(Dated: July 16, 2021)

We investigate the high-temperature dynamical conductivity \( \sigma(\omega) \) in two one-dimensional integrable quantum lattice models: the anisotropic XXZ spin chain and the Hubbard chain. The emphasis is on the metallic regime of both models, where besides the ballistic component, the regular part of conductivity might reveal a diffusive-like transport. To resolve the low-frequency dynamics, we upgrade the microcanonical Lanczos method enabling studies of finite-size systems with up to \( L \leq 32 \) sites for XXZ spin model with the frequency resolution \( \delta \omega \sim 10^{-3}J \). Results for the XXZ chain reveal a fine structure of \( \sigma(\omega) \) spectra, which originates from the discontinuous variation of the stiffness, previously found at commensurate values of the anisotropy parameter \( \Delta \). Still, we do not find a clear evidence for a diffusive component, at least not for commensurate values of \( \Delta \), particularly for \( \Delta = 0.5 \), as well as for \( \Delta \to 0 \). Similar is the conclusion for the Hubbard model away from half-filling, where the spectra reveal more universal behavior.

I. INTRODUCTION

One of the basic features of the integrable quantum many-body lattice is the possibility of the ballistic/dissipationless transport at finite temperatures (for a recent review see [1]). This property, which is manifested in a finite value of corresponding transport stiffnesses \( D > 0 \), has been well established in the most investigated one-dimensional (1D) integrable model, the anisotropic XXZ spin chain within the easy-plane regime with the anisotropy \( \Delta < 1 \), but also in the 1D Hubbard model away from half-filling. Finite stiffness \( D > 0 \) has been resolved via the sensitivity of levels to the imposed magnetic flux [2], using the thermodynamic Bethe Ansatz (TBA) [3–6], and with more rigorous bounds via the Mazur inequality [7] which relate \( D \) to the overlap with local and quasilocal conserved quantities [8–11]. The latter result agrees also with a more general approach via the generalized Hydrodynamics (GHD) [12–14]. Furthermore, results for \( D > 0 \) and ballistic transport have been confirmed in numerous numerical studies of finite XXZ chains [15–26]. In spite of these advances there remains an open question whether analytical theories also quantitatively fix values of \( D \), in particular its dependence on the anisotropy \( \Delta \) within the XXZ chain in the high-\( T \) regime [9, 14, 23, 25, 27–29] (see the discussion in [1]).

Much less attention has been devoted to the whole dynamical response, as represented by the real part of the frequency-dependent conductivity at \( T > 0 \),

\[
\sigma(\omega) = 2\pi D \delta(\omega) + \sigma_{\text{reg}}(\omega),
\]

which can be (in a metallic regime of considered models) decomposed into the ballistic \( D > 0 \) component and the regular (incoherent) part \( \sigma_{\text{reg}}(\omega) \). Exact-diagonalization (ED) results on finite-size XXZ chains [15, 22], as well as on the particular case of the Hubbard chain [16], indicate on vanishing (dc) limit, \( \sigma^0_{\text{reg}} = \sigma_{\text{reg}}(\omega \to 0) \to 0 \), consistent with the argument based on the level crossing in integrable lattice models [30] implying \( \sigma_{\text{reg}}(\omega \to 0) \propto \omega^2 \), at least for finite-size systems. Less conclusive are results obtained via time-dependent density-matrix renormalization group (tDMRG) method on larger system but with restricted time evolution (or equivalently with limited frequency resolution), allowing for \( \sigma^0_{\text{reg}} > 0 \) [25, 26]. The latter can be interpreted as coexistence of ballistic transport and (subleading) diffusion response. This question is challenging since some analytical approaches [31, 32], and in particular more recently the GHD approach [33–37], generally predict besides \( D > 0 \) also \( \sigma^0_{\text{reg}} > 0 \). I.e., within the XXZ chain the GHD yields finite values of \( \sigma^0_{\text{reg}} > 0 \) at the commensurate values \( \Delta_m = \cos(\pi/m) \) and, moreover, singular \( \sigma_{\text{reg}}(\omega \to 0) \propto \omega^{-\alpha}, \quad \alpha > 0 \) [36, 37] behavior.

To comment on the dynamical transport \( \sigma(\omega) \), at least from the perspective of the linear response in finite-size systems with periodic boundary conditions (PBC), we perform the numerical calculation of high-\( T \) limit of \( \delta(\omega) = T\sigma(\omega) \) in XXZ chain, scanning the whole range of anisotropies \( \Delta < 1 \), but also in the Hubbard chain away from half-filling. Note that both models exhibit the finite stiffness \( D = TD > 0 \) for the considered model parameters. To resolve the low-\( \omega \) regime, we employ, besides ED for smaller systems, the upgraded microcanonical Lanczos method (MCLM) [38] with the high-\( \omega \) resolution, i.e., for the XXZ chain of length \( L \leq 32 \) we reach \( \delta \omega \sim 10^{-3}J \) (equivalent to time evolution up to \( \tau \sim 5.10^3/J \)). Such a resolution allows to disentangle, according to Eq. (1), well enough the dissipationless part from the low-\( \omega \) \( \sigma_{\text{reg}}(\omega) \).

