagonal conductivity spectra.

For $\sigma_{xx}$, we observe a step edge at 0.25 eV and a broad hump centered at 0.9 eV, both located well above the Drude tail. Our diagonal optical conductivity spectrum agrees with that published in Ref. [16] apart from the prominent peak reported below $\sim 0.02$ eV. Although this excitation emerges close to the low-energy cutoff of our reflectivity measurements we do not see any decrease in the reflectivity towards low frequencies, which would be a signature of such an excitation. Fig. 3 b) and c) display the real and imaginary part of the off-diagonal conductivity respectively. For the real part the dc Hall effect values extracted from the measurement in Fig. S2 are presented for comparison. Since at the low-energy cutoff, 0.08 eV, the Hall spectra have the same sign and similar magnitude as the corresponding static values, we assume a smooth interpolation of the real part of the $\sigma_{xy}$ spectra to dc with a slight upturn towards low frequencies. Around 0.4 eV, the spectra exhibit a maximum whose magnitude increases with increasing temperature. At higher energies, the real part of the Hall conductivity is strongly suppressed. In the imaginary part of $\sigma_{xy}$, two prominent features are visible at the same energies as the main features of $\sigma_{xx}$: a sharp minimum at 0.25 eV and a broad hump around 0.9 eV.

The close correspondence between the optical and Hall conductivity spectra motivated us to model the $\sigma_{xx}$ spectrum of Fe$_3$Sn$_2$ by ab initio calculations. The magnetic moment of Fe obtained from our theory, 2.17 $\mu_B$ is in good agreement with its measured value [30]. The calculated bandstructure along high symmetry lines for energies close to $E_F$ is shown in Fig. 1c, in agreement with previously published results [21, 31]. The subset of colored bands 1 – 4 is vital for analysing the transitions of the low-energy conductivity.

The theoretical and experimental optical conductivity are compared over a wide energy range in Fig. S3. Apart from the intraband (Drude) contributions that are not included in our calculation, the experimental and theoretical spectra qualitatively agree up to 2.5 eV. Most importantly, the ab-initio calculation reproduce the optical conductivity at low energies, as seen in Fig. 4b. Specifically, the step edge observed at 0.25 eV in the experiments is captured by the theory, though, it is slightly shifted to higher energies. In order to assign the transitions
FIG. 4. Momentum and band decomposition of the optical conductivity $\sigma_{xx}$. a) Colored cylinders show the regions around the K-points where the momentum-resolved optical conductivity is integrated. b) k-resolved optical conductivity. Only interband transitions are considered in the calculation. The red, yellow and blue colors correspond to the masks shown in panel a). Integration for the whole Brillouin-zone is shown in black. Experimental data measured at 10 K is displayed in purple. c) The band resolved optical conductivity. All transitions starting from the colour-indexed band are summed up. The band indexing follows the convention introduced in Fig. 1. For detailed decomposition see Fig. S4.

From the experimental $\sigma_{xx}$ spectrum, we estimate the Drude scattering rate to $\sim 25$ meV. Since this is far below the cutoff-energy of the MOKE-experiment, we can attribute the measured off-diagonal conductivity $\sigma_{xy}$ solely to interband transitions, thus it exclusively represents intrinsic contributions to the static AHE. The temperature independent intrinsic AHE is around $160 \, \Omega^{-1} \, \text{cm}^{-1}$ with slight sample dependence according to Ref. 5, which coincides with the real part of the $\sigma_{xy}$ spectra at the low-energy cutoff. We note that the 300 K spectrum is slightly split off, which may be caused by uncertainties in the MOKE-parameters and an increased scattering rate for the higher temperatures. Since the imaginary part of $\sigma_{xy}$ consists of the sum of delta-peaks weighted by the transition matrix elements, we analyze the excitations in this part of the complex response. The two dominant features are a sharp dip at 0.25 eV and a broad hump around 0.9 eV (Fig. 3c). Because of the Kramers-Kronig-relation, these contribute to the real part by dispersive lineshapes. Correspondingly, the broad hump at 0.9 eV increases the real part of the Hall response to about $350 \, \Omega^{-1} \, \text{cm}^{-1}$ at 0.4 eV, which decreases toward low energies. In contrast, the transitions responsible for the step edge in the diagonal conductivity cause the dip feature in the imaginary part of $\sigma_{xy}$ at 0.25 eV, thus, significantly reduce the static Hall response. Therefore the set of bands in the vicinity of the H’-K-H”-line responsible for the step-edge reduce the AHE induced by the higher energy transitions related to a combined response of the bandstructure contributions from the entire the Brillouin zone.

