Spin pumping in noncollinear antiferromagnets

Mike A. Lund, Akshaykumar Salimath, and Kjetil M. D. Hals
Department of Engineering Sciences, University of Agder, 4879 Grimstad, Norway

The ac spin pumping of noncollinear antiferromagnets is theoretically investigated. Starting from an effective action description of the spin system, we derive the Onsager coefficients connecting the spin pumping and spin-transfer torque associated with the dynamics of the SO(3)-valued antiferromagnetic order parameter. Our theory is applied to a kagome antiferromagnet resonantly driven by a uniform external magnetic field. We demonstrate that the reactive (dissipative) spin-transfer torque parameter can be extracted from the pumped ac spin current in-phase (in quadrature) with the driving field. Furthermore, we find that the three spin-wave bands of the kagome AF generate spin currents with mutually orthogonal polarization directions. This offers a unique way of controlling the spin orientation of the pumped spin current by exciting different spin-wave modes.

Over the last years, there has been rapidly growing interest in implementing antiferromagnetic elements in spin-based electronics. This has led to the development of antiferromagnetic spintronics [1–6], in which the information is coded into the magnetic moments of antiferromagnets (AFs) [7]. Unlike ferromagnets, which have been the traditional building blocks of spintronics, the AFs are remarkably stable against magnetic field noise due to their vanishing magnetization. Furthermore, the AFs are characterized by terahertz (THz) spin dynamics, which is a thousand times faster than the characteristic frequency of ferromagnets. The ultrahigh-frequency of AFs is desirable for use in future spin electronics because it allows for significantly higher operational speeds of the devices. Ultrafast switching of AFs has been experimentally demonstrated [5], and recent works have shown that AFs are efficiently manipulatable via electric currents [8–21] as well as optical pulses [22–24].

A cornerstone of spintronics is the ability to manipulate the order parameter of magnetic materials via spin-transfer torques (STTs) – the process where spin currents produce magnetic torques via direct transfer of spin angular momentum from the itinerant electrons to the ordered spin system [25]. The reciprocal process of the STT is spin pumping and refers to the phenomenon where the collective spin excitations of the magnet pump a spin current into adjacent metallic leads [26]. Notably, the linear response coefficients describing the STT and spin pumping are connected via the Onsager reciprocal relations [27–30]. Consequently, one can obtain significant insight into the strength, symmetry, and governing mechanisms of the STT by investigating spin pumping.

In AFs, the spin pumping [20,31] and STT [10,15,17] have been theoretically investigated in several works, and two experiments recently observed sub-THz spin pumping in the uniaxial insulating AFs MnF$_2$ [32] and Cr$_2$O$_3$ [33]. Most of these works have concentrated on collinear AFs, which are antiferromagnetic systems characterized by a single order parameter (commonly known as the staggered field or Néel vector). Typically, the collinear AFs have two magnetic atoms in each unit cell, where the Néel vector parameterizes the spatial orientation of the two antiparallel magnetic moments. However, several AFs consist of more than two magnetic sublattices, requiring two or three mutually orthogonal staggered fields to describe the spin order correctly (Fig. 1) [35]. In this case, the system is referred to as a noncollinear AF (NCAF). The spin order of NCAFs is parameterized by a rotation matrix, which defines the orientation of the reference frame spanned by the orthogonal staggered fields [34,35]. Except for a work on the STT in NCAFs [17], there have been no thorough investigations of spin pumping in these nontrivial spin systems.

FIG. 1: (color online). A NCAF represented by the staggered fields $L_1$, $L_2$, $L_3$ pumps a spin current $I_s$ into a NM.

Because a multiplet of staggered fields define the NCAFs, their current-driven spin dynamics are generally hard to detect. In contrast, a spin current is easily detected via the inverse spin Hall effect (ISHE) [32,33]. Spin pumping may therefore represent an advantageous technique for exploring the STTs of NCAFs. In this work, we derive a general theory of the ac spin pumping in NCAFs. The general formalism is applied to NCAFs with kagome lattice structure. Importantly, we find that both the reactive and dissipative STT parameters can be mapped out from the spin pumping signal measured via the ISHE. Additionally, we show that the three spin-wave bands of the kagome AF produce spin currents with orthogonal spin polarizations, which enables manipulation of the spin current’s orientation by only tuning the fre-
quency of the external driving field. When the driving field hits the resonance frequency of a spin-wave band, a current with a fixed spin polarization is created. This phenomenon differs markedly from spin pumping of ferromagnets and collinear AFs, where a reorientation of the magnetic state is required for changing the polarization.