In Fig. 1 we present one of the main results of our findings (in more detail discussed in Sec. II C), i.e., changing the value of anisotropy \( \Delta \) reveal a quite complicated fine-structure of \( \sigma_{\text{reg}}(\omega) \) spectra, here presented as the result of full ED for \( L = 20 \) system, as well as for \( L = 32 \) chain evaluated with MCLM. The structure can be traced back to discontinuities (or at least anomalies) of \( D \) found at commensurate \( \Delta = \Delta_m \) [1] (even in finite systems). The spectral weight related with the discontinuities, \( D(\Delta_m) - \lim_{\Delta \to \Delta_m} D(\Delta) \), is transferred to low-frequency peaks of \( \sigma_{\text{reg}}(\omega) \) centered at \( \omega_{\pi} \propto |\Delta - \Delta_m| \). Still, we do not find a clear evidence (or at least very small
We focus on the metallic regime with the anisotropy parameter on a chain with length $L$ with $\tilde{\alpha} \sim L$ calculated by (a) ED for $L = 20$ sites and (b) MCLM for $L = 32$ sites. Each consecutive curve is given an offset for better visibility. (c) and (d) show heatmaps of results from (a) and (b), respectively. For clarity, the latter results are normalized by maximum of $\sigma_{\text{reg}}(\omega)$. Guidelines on both panels mark the positions of the low-frequency peaks obtained for $L = 20$.

upper bound) for $\bar{\sigma}_\text{reg}^0$ at commensurate $\Delta_m = \cos(\pi/m)$, in particular for $\Delta = \Delta_3 = 0.5$. In order to identify the positions of peaks at $\omega_p$, Fig. 1(c,d) we plot $\sigma_{\text{reg}}(\omega)/\sigma_{\text{max}}$, where $\sigma_{\text{max}}$ is the maximum of $\sigma_{\text{reg}}(\omega)$. The lines mark the positions of $\omega_p$ determined from $L = 20$ ED data, Fig. 1(c), and are put also on top of $L = 32$ MCLM data, Fig. 1(d). Here, the main message is that generally $\omega_p$ weakly depend on $L$, whereby the exception are the regime of $\Delta \to 1$, but also at $0.1 < \Delta < 0.5$ where we notice possibly significant reduction of $\omega_p$ with $L$. In order to properly resolve the latter regime $\Delta \to 0$, we apply also the degenerate-perturbation-theory (DPT) method [29]. Results confirm a pronounced peak in $\sigma_{\text{reg}}(\omega)$ with $\omega_p \propto \Delta$ and $\sigma_{\text{reg}}(\omega \ll \omega_p) \sim \omega^2$. Furthermore, results for the 1D Hubbard model obtained at generic quarter-filling, $n = 1/2$, also reveal - besides more universal structure of dynamical charge conductivity $\tilde{\sigma}_c(\omega)$ - no clear indication for finite diffusion component $\tilde{\sigma}_c^0$.

II. SPIN CONDUCTIVITY IN THE XXZ CHAIN

We consider in more detail 1D anisotropic XXZ spin model,

$$H = \frac{J}{2} \sum_i (e^{i\phi} S_{i+1}^+ S_i^- + \text{H.c.}) + J \Delta \sum_i S_{i+1}^z S_i^z,$$

(2)
on a chain with length $L$ and with generalized PBC. Here, $S_i^\alpha$ with $\alpha = +, -, z$ represent the standard $S = 1/2$ operators. We focus on the metallic regime with the anisotropy parameter $0 < \Delta \leq 1$, revealing the $T > 0$ dissipationless transport with $D > 0$. We further on evaluate only canonical systems with zero magnetization, i.e., $S^z_{\text{tot}} = 0$. At fixed $L$ and at PBC, the results might depend on the phase shift $\phi$. Since in the following we numerically study systems $L = 4L$, i.e., $L = 16, 20, \ldots, 32$, we choose $\phi = \pi/L$ (equivalent to anti-PBC) in order to stay consistent with our previous studies of the fermionic version of the model, i.e., the $t$-$V$ model [15, 29]. Note that considered systems have at $S^z_{\text{tot}} = 0$ even number of fermions. We further on use $\hbar = k_B = 1$ as well as fix $J = 1$ as the unit of energy.

We concentrate on high-$T$ dynamical spin conductivity $\tilde{\sigma}(\omega) = T \sigma(\omega)$, within the linear response theory for $T \gg J$ given by

$$\tilde{\sigma}(\omega) = \frac{\pi}{LN_{\text{st}}} \sum_{n,m} |\langle n| j|m \rangle|^2 \delta(\omega - \epsilon_m + \epsilon_n),$$

(3)
expressed here in terms of many-body (MB) eigenstates $|n\rangle$ and eigenvalues $\epsilon_n$, with the spin current $j = (J/2) \sum_i (i e^{i\phi} S_{i+1}^+ S_i^- + \text{H.c.})$, and $N_{\text{st}}$ as the total number of MB states for given $L$ and $S^z_{\text{tot}}$. Besides $S^z_{\text{tot}} = 0$ we use also translational symmetry of the model, (2), so that calculation of Eq. (3) is performed as the sum over wavevector-$q$ sectors.