In summary, our complementary magneto-optical and theoretical investigation of the low-energy excitations allowed us to determine the origin of the AHE in Fe$_3$Sn$_2$. We identified two spectral features: a step edge at 0.25 eV and a broad...
hump around 0.9 eV dominating the optical response as well as the static AHE. The k-resolved calculation shows that the transitions responsible for the step edge are located in the vicinity of the K-points, while the band decomposition reveals its multiband nature. For all higher energy features, a broad mixture of interband contributions is expected. We found that the two main features induce intrinsic AHE with opposite signs, i.e. their contributions compete with each other. Finally, we note that our magneto-optical approach is widely applicable for other materials, where the interplay of magnetism and electronic topology leads to a large AHE. Since these bulk measurements are sensitive to the position of the Fermi energy, they are also suitable to evaluate the effect of doping, which can serve as a tool to control the AHE.

SUPPLEMENTARY MATERIAL

Crystal growth

Fe$_3$Sn$_2$ single crystals have been synthesized by the chemical transport reactions method. As starting material, preliminary synthesized polycrystalline powder prepared by solid state reactions from the high-purity elements was used with iodine as transport agent. The growth was performed in quartz ampoules in two-zone furnaces at temperatures between 730 and 680 °C. After 4 – 6 weeks of transport, the plate-like single-crystalline samples of thickness 20 – 40 µm along the c-axis and 3 – 5 mm within the ab-plane were found in the hot part of ampoule.

Reflectivity measurements

The reflectivity spectra of Fe$_3$Sn$_2$ were obtained by using a Hyperion IR-microscope, equipped with a 15x Cassegrain objective, coupled to a Bruker Vertex 80v FT-IR spectrometer. The spectra at low temperature were measured in the frequency range 120-6000 cm$^{-1}$ (0.01-0.74 eV) from room temperature down to 7 K. A silver film evaporated on half of the measured surface of the Fe$_3$Sn$_2$ single crystal, have been used as a reference and the obtained spectra have been corrected with the reflectivity of the silver later on. Each low temperature spectrum was merged to the NIR-VIS spectrum [6000 to 20000 cm$^{-1}$ (0.74-2.5 eV)] which was measured at room temperature. The optical conductivity $\sigma_1$ was calculated by using Kramers-Kronig analysis. At this point, the low energy of the reflectivity spectrum (0-120 cm$^{-1}$) was extrapolated by using a Drude-Lorentz fitting, while above 2.5 eV the reflectivity spectrum was extrapolated to high energies using x-ray atomic scattering functions [32].

MOKE-spectroscopy

The broadband MOKE spectra were recorded in near-normal incidence and were combined from several measurements in different frequency ranges, employing grating and interferometer based spectrometers as described elsewhere [25, 33, 34]. Small permanent magnets provided a field of 0.3 T at the sample position.

DFT-calculations

We performed these within Density Functional Theory using the Wien2k [35] code. The generalized gradient approximation as parameterized by Perdew-Burke-Ernzerhof was used as exchange-correlation functional. Spin-orbit interaction was introduced in a second variational procedure. 10000 k points were used to sample the full Brillouin zone in the self-consistent calculation. A rmax value of 8 was chosen as cutoff for the plane wave expansion. The optical conductivity was evaluated on a twice as large grid of 20000 k points. The crystal structure was taken from Fenner et al. [20] with the magnetization pointing along the c-axis.