We consider an NCAF with a volume of $V$ interfaced with a normal metal (NM). To second order in the space-time gradients and external forces (i.e., STTs and magnetic fields), the effective action $S$ of the NCAF is

$$S = \int dV dt \mathcal{L}. \quad (1)$$

The Lagrangian density $\mathcal{L} = T - U - U_s$ of the spin system consists of a kinetic term $T$

$$T = \frac{a_1}{2} \mathbf{V} \cdot \mathbf{m}, \quad (2)$$

the energy $U$ produced by the exchange interaction, the spin-orbit coupling (SOC), and the magnetic field $\sim \mathbf{h}$

$$U = \lambda \sum_{ij} \delta \mathbf{R} \cdot \partial_i \mathbf{R}, \quad \nu_{ij} \mathbf{R}_i \mathbf{R}_k \mathbf{l} + \kappa_{ij} m_i m_j - \mathbf{h} \cdot \mathbf{m}, \quad (3)$$

and a term $U_s$ representing the coupling to the spin accumulation $\mu_s$ of the itinerant quasi-particles that diffuse into the NCAF from the adjacent NM layer

$$U_s = \lambda \mathbf{m} \cdot \mathbf{f}_s. \quad (4)$$

Here, $a_1$ is a constant that depends on the lattice structure, $\mathbf{R}$ is a rotation matrix that describes the orientation of the reference frame spanned by the staggered fields of the NCAF, $V_i = -(1/2)\epsilon_{ijk} [\mathbf{R}^T \partial_j \mathbf{R}]_{ij}$ where $\epsilon_{ijk}$ is the Levi-Civita tensor and $\partial_j \mathbf{R}$, $\mathbf{f}_s = \mu_s / \hbar$, and $\mathbf{m}$ is proportional to the out-of-equilibrium magnetization produced by a relative tilting of the magnetic sublattices. $\partial_i \mathbf{R}$ represents the partial derivatives of the rotation matrix with respect to the spatial coordinates, i.e., $\alpha \in \{x, y, z\}$. For further analysis, it is convenient to split $\kappa_{ij}$ into isotropic and anisotropic terms: $\tilde{\kappa}_{ij} = a_2 \delta_{ij} + \eta_{ij}$ ($\delta_{ij}$ is the Kronecker delta). The coefficients $\lambda_{ij}^\alpha$ and $a_2$ ($\nu_{ij}^L$ and $\eta_{ij}$) are proportional to the isotropic exchange interaction (the anisotropy energy), whereas the constant $\lambda$ parameterizes the strength of the reactive STT induced by the spin accumulation. Throughout, Einstein’s summation convention is implied for repeated indices.

The dissipative processes in the NCAF are determined by the dissipation functional

$$\mathcal{G} = \int dV dt \left[ \frac{\tilde{\alpha}}{8} \text{Tr} \left( \mathbf{R}^T \mathbf{R} \right) + \frac{\tilde{\lambda}}{2} \mathbf{V} \cdot \mathbf{f}_s \right], \quad (5)$$

where $\tilde{\alpha}$ and $\tilde{\lambda}$ determine the damping of the spin system and the dissipative STT, respectively.

We consider small deviations from the uniform equilibrium state of the NCAF. In this case, it is convenient to use a Gibbs vector representation of the SO(3) rotation matrix $\mathbf{R}$. The Gibbs vector $\mathbf{r}$ corresponding to a rotation by an angle of $\theta$ about the axis $\hat{n} = \tan(\theta/2) \hat{n}$, and the action of $\mathbf{R}$ on a general vector $\mathbf{v}$ is

$$\mathbf{R} \mathbf{v} = \mathbf{v} + \frac{2}{1 + |\mathbf{r}|^2} \left[ \mathbf{r} \times \mathbf{v} + \mathbf{v} \times (\mathbf{r} \times \mathbf{v}) \right]. \quad (6)$$

Furthermore, it is possible to represent the partial derivatives $\partial_i \mathbf{R}$ of the rotation matrix in terms of the Gibbs vector via the relationship (here, $\mu \in \{t, x, y, z\}$)

$$\left[ (\partial_i \mathbf{R}) \mathbf{R}^T \right]_{ij} = \epsilon_{ikj} \frac{2}{1 + |\mathbf{r}|^2} \left[ \partial_i \mathbf{r} + \mathbf{r} \times \partial_i \mathbf{r} \right]_k. \quad (7)$$