A. Numerical method

For smaller systems $L \leq 20$ (for the XXZ model) we evaluate Eq. (3) directly via the full ED finding all $|n\rangle, \epsilon_n$. For
larger $L$ we employ the MCLM [38, 39], used in several studies of dynamical transport in (mostly disordered) spin systems [40]. Since the aim in the present problem is to achieve besides large $L$ (with the Hilbert space up to $N_{st} \sim 10^{6}$) also well resolved spectra at $\omega \sim 0$, we upgrade MCLM by enabling very high frequency resolution $\delta \omega \sim 10^{-3} J$. The calculation steps are the following: (a) The sum over eigenstates in Eq. (3) is replaced with the microcanonical state $|\Psi_\varepsilon\rangle$ corresponding to the energy $E$. The latter is obtained with $M_L \gg 1$ Lanczos steps using the operator $V = (H - \varepsilon)^2$. For larger systems, such procedure is not expected to converge to exact eigenvalues of $H$, but rather to wavefunction with a small energy dispersion $\sigma_\varepsilon^2 = \langle \Psi_\varepsilon | V | \Psi_\varepsilon \rangle$. By performing Lanczos procedure twice and by extracting lowest eigenfunction only, we avoid the full diagonalization of $M_L \times M_L$ matrix. (b) In the second step $\tilde{\sigma}(\omega)$ is evaluated as the resolvent

$$\tilde{\sigma}(\omega) = \frac{1}{L} \text{Im} \langle \Psi_\varepsilon | \frac{i}{\omega + i\gamma + \varepsilon - H} | \Psi_\varepsilon \rangle,$$

(4)
evaluated again with $M_L$ Lanczos steps starting with initial wavefunction $|\Psi_\varepsilon\rangle$. Finally, Eq. (4) is expressed in terms of continued fractions and is evaluated for small $\eta$. $M_L$ determines the frequency resolution as $\delta \omega \sim \Delta E / M_L$, where $\Delta E$ is the energy span of $H$ for fixed $L$. Since for given $M_L$ we have $\sigma_\varepsilon < \delta \omega \sim \eta$, one can directly choose desired $\delta \omega$ by increasing $M_L$, even well beyond $M_L \sim 10^4$. To reduce statistical error, we use besides translational symmetry (with $M_q = L$ different $q$) also additional sampling over $M_s \geq 1$ targeted energies $E_{qs}$ with a Gaussian distribution corresponding to high-$T$ value of $\langle H^2 \rangle \sim L/8$ for given $L$. The final result is the average $\tilde{\sigma}(\omega) = 1/(M_q M_s) \sum_{qs} \tilde{\sigma}(E_{qs}, \omega)$.

In the present application to XXZ chain, we choose $M_L = 2 \times 10^4$, $M_s = 4$ for $L = 28$ system and $M_L = 10^4$, $M_s = 1$ for $L = 32$ chain which has $N_{st} \sim 2 \times 10^7$ in given symmetry sector with fixed $q$ and $S_{tot}^z$. It is worth noting that that our method is quite related to dynamical-quantum-typicality (DQT) approach to time-dependent correlation functions at $T \gg 0$ [24]. The latter method employs the evolution in the time domain, whereby our results would imply reaching times up to $\tau \sim 2\pi / \delta \omega > 5 \times 10^3 / J$ for considered systems.

To capture $\tilde{\sigma}(\omega)$ spectra including the singular $D > 0$ component, it is convenient to present the integrated intensity $I(\omega) = \int_0^\omega \sigma(\omega')d\omega'$. Here we note that $I(\omega \to 0) = 2D$, while the sum rule at $S_{tot}^z = 0$ gives $I_{\infty} = I(\omega \to \infty) = \langle j^2 \rangle / L = (1/8)(1 + 1/(L - 1))$ including small $1/L$ correction. To reveal the feasibility of the MCLM, in Fig. 2 we present the renormalized $\tilde{I}(\omega) = I(\omega) / I_{\infty}$ as obtained for different sizes $L = 16 - 32$ (whereby $L = 16, 20$ results are obtained via full ED) for three characteristic $\Delta = 2, 0, 6, 1.0$. Results are presented in log-$\omega$ scale in order to amplify the low-$\omega$ regime at $\omega > 2.10^{-3}$, beyond the $D > 0$ contribution (in MCLM smeared within $\omega < \delta \omega$). Presented results reveal quite small $\tilde{\sigma}_{\text{reg}}(\omega)$ at low-$\omega < 0.02$ for presented $\Delta \lesssim 0.6$ and for all $L$. Still, $\omega$-dependence is quite pronounced in the intermediate frequency regime, depending crucially on $\Delta$. On the other hand, on approaching the isotropic case $\Delta \to 1$, the results on Fig. 2 confirm pronounced $L$ dependence of the dissipationless component $I(\omega \to 0) = 2D$. The latter is expected to vanish for $L \to \infty$ [41] for $\Delta = 1$ while the regular part should approach the superdiffusive transport [34, 42–45].