Note that the identity matrix corresponds to $\mathbf{r} = 0$. Thus, $|\mathbf{r}| \ll 1$ since we consider small deviations from the equilibrium state. Using Eqs. (3)-(7) and keeping terms in Eqs. (2)-(4) up to second order in the out-of-equilibrium quantities $\{\mathbf{r}, \mathbf{m}\}$ and external force fields $\{\mathbf{f}_s, \mathbf{h}\}$, we find the Lagrange density

$$\mathcal{L} = a_1 \mathbf{m} \cdot \dot{\mathbf{r}} - U(\mathbf{r}, \mathbf{m}) - U_s(\mathbf{m}, \mathbf{f}_s). \quad (8)$$

Here, $U_s(\mathbf{m}, \mathbf{f}_s)$ is given by Eq. (4), and the potential $U(\mathbf{r}, \mathbf{m})$ takes the form of

$$U = \Gamma_{ij} \frac{\alpha_2}{2} \partial_i \mathbf{r} \partial_j \mathbf{r} + \kappa_{ij} \mathbf{r}_i \mathbf{r}_j + \tilde{\kappa}_{ij} m_i m_j - \mathbf{h} \cdot \mathbf{m}, \quad (9)$$

where we have introduced the anisotropy tensor $\kappa_{ij} = 2 \epsilon_{ikl} \nu_{il}^L + \nu_{ij}^L$ and the exchange tensor $\Gamma_{ij} = 4\Lambda_{kk} \delta_{ij} - \Lambda_{ij}$. The dissipation $\mathcal{G}$ becomes

$$\mathcal{G} = \int dV dt \left[ \tilde{\alpha} \dot{\mathbf{r}}^2 + \tilde{\lambda} \mathbf{r} \cdot \mathbf{f}_s \right]. \quad (10)$$

Eqs. (8) and (10) provide a general effective description of the NCAF’s dynamics. In absence of external force fields, the Lagrangian (8) is equivalent to the phenomenological theory derived from symmetry arguments in Ref. 35. This can be seen by minimizing the action with respect to $\mathbf{m}$, which yields $\mathbf{m} = (a_1/2a_2)[I + \eta/2a_2]^{-1} \mathbf{r}$ ($I$ is the identity matrix). The norm of the matrix $\eta/2a_2$ is small, because $\eta$ is proportional to the SOC whereas $a_2$ is linear in the strong antiferromagnetic exchange interaction. This implies that $[I + \eta/2a_2]^{-1} \approx [I - \eta/2a_2]$. Substituting the expression for $\mathbf{m}$ back into the Lagrange density leads to

$$\mathcal{L} = \chi_{ij} \dot{r}_i \dot{r}_j - \Gamma_{ij} \frac{\alpha_2}{2} \partial_i r_j \partial_j - \kappa_{ij} r_i r_j, \quad (11)$$

where $\chi_{ij} = (a_1^2/4a_2^2) \partial_i r_j - \eta_{ij}/a_2$. To second order in $\mathbf{r}$, Eq. (11) is identical to the phenomenology developed in Ref. 35. The STT-induced coupling terms in Eqs. (4) and (5) was phenomenologically derived in Ref. 17. Note that Eqs. (8)-(10) also can be microscopically derived from a path integral description of the spin system 34 38. Next, we will use Eqs. (8)-(10) to derive a general expression for the spin pumping in NCAFs. We
consider a spatial uniform driving field \( \mathbf{h}(t) \) such that the spatial variations of \( \mathbf{r} \) and \( \mathbf{m} \) can be disregarded.

Generally, the state of a system can be described by a set of thermodynamic variables \( \{ q_i | i = 1, 2, 3, \ldots \} \). Let \( f_i \) denote the thermodynamic force that induces a flux \( J_i \) in the quantity \( q_i \). In linear response, the fluxes are given by the equation \( J_i = L_{ij} f_j \), where the off-diagonal elements of the response matrix \( \{ L_{ij} \} \) are related via the Onsager reciprocal relations \( L_{ij} = \epsilon_i \epsilon_j L_{ji} \). Here, \( \epsilon_i = 1 \) (\( \epsilon_i = -1 \)) if the thermodynamic variable \( q_i \) is even (odd) under time reversal [27]. NCAF's are described by the variables \( \mathbf{r} \) and \( \mathbf{m} \), which undergo time reversal transform as \( \mathbf{r} \rightarrow -\mathbf{r} \) and \( \mathbf{m} \rightarrow -\mathbf{m} \). The fluxes of the NCAF are \( \dot{\mathbf{r}} \) and \( \dot{\mathbf{m}} \), whereas the associated forces are \( f_r = -V \partial_r U \) and \( f_m = -V \partial_m U \), respectively [28–30].