**B. Commensurate anisotropies $\Delta_m$**

Let us first focus on results for the commensurate values of the anisotropy $\Delta_m = \cos(\pi / m)$ and on the possibility of the coexistence of ballistic component $D > 0$ and finite diffusion, i.e., $\tilde{\sigma}_{\text{reg}} > 0$. Since $L$ dependence might be important, in Fig. 3 we present results obtained for different $L = 20 - 32$ for two specific commensurate points $m = 3 (\Delta_3 \approx 0.5)$ and $m = 4 (\Delta_4 = 1/\sqrt{2} \approx 0.707)$. The most clear case appears to be $\Delta = 0.5$, where taking into account finite smearing due to $\delta \omega$, it is hard to claim finite $\tilde{\sigma}_{\text{reg}} > 0$. Still, the gap $\omega_g \sim 0.08$ reveals some $L$ dependence, which could be possibly made compatible even with its vanishing in the $\rightarrow \infty$ as $\omega_g \propto 1/L^\gamma$ with $\gamma \leq 1$. At least, we can put some upper bound as $\tilde{\sigma}_{\text{reg}} < 0.1$, which can be compared with the value $\tilde{\sigma}_{\text{reg}} \approx 0.0685$ obtained by the GHD approach [33, 36]. On Fig. 3(a) we plot also the result obtained with tDMRG on much bigger system [25], but with a restricted time span $\tau < 35/L$. The agreement for larger $\omega > 0.1$ is quite satisfactory indicating less relevant $L$ dependence in this regime. On the other hand, the deviation for $\omega < 0.1$ is not surprising (since (referring to the authors of [25]) the spectra for $\omega < 0.15$ are beyond the reach of their study).

Our results for $\Delta_4$ are somewhat less conclusive due to quite pronounced low-$\omega$ peak at $\omega \sim 0.1$ which, however, does not shift significantly with $L$ (in contrast to the case $\Delta \to 1$ as presented in Fig. 2). We should also point out that when speculating on possible closing of the of the spectral gap in Fig. 3(a) or Fig. 3(b) for both $\Delta_m$ with $L \to \infty$, this should be done by keeping moments $\mu_\gamma = \int_0^\infty \omega^\gamma \tilde{\sigma}(\omega) d\omega$ unchanged, since they are correctly reproduced in finite systems (as well as in MCLM) up to high order $n = L$. In any case, our results for $m = 4$ should be compared with the GHD result $\tilde{\sigma}_{\text{reg}} \approx 0.14$ [33, 36].

![Figure 2. Integrated and normalized dynamical spin conductivity $\tilde{I}(\omega) = I(\omega) / I_{\infty}$ in a log-$\omega$ scale within the XXZ spin chain for selected $\Delta = 0.2, 0.6, 1.0$, as calculated for different sizes, i.e., $L = 16, 20$ using full ED, and $L = 24, 28, 32$ using MCLM.](image-url)
that for result \cite{1, 9, 37}. For \( \Delta \) significantly above the one representing the lower-bound/GHD \( \tilde{\sigma} \), the apparent for \( \Delta \) is in the dissipationless component \( \mathcal{D} > 0 \). Nevertheless, the structure of peaks consistent with Fig. 1(a) is still visible in Fig. 1(b).

In the intermediate regime \( 0.2 \leq \Delta < 0.5 \) the structure evolves into two peaks, i.e., the upper part still with \( \omega_{p1} \propto \Delta \) retaining most of the sum rule of \( \sigma_{\text{reg}}(\omega) \), while the lower peak \( \omega_{p2} \) splits off and is expected to vanish at commensurate \( \Delta_3 = 0.5 \) as \( \omega_{p2} \propto |\Delta_3 - \Delta| \). Such evolution is consistent with the specific behavior at commensurate points, \( \Delta_m = \cos(\pi/m) \) \cite{3, 8, 9}, where also additional degeneracies (diagonal as well as off-diagonal in \( S_{\text{tot}} \)) exist. The latter macroscopic degeneracies of the energy spectrum should coincide with discontinuous variation (jumps) of the stiffness \( \mathcal{D} \) at these particular values \( \Delta = \Delta_m \). At the same time, the frequency moments \( \mu_n \) (up to large \( n \sim L \)), are continuous functions of \( \Delta \) even close to commensurate values. The simplest scenario which may capture both features is that the missing spectral weight, \( \mathcal{D}(\Delta_m) - \lim_{\Delta \to \Delta_m} \mathcal{D}(\Delta) \), is transferred to narrow low-frequency peaks centered at frequencies \( \omega_{p_{mn}} \propto |\Delta_{n+1} - \Delta_m| \) with \( \zeta \sim 1 \). In particular, we can confirm such a scenario by our detailed numerical analysis (ED for \( L = 20 \)) for the vicinity of \( \Delta_4 = 1/\sqrt{2} \), as presented in Fig. 5(a). It clearly shows the emergence of symmetric peaks at \( \Delta \sim \Delta_4 \). In this sense the situation is qualitatively similar (but much less pronounced) as the case of \( \Delta = \Delta_2 = 0 \) presented in Fig. 5(b), with a single peak at \( \omega \propto \Delta \) \cite{29} (see also discussion in Sec. II D). It should be however, noted that in a finite system, one can follow a jump in \( \mathcal{D} \) and related emergence of peaks in \( \sigma_{\text{reg}}(\omega) \) only provided that the particular MB states at given \( L \) and \( S_{\text{tot}} \) display a large degeneracy at commensurate \( \Delta_m \). This is indeed the case for \( \Delta_3 \) and \( \Delta_4 \) assuming the considered here finite systems \( L = 4L \). On the other hand, at \( \Delta_3 = 0.5 \) our systems do not reveal explicit (large) degeneracy, so the above phenomena cannot be followed in the very vicinity of \( \Delta_4 \) but they become more evident with the increasing system size, as in Figs. 1(b) and (d) for \( L = 32 \).