The spin current \( \mathbf{I}_s \) represents the spin flux of the itinerant quasi-particles and \( \mathbf{f}_s \) is the thermodynamic force inducing this response [28–30]. The Onsager coefficients connecting the fluxes and forces can be derived from the NCAF's equations of motion. From the variational equation \( \delta S/\delta q = \delta G/\delta \dot{q} \) (where \( q \in \{ \mathbf{r}, \mathbf{m} \} \)), we find

\[
\dot{r}_i = L_{rr,i} f_{r,j} + L_{rm,i} f_{m,j} + L_{rs,i} f_{s,j},
\]
\[
\dot{m}_i = L_{mr,i} f_{r,j} + L_{mm,i} f_{m,j} + L_{ms,i} f_{s,j},
\]

where the Onsager coefficients are \( L_{rr,i} = 0 \), \( L_{rm,i} = -\delta_{ij}/a_1 V \), \( L_{rs,i} = 2\delta_{ij}/a_1^2 V \), \( L_{mm,i} = -\sigma_i \delta_{ij}/a_1 \), and \( L_{ms,i} = -\tau_i \delta_{ij}/a_1 \). Here, we have defined \( \tau = (\lambda_1 + 2\alpha_1)/a_1 \). We see that the off-diagonal elements describing the dynamics of the isolated spin system satisfy the expected reciprocity relations \( L_{mr,i} = -L_{rm,j} \). The coefficients \( L_{rr,i} \) and \( L_{mm,i} \) define the STT produced by the spin accumulation. The reciprocal spin pumping process is determined by the equation \( \dot{I}_s = L_{sr,i} f_{r,j} + L_{sm,i} f_{m,j} \). The Onsager reciprocal relations implies that \( L_{sr,i} = -L_{rs,j} \) and \( L_{sm,i} = -L_{ms,j} \), which yields the following spin pumping expression

\[
\dot{I}_s = -\frac{\lambda}{a_1} f_r - \frac{\tau}{a_1} f_m.
\]

Eq. (14) is the first central results of this paper and presents a general theory for the ac spin pumping of NCAF's.

We now apply the general theory to a thin-film (monolayer) NCAF with kagome structure [30] interfaced with a NM along \( z \) (Fig. [2]). Important examples of kagome AFs include Weyl semimetals and iron jarosites [41, 42]. The Hamiltonian of the spin system is [36, 43]

\[
H = J \sum_{\langle ij \rangle} \mathbf{S}_i \cdot \mathbf{S}_j + \sum_i \left[ K_z \left( \mathbf{S}_i \cdot \mathbf{e}^{(z)} \right)^2 - K \left( \mathbf{S}_i \cdot \mathbf{n}_i \right)^2 \right].
\]

Here, the first term represents the nearest-neighbor exchange interaction \( J > 0 \), whereas the last term is the anisotropy energy with \( K_z > 0 \) and \( K > 0 \). \( \mathbf{e}^{(z)} \) is the unit vector along \( z \). Note that the three magnetic sublattices of the kagome AF experience different in-plane easy axes defined by \( \mathbf{n}_1 = [0, 1, 0], \mathbf{n}_2 = [\sqrt{3}/2, -1/2, 0] \), and \( \mathbf{n}_3 = [-\sqrt{3}/2, -1/2, 0] \). Consequently, the ground state of the kagome AF is given by a 120° ordering of the sublattice spins such that \( \mathbf{S}_1 = \pm \mathbf{n}_1 \) (or \( \mathbf{S}_2 = -\mathbf{n}_1 \)).

Following Ref. [33], the Lagrange density \( S \) of the above spin Hamiltonian can be microscopically derived [34]. For the constants in Eq. (5), we find that \( a_1 = 24hS/\sqrt{3}a^2 \) and \( a_2 = 36S^2J/\sqrt{3}a \), where \( a \) is the lattice constant. The exchange energy tensor has the non-vanishing tensor elements \( \Gamma_{xy} = \Gamma_{yx} = \Gamma_{zz} = \Gamma_{yy} = 4\sqrt{3}JS^2/a \) and \( \Gamma_{xz} = \Gamma_{zx} = -4\sqrt{3}JS^2/a \), whereas for the second rank tensors we find \( \kappa_{xx} = \kappa_{yy} = K_1 \), \( \kappa_{zz} = K_2 \), \( \kappa_{xz} = \kappa_{yz} = a_2 \), and \( \kappa_{zx} = a_2 + 4\sqrt{3}K_2S^2/a \). Here, we have introduced the anisotropy constants \( K_1 = 8\sqrt{3}(K_z + K)S^2/a^2 \) and \( K_2 = 16\sqrt{3}KS^2/a^3 \). Eq. (11) implies that the anisotropic part of \( \mathbf{n}_i \) yields a correction on the order of \( \sim K_z/J \) to the spin dynamics. In AFs, the exchange energy is typically much larger than the anisotropy energy. In what follows, we therefore disregard the anisotropic part and assume \( \kappa_{ij} = a_2 \delta_{ij} \).

The thermodynamic forces in the spin pumping expression (14) are \( f_r(t) = -2V\mathbf{K} \cdot \mathbf{r}(t) \) and \( f_m = -2a_2 V \mathbf{h}(t) \). Here, \( \mathbf{K} \) is a diagonal ma-
and antisymmetric functions of $\delta\omega$ derive at an expression for the pumped spin current \[44\]. Importantly, we notice that the spin current reduces to second central results of this Letter and provides a theory \[\Delta\]

where $A^{(i)} = 4\Gamma(e^{(i)} \cdot \mathbf{K} \cdot e^{(i)})a_2/a_1\omega_0^{(i)} (e^{(i)}$ are the three unit vectors along the $x$, $y$, and $z$ axes, respectively), $\Gamma = 1/2a_1\Delta \omega$ with $\Delta \omega = 2a_2a_1/a_2^2$, and $\omega_0^{(x)} = \omega_0^{(y)} = \sqrt{4K_1a_2/a_1^2}$, $\omega_0^{(z)} = \sqrt{4K_2a_2/a_1^2}$ are the resonance frequencies for the three spin wave bands of the kagome AF (i.e., the frequencies of the $k = 0$ spin waves). $L^{(i)}(\omega) = (\Delta \omega)^2/((\Delta \omega)^2 + (\omega_0)^2)$ and $L_n^{(i)}(\omega) = \delta\omega^{(i)}\Delta \omega/((\delta\omega^{(i)})^2 + (\Delta \omega)^2)$ are symmetric and antisymmetric functions of $\delta\omega^{(i)} = \omega - \omega_0^{(i)}$, respectively. In arriving at the above expressions, we have expanded around the resonance frequencies and assumed $\Delta \omega/\omega_0^{(i)} \ll 1$. Substituting the above stationary solutions into the thermodynamic forces in Eq. \[14\], we arrive at an expression for the pumped spin current \[14\].

Here, the frequency-dependent functions are $g_1^{(i)}(\omega) = VA^{(i)}[\tau L^{(i)}(\omega)/a_1 - \lambda\omega_0^{(i)}L_n^{(i)}(\omega)/2a_2]$ and $g_2^{(i)}(\omega) = VA^{(i)}[\lambda\omega_0^{(i)}L_n^{(i)}(\omega)/2a_2 + \tau a_2^{(i)}(\omega)/a_1]$. Eq. \[15\] is the second central results of this Letter and provides a theory for the spin pumping of NCAFs with kagome structure. Importantly, we notice that the spin current reduces to $I_{s,i} = VA^{(i)}h_{0,i}[\tau \sin(\omega_0^{(i)}t)/a_1 - \lambda\omega_0^{(i)} \cos(\omega_0^{(i)}t)/2a_2]$ at the resonance frequencies $\omega_0^{(i)}$ where $L^{(i)} = 1$ and $L_n^{(i)} = 0$. This implies that the reactive (dissipative) STT parameter can be extracted from the in-phase (quadrature) component of $I_s$ with respect to the driving field. By applying the driving field along $e^{(i)}$, the spin current peaks at the resonance frequency $\omega_0^{(i)}$. The induced current then only contains contributions from one of the three spin wave bands -- the $k = 0$ spin wave with a frequency of $\omega_0^{(i)}$. Interestingly, this makes it very easy to change the polarization direction of the pumped spin current since the different spin wave bands lead to different polarizations (Fig. 2). Specifically, a driving field $h = h_0e^{(i)}\cos(\omega_0^{(i)}t)$ generates a spin current with a spin polarization along $e^{(i)}$. This is very different from the situation in ferromagnets and collinear AFs, where the entire magnetic state must be rotated for changing the polarization direction of the pumped spin current.