Above scenario should imply also for \( \Delta > \Delta_3 = 0.707 \) further peaks emerging and leading to quite complex low-\( \omega \)

\[ \text{Figure 3. Spin conductivity } \tilde{\sigma}(\omega) \text{ obtained for different } L = 20-32 \text{ for two commensurate } \Delta = \cos(\pi/m): (a) } m = 3 \text{ (} \Delta = 0.5\text{), where the dotted line is the result of tDMRG } [25], \text{ and (b): } m = 4, \Delta = 1/\sqrt{2} \approx 0.707. \]

\[ \text{C. General structure of } \tilde{\sigma}(\omega) \]

To discuss the structure of \( \tilde{\sigma}(\omega) \) in the whole range \( \Delta < 1 \), we first present in Fig. 4 the evolution of \( I(\omega) \) with \( \Delta \) as obtained via MCLM on \( L = 32 \) system with the resolution \( \delta \omega \sim 10^{-3} \). The advantage of \( I(\omega) \) is that it yields direct information on the stiffness \( 2\mathcal{D} = I(\omega \to 0) \) discussed before \cite{1, 29}. Results indicate that in the regime \( \Delta \leq 0.5 \) the major part of the \( I(\omega) \) response is in the dissipationless component \( \mathcal{D} \). Moreover, our results for \( \mathcal{D} \) are in this regime quantitatively consistent with previous DQPT analysis \cite{23, 24} and with the DPT method for \( \Delta \to 0 \) \cite{29}, which both yield a value significantly above the one representing the lower-bound/GHD result \cite{1, 9, 37}. For \( \Delta > 0.5 \) the major part in \( I(\omega) \) is in the regular response and the mismatch with GHD lower bound is less evident. It follows from Fig. 2 that ED/MCLM results for \( \Delta \to 1 \) exhibit considerable \( L \) dependence showing up in the apparent \( \mathcal{D} > 0 \), but also in closing of the finite-size gap (being \( \omega_g \sim 0.05 \) for \( L = 32 \)). It is, however, well visible that for \( \omega > \omega_g \) at \( \Delta = 1 \) the spectra in Fig. 4 can be well fitted with \( I(\omega) \propto \omega^{2/3} \) implying the superdiffusive response \( \tilde{\sigma}(\omega) \propto \omega^{-1/3} \) \cite{34, 36, 37, 42–45}.

Beyond dissipationless \( \mathcal{D} > 0 \) component, \( I(\omega) \) in Fig. 4 reveals quite complex evolution of \( \sigma_{\text{reg}}(\omega) \) with \( \Delta \), in particular for \( \Delta > 0.2 \) there are visible more than one inflexion points with \( d^2I(\omega)/d\omega^2 = 0 \) corresponding to peaks in \( \tilde{\sigma}_{\text{reg}}(\omega) \). Moreover, a direct information on \( \tilde{\sigma}_{\text{reg}}(\omega) \) is presented in Fig. 1 (obtained on \( L = 20 \) via ED and \( L = 32 \) via MCLM). Note that in the latter case, at \( \omega < \delta \omega \sim 10^{-3} \), the spectra are dominated by the singular (but broadened) dissipationless component \( \mathcal{D} > 0 \). Nevertheless, the structure of peaks consistent with Fig. 1(a) is still visible in Fig. 1(b). As discussed recently \cite{29}, at small \( \Delta < 0.2 \) a single peak at \( \omega_p \propto \Delta \) dominates \( \sigma_{\text{reg}}(\omega) \) and is analyzed in Sec. II D in more detail.

In the intermediate regime \( 0.2 \leq \Delta < 0.5 \) the structure evolves into two peaks, i.e., the upper part still with \( \omega_{p1} \propto \Delta \) retaining most of the sum rule of \( \sigma_{\text{reg}}(\omega) \), while the lower peak \( \omega_{p2} \) splits off and is expected to vanish at commensurate \( \Delta_3 = 0.5 \) as \( \omega_{p2} \propto |\Delta_3 - \Delta| \). Such evolution is consistent with the specific behavior at commensurate points, \( \Delta_m = \cos(\pi/m) \) \cite{3, 8, 9}, where also additional degeneracies (diagonal as well as off-diagonal in \( S_{\text{tot}} \)) \cite{29, 46} exist.

The latter macroscopic degeneracies of the energy spectrum should coincide with discontinuous variation (jumps) of the stiffness \( \mathcal{D} \) at these particular values \( \Delta = \Delta_m \). At the same time, the frequency moments \( \mu_n \) (up to large \( n \sim L \)), are continuous functions of \( \Delta \) even close to commensurate values. The simplest scenario which may capture both features is that the missing spectral weight, \( \mathcal{D}(\Delta_m) - \lim_{\Delta \to \Delta_m} \mathcal{D}(\Delta) \), is transferred to narrow low-frequency peaks centered at frequencies \( \omega_{p_{mn}} \propto |\Delta_{n+1} - \Delta_m| \) with \( \zeta \sim 1 \). In particular, we can confirm such a scenario by our detailed numerical analysis (ED for \( L = 20 \)) for the vicinity of \( \Delta_4 = 1/\sqrt{2} \), as presented in Fig. 5(a). It clearly shows the emergence of symmetric peaks at \( \Delta \sim \Delta_4 \). In this sense the situation is qualitatively similar (but much less pronounced) as the case of \( \Delta = \Delta_2 = 0 \) presented in Fig. 5(b), with a single peak at \( \omega \propto \Delta \) \cite{29} (see also discussion in Sec. II D). It should be however, noted that in a finite system, one can follow a jump in \( \mathcal{D} \) and related emergence of peaks in \( \sigma_{\text{reg}}(\omega) \) only provided that the particular MB states at given \( L \) and \( S_{\text{tot}} \) display a large degeneracy at commensurate \( \Delta_m \). This is indeed the case for \( \Delta_3 \) and \( \Delta_4 \) assuming the considered here finite systems \( L = 4L \). On the other hand, at \( \Delta_3 = 0.5 \) our systems do not reveal explicit (large) degeneracy, so the above phenomena cannot be followed in the very vicinity of \( \Delta_4 \) but they become more evident with the increasing system size, as in Figs. 1(b) and (d) for \( L = 32 \).

Above scenario should imply also for \( \Delta > \Delta_3 = 0.707 \) further peaks emerging and leading to quite complex low-\( \omega \)}
structure of $\bar{\sigma}_{\text{reg}}(\omega)$ on approaching $\Delta \to 1$. However, results for $\Delta > 0.8$ should be taken with some reservation, since they already reveal significant $L$-dependence. In particular, at $\Delta \to 1$ one expects the vanishing coherent part $F \to 0$ while the observed spectral gap $\omega_p \propto 1/L^2$ well visible in Fig. 1 (including its $L$-dependence through the comparison of $L = 20$ and $L = 32$ results) below quite featureless spectra is known to be finite-size effect [41]. This gap reflects the anomalous $L$-dependence of $\bar{\sigma}_{\text{reg}}(\omega)$ in the integrable XXZ chain in the insulating regime $\Delta > 1$ [21] and, in particular, the superdiffusion at $\Delta = 1$ [34, 42–45], discussed in connection with the Fig. 4.

D. The case of small $\Delta \ll 0.5$

Results for $L = 20$ and $L = 32$ shown in Figs. 1(c,d) demonstrate that the position of the single peak at $\omega_p$, strongly depends on $L$ only for $\Delta < 0.5$. In this subsection we carry out the finite-size scaling of $\bar{\sigma}_{\text{reg}}(\omega \to 0)$ in the regime of small $\Delta$. At $\Delta = 0$, the current operator commutes with the Hamiltonian, thus $\bar{\sigma}(\omega) = 2\pi D\delta(\omega)$ and the regular part is absent. There is also a large jump (discontinuity) of the stiffness at $\Delta \to 0$ [1, 29]. Similarly to other commensurate points, the spectral weight $D(0) - \lim_{\Delta \to 0} D(\Delta)$ is transferred to $\omega > 0$ for $\Delta \neq 0$. The latter weight forms a peak at $\omega_p \propto \Delta$, see Fig. 1 and Fig. 5(b). As a consequence, the regime of weak interaction is unique in that the structure of $\bar{\sigma}(\omega)$ is relatively simple.

To evaluate $\bar{\sigma}(\omega)$, we employ a recent approach which targets the regime of $\Delta \ll 0.5$. For the details we refer to [29], where the focus was on the stiffness $D$, which requires calculation of the diagonal matrix elements $\langle n| j|m \rangle$ for $\Delta \neq 0$. The eigenstates $|n\rangle$ can be obtained via the DPT starting from the noninteracting case, $\Delta = 0$, with a highly degenerate energy spectrum. The value of $D$ obtained from the latter approach agrees with the ED results up to the numerical precision [29]. We extend these calculations to obtain also the off-diagonal matrix elements, $\langle n| j|m \rangle$, and the corresponding $\bar{\sigma}_{\text{reg}}(\omega)$ defined in Eq. (3). In Fig. 5(b) we compare the DPT and ED results for $L = 20$ sites and find perfect agreement. Note however, that the DPT does not require any $\omega$-smoothing, i.e., it has full frequency resolution, and allows for full analysis of large system sizes, i.e., up to $L = 28$.