A common way to detect spin pumping is to interface the magnet with an NM having a large spin Hall angle. The spin current injected into the normal NM-layer generates a transverse charge current due to the ISHE, which produces a measurable Hall voltage \[45–47\]. We assume the NM-layer to be a heavy metal with strong SOC such that the backflow of spin into the magnetic layer can be neglected. Further, we consider the thickness $t_{NM}$ of the NM to be much larger than the spin diffusion length $\lambda_s$ so that the spin current vanishes completely at the outer edge where $z = t_{NM}$. An external magnetic field $h = h_0\cos(\omega t)$ is used to excite the magnet. A spin current $I_s$ (given by Eq. \[18\]) is then pumped into the normal metal. The spin current density $j_s$ through the NM layer is found by solving the spin-diffusion equation $\partial_t\rho_s = D\partial_z^2\rho_s - \rho_s/\tau_s$ with the boundary condition $\partial_x\rho_s(0,t) = I_s/A$ at the NCAF/NM interface and $\partial_x\rho_s(t_{NM},t) = 0$ at the outer edge. Here, $\rho_s$ is the spin density in the normal metal, $D$ is the electron diffusion constant, $\tau_s$ is the spin-flip time, and $A$ is the cross section area of the NCAF/NM interface. The spin current density is found from the solution of the spin density via the relationship $j_s = -D\partial_z\rho_s$, which yields \[16\] $j_s(z,t) = -(I_s/A)\sin((z-t_{NM})/\lambda_s)/\sinh(t_{NM}/\lambda_s)$ (here, $\lambda_s = \sqrt{D/\tau_s}$). The charge current density generated by ISHE is \[16–17\] $j^{ISHE}_s = \gamma_H 2e/\hbar (|e|\times j_s)$, where $\gamma_H$ is the spin Hall angle. The system constitutes an open circuit. Thus, the deflected charges accumulate at the interfaces, which induce an electric field that exactly cancel $j^{ISHE}_s$. Integrating the net current density over the metallic layer, one finds the electric field \[16\].

$E_{ISHE} = -2e\gamma_H \lambda_s \frac{h_0s_{NM}}{2\sigma_{NM}} \tan \left( \frac{t_{NM}}{2\lambda_s} \right) (|e|\times j_s) \hat{e}_z$, \[19\]

where $\sigma_{NM}$ is the conductance of the NM-layer. We have here disregarded any electric currents in the kagome AF layer because it is a thin film. $E_{ISHE}$ is proportional to the spin current. Thus, the reactive (dissipative) STT can be determined from the in-phase (quadrature) component of the electric signal with respect to $h(t)$.

In conclusion, we have derived a general theory for spin pumping in NCAFs and applied the formalism to NCAFs with kagome lattice. Our findings reveal that spin pumping represents a powerful mechanism for exploring both the reactive and dissipative STTs of NCAFs. We show that the reactive (dissipative) part of the STT is proportional to the in-phase (quadrature) component of the pumped spin current at resonance. Additionally, we find that the three spin-wave bands of the kagome AF lead to currents with spin polarizations along the $x$, $y$, and $z$ axis, respectively. This makes it possible to orient the spin current along any axis by exciting different spin-wave modes. Thus, our work demonstrates that the spin pumping of NCAFs is richer and more complex than in ferromagnets and collinear AFs, and opens the door for tuning the spin current’s orientation through the frequency of $h$.\[4\]
This work received funding from the Research Council of Norway via the Young Research Talents Grant No. 286889 "Antiferromagnetic Spinmechatronics".

[38] Note that Eqs. (17) and (18) also contain a term according to a two-dimensional irreducible representation \{D_{ij}(R)|R \in G\} of the system’s point group \(G\) (see Ref. [22] for details): \(L_1 = D_{ij}L_2\). In this case, the rotation matrix in Eq. [1] defines the orientation of the reference frame spanned by \(\{L_1, L_2, L_1 \times L_2\}\).
[39] We assume the kagome AF to be a monolayer with a thicknesses of \(L_2 \sim a\).
[43] Note that Eqs. [17] and [18] also contain a term \(h_0 \cos(\omega t)\), which does not depend on the functions \(L^{(i)}_1\) and \(L^{(i)}_2\). However, close to the resonance frequencies this term is negligible.