Fig. 6(a) shows the integrated regular part $I_{\text{reg}}(\omega)$ for (arbitrarily chosen small) $\Delta = 0.1$ and various system sizes $L$. For convenience, the presented quantity is normalized so that $I_{\text{reg}}(\omega \to \infty) = 1$. Since we apply the perturbative approach, the very same results hold true for arbitrary $\Delta \ll 0.5$, up to rescaling of frequency, $\omega \to \omega/\Delta$. In order to estimate the $\bar{\sigma}_{\text{reg}}(\omega \to 0)$ in the $L \to \infty$ limit, we first note the power-law dependence of the low-$\omega$ part, $I_{\text{reg}}(\omega \ll \omega_p) \propto \omega^{b+1}$ so that $\bar{\sigma}_{\text{reg}}(\omega) \propto \omega^{b}$. The power-law fits are shown as straight lines in Fig. 6(b) and the resulting exponents, $b$, are plotted in Fig. 6(d) as a function of $1/L$. The latter function shows a positive curvature, thus a straight (continuous, green) line going through the results for two largest $L$ may serve as a lower bound for $b$. These results indicate that $1 \leq b \leq 2$ for $L \to \infty$ with the possibility of the analytic form $\bar{\sigma}_{\text{reg}}(\omega \ll \omega_p) \propto \omega^2$ [30]. Fig. 6(c) shows the asymptotic behavior of $1 - I_{\text{reg}}(\omega)$, where one observes that the response decays exponentially for $\omega \gg \omega_p$. Finally, we estimate the $L$-dependence of $\omega_p$, which corresponds to the position of largest slope in Fig. 6(a), and is shown in Fig. 6(d). For comparison, we show also the median value, $\omega_m$, defined as $I_{\text{reg}}(\omega_m) = 0.5$. Both quantities apparently follow linear dependence in $1/L$. The extrapolation (which within DPT represents more a lower bound) of this trend suggests that in the thermodynamic limit $\omega_m > 0$ and $\omega_p > 0$.

III. 1D HUBBARD MODEL

Another relevant model for the possible coexistence of ballistic and diffusive transport is the integrable 1D Hubbard model of interacting fermions,

$$H = -t \sum_{i,s} \left( c_{i+1,s}^{\dagger} c_{i,s} + \text{H.c.} \right) + U \sum_i n_{i\uparrow} n_{i\downarrow},$$

again on a chain of length $L$ with PBC, where we consider states with fixed number $N_{\uparrow}$, $N_{\downarrow}$ of up- and down-spin fermions, respectively. The properties of the model depend on the filling (density) $\tilde{n} = (N_{\uparrow} + N_{\downarrow})/L$ and the magnetization $\tilde{m} = (N_{\uparrow} - N_{\downarrow})/L$. Here, one can define both charge $j_c$ and spin $j_s$ currents, so we can discuss corresponding conductivities as well as stiffnesses $D_c$, $D_s$, respectively. Most recent studies of 1D Hubbard model focused on the half-filling...
case, i.e., $\bar{n} = 1$ and $\bar{m} = 0$ [1, 12, 13, 26], where both stiffnesses vanish, i.e., $D_c = D_s = 0$, due to the relation with the isotropic Heisenberg model. This is not the case for $\bar{n} \neq 1$ [13], where $D_c$ and $D_s$ also exhibit in general a jump in the proximity to the noninteracting limit $U \to 0$ [29] (in analogy to the $\Delta \to 0$ in the XXZ model). It should be also reminded that the first example of the ballistic transport at $T > 0$ was the Hubbard chain with one particle $N_1 = 1$ in a bath of fermions corresponding to $N_L \sim L/2$ [2, 16].

As in the XXZ spin chain, there might in the Hubbard model at $U > 0$ persist finite dc contributions $\sigma_c(\omega \to 0) > 0, \sigma_s(\omega \to 0) > 0$ [13] besides the ballistic components at general $\bar{n} \neq 1, \bar{m} \neq 0$. On the other hand, the evolution with $U > 0$ is expected to be more generic since, unlike the XXZ chain, there are no anomalies associated with particular $U$ values. We investigate here numerically only the case of charge conductivity $\sigma_c(\omega)$ at quarter filling $\bar{n} = 1/2$ and $\bar{m} = 0$. In Fig. 7 we present results obtained on the chain of $L = 20$ sites via MCLM, presented in Fig. 7(a) as a scan through the range of small/modest $0 < U/t < 2$ and in Fig. 7(b) for selected modest/large $U/t = 1, 2, 4, 8$. It should be first mentioned, that quite similar results emerge when performing ED for $L = 16$, hence the $L$-dependence appears to be weak, at least in the accessible $L$-range.

Apart from the dissipationless component which in the presented quarter-filling case takes approximately half of the sum rule [29], the variation for small/modest $U/t > 0$ is quite analogous to the $\Delta \gtrsim 0$ in the XXZ spin chain. For $U/t \leq 1.5$ the spectra $\sigma_{\text{reg}}(\omega)$ are dominated by a single peak at $\omega_p \propto U$ with a vanishing dc limit $\sigma_{\text{reg}}(\omega) \to 0$. For larger $U/t > 1.5$ the structure in Fig. 4 develops more components: a) large-$\omega$ contribution which directly reflects the scale $\omega \sim U$, b) the remaining low-$\omega$ structure apparently still reveals two not well separated peaks, where the lower one remains at $\omega_m \sim t/2$ and the upper broader one $\omega \lesssim 1.5 t$ is related to the incoherent bandwidth. Most important for the present study, presented results suggest vanishing $\sigma_{\text{reg}}(\omega \to 0)$ or at least allow only for a very small upper bound of $\sigma_{c,\text{reg}}$.

**Figure 6.** (a) Integrated and normalized regular part of the optical conductivity $I_{\text{reg}}$ obtained for $L = 16 – 28$ sites via the DFT calculation for $\Delta \to 0$. (b) The low-frequency part of $I_{\text{reg}}(\omega \ll \Delta)$ fitted by $I_{\text{reg}} \propto \omega^{b + 1}$ (fits are shown as dashed lines). (c) Exponential decay of $1 - I_{\text{reg}}(\omega)$. (d) Finite-size scaling of the exponent $b$ from panel (b), where dashed line shows fits linear in $1/L$ and the continuous guideline goes through results for $L = 24$ and $L = 28$. In (d) we present also the position of peak $\omega_p$ and median $\omega_m$, together with the linear fits.

**Figure 7.** (a) Charge conductivity $\sigma_c(\omega)$ for the 1D Hubbard model at quarter filling $\bar{n} = 1/2$ and zero magnetization $\bar{m} = 0$, obtained via MCLM for a chain of $L = 20$ sites and $M_L = 5 \cdot 10^4$ steps. (a) The scan for the whole interaction $0 < U/t < 2$ range. (b) Spectra for selected moderate/large $U/t = 1, 2, 4, 8$.

**IV. CONCLUSIONS**

In this paper we presented the numerical results for dynamical transport response, i.e., high-temperature $T \to \infty$ conductivities $\sigma(\omega)$, in two basic integrable lattice 1D models, i.e., the anisotropic Heisenberg XXZ model and the Hubbard model. Since our aim was to resolve the low-$\omega$ behavior in terms of dissipationless $D$ component and the potential remnant diffusive contribution $\sigma_{\text{reg}}(\omega \to 0)$, we adapted the MCLM approach by allowing for large systems (up to $L = 32$ for the XXZ and $L = 20$ for the Hubbard model), as well as high frequency resolution $d\omega/(J,t) \sim 10^{-3}$. Our results can
be summarized as:

a) Concerning the comparison with previous numerical results (nearly exclusively) on the XXZ chain, we are in agreement with DQT results for the stiffness $\mathcal{D}(\Delta) = I(\omega \to 0)/2$ obtained for system sizes $L \leq 30$ with PBC [23, 24]. Apparently, we also agree with the results of tDMRG method [25, 26] obtained for larger systems $L \leq 200$, e.g., presented for $\Delta = 0.5$ in Fig. 3b. Since the latter time-dependent correlations are followed only up to times $\tau J \sim 35$, one cannot uniquely extract results for $\omega/J < 0.15$ [25], which is the essential range for the understanding of dynamics in the metallic $\Delta < 1$ regime.

b) Besides well established ballistic $D > 0$ contribution, regular part of dynamical spectra $\tilde{\sigma}(\omega)$ are quite complex in the XXZ model, revealing several-peak structure at general $\Delta \neq \Delta_m$. The most controlled regime appears to be that of small $\Delta \ll 0.5$, where both ED and MCLM calculation at finite $\Delta$ confirm single-peak structure of $\tilde{\sigma}(\omega)$ with the position at $\omega_p \propto \Delta$ and fast exponential-like decay for $\omega > \omega_p$. The latter is also consistent with the calculation within the level-crossing scenario [30]. The most controlled regime appears to be that of small $\Delta \ll 0.5$, where both ED and MCLM calculation at finite $\Delta$ confirm single-peak structure of $\tilde{\sigma}(\omega)$ with the position at $\omega_p \propto \Delta$ and fast exponential-like decay for $\omega > \omega_p$. The latter is also consistent with the calculation within the level-crossing scenario [30].

c) Quite informative are the results for commensurate $\Delta = \Delta_m$, e.g., directly followed via ED and MCLM (besides $\Delta = 2$) for finite-size systems, although the observed finite-size gap $\omega_0$ reveals some $L$ dependence, so that we cannot exclude its closing for $L \to \infty$ and possible agreement with the GHD results for $\sigma^0_{\text{reg}}$ [33, 36].

d) The spectral evolution is most difficult to follow in the vicinity of commensurate anisotropy $\Delta \sim \Delta_m$, which becomes very involved in the regime $\Delta > 0.5$. Namely, each $\Delta_m$ appears to be a source for additional structure appearing as the peak at $\omega_{pm} \propto |\Delta - \Delta_m+1|$. Such development can be, e.g., directly followed via ED and MCLM (besides at $\Delta = 0$) for $m = 4$, emerging from the lifting of additional large (exponentially increasing with $L$) degeneracies at $\Delta_m$ (see Fig. 1 and Fig. 5). Less conclusive is the case of $\Delta_4 = 0.5$, where large-$L$ results still reveal such peaks, but considered systems with $L = 4L$ with chosen PBC do not seem to exhibit explicitly such degeneracies. In any case, such scenario should effectively reappear with increasing $L$, as we also confirm by comparing in Fig. 1 results for systems with $L = 20$ and $L = 32$.

e) It should be remarked that the emerging spectral components for $\Delta \neq \Delta_m$ are also the origin for the GHD expectation concerning a singular $\sigma_{\text{reg}}(\omega) \propto \omega^{-\alpha}$ with $\alpha > 0$ [36] in the vicinity of commensurate $\Delta_m$. To justify the latter, besides the jump of $D$ and of the remaining sum rule $\tilde{\sigma}_{\text{reg}}(\omega)$, an additional assumption is a power-law decay in time of current correlation $\langle j(\tau)j \rangle \propto \langle j(\infty)j \rangle$. However, our finite-$L$ results for $\sigma^0_{\text{reg}}(\omega)$ are compatible with an oscillating time-evolution to final $\langle j(\tau)j \rangle \propto D > 0$ value, which is visible also in the tDMRG results in [25].
