Generating and manipulating Dirac points in artificial atomic crystals has received attention especially in photonic systems due to their ease of implementation. In this paper, we propose a two-dimensional photonic crystal (PC) made of a Kekulé lattice of pure dielectrics, where the internal rotation of cylindrical pillars induces optical Dirac degeneracy-breaking. Our calculated dispersion reveals that the synchronized rotation reverses bands and switches parity as well so as to induce topological phase transition. Our simulation demonstrates that such topologically protected edge states can achieve robust transmission in almost arbitrarily-deformed defect waveguides and therefore provides a pragmatically tunable scheme to achieve reconfigurable topological phases.

I. INTRODUCTION

In the past decades, topological photonics has become a rapidly developing research field that aims to explore the wave physics of topological phase of matter in analogue. The concept of topology insulators in condensed matter physics has been lent to many wave physics fields \cite{1, 2}. Haldane and Raghu \cite{3, 4} firstly brought the quantum Hall effect (QHE) to the field of photonics and theoretically proved the photonic quantum Hall effect (PQHE), which opened new avenues for topology-protected optical transmission devices (such as topological lasers, waveguides and quantum circuits) \cite{5, 6}. The topological edge states generated on the interface between different topological phases promise fascinating features such as robust transmission, backscattering suppression and defect immunity. Topological photonic devices enabling edge state transmission have brought unprecedented opportunities in controlling EM waves at microwave and optical frequency bands \cite{6, 5, 7}.

The first realization of the photonic topological state are based on the microwave platform of gyromagnetic photonic crystals by applying a magnetic field to break the TR symmetry of the system \cite{8, 9}. However, the weak gyromagnetic effect hinders their extension towards higher frequency bands and more manipulative scenarios. To sidestep this issue, all-dielectric PCs with judiciously-designed unitcells have been proposed \cite{8, 10} to achieve topological phases through adjusting geometrical structures in the primitive cell of the all-dielectric PCs with C\textsubscript{6} symmetry \cite{11, 14}. Floquet insulators, valley Hall effect and photonic quantum spin Hall effect (PQSHE) have been realized both in theory and in experiment \cite{8, 15, 16}. The PCs with C\textsubscript{6} symmetry including circular pillars (dielectric cylinders or pores), core-shells (circular rings) and elliptical dielectric cylinders clusters were proposed to achieve QSH effects \cite{3, 15, 17}. At the interface between different topological phases, the helical edge states are sandwiched which lead to unidirectional scattering-less propagation. This unique robust feature can be used to realize band-gap devices topology lasers, integrated optical circuits, etc.\cite{15, 18}.

In this paper, we propose an internal rotating mechanism to achieve topological edge states via sandwiching two distinct topological phases, on a two-dimensional PC made of a Kekulé lattice in dielectrics \cite{8, 15, 16, 19}. This proposal provides a flexible way to achieve optical topological phase transition. The physical principle is, by the internal rotation, the crystal lattice with C\textsubscript{6v} symmetry (representing six-fold rotational symmetry and mirror symmetry in six different directions) turns to C\textsubscript{6} symmetry. Destruction of the mirror symmetry of the lattice makes Dirac point \Gamma to break its degeneracy. Generation and breaking of the Dirac degeneracy result in occurrence of topological phase transitions \cite{19}. At the interface of different topological phases generated in this manner, we observe in simulation the edge states protected by the pseudo time-reversal (TR) \cite{20, 21} symmetry accompanied by C\textsubscript{6} symmetry. As a merit of that, we also design a bent waveguide and a defected one and observe in simulation that even in the presence of sharp turns or defects, these edge states still propagate robustly.

II. THEORY AND MODEL

The structure of the proposed artificial meta-atom in a Kekulé lattice is shown in Fig. 1(a), where the black solid hexagons embedding six cylindrical pillars in dark blue are the original units of a Kekulé lattice. At the Brillouin zone \Gamma point of the Kekulé unit exists an odd parity for spatial inversion, and also double degenerate Dirac cones occur \cite{4, 20}. Therefore, with the hexagon in composition of the triangular lattice, \alpha\textsubscript{0} is the lattice constant and a\textsubscript{1} and a\textsubscript{2} are unit vectors. The geometric parameters used in the model throughout this paper are \alpha\textsubscript{0} = 1, \alpha\textsubscript{0}/R = 2.92, d = 0.11\alpha\textsubscript{0} unless otherwise

\end{center}
In the analog electronic system [20], the two eigenstates of odd parity in the photonic system can be represented by \(p_+\) and \(p_-\), corresponding to the p-band pseudo-spin-up and pseudo-spin-down states. Similarly, the two states of even parity in \(d_+\), can be mapped as the pseudo-spin-up and pseudo-spin-down states for d-band.

According to the \(k \cdot p\) theory [23], effective photonic Hamiltonian under the representation of \([p_+, d_+, p_-, d_-]^T\) is (cf. Sec. II of Supplementary Material):

\[
H_0 = \begin{bmatrix}
\frac{\omega^2}{c^2} A k_+ & 0 & 0 \\
A^* k_- & \frac{\omega^2}{c^2} & 0 & 0 \\
0 & 0 & \frac{\omega^2}{c^2} A^* k_- \\
0 & 0 & A k_+ & \frac{\omega^2}{c^2}
\end{bmatrix}
\]

In Eq. (4), \(k_{\pm} = k_x \pm ik_y\), \(A\) is the coupling coefficient between \(p\)- and \(d\)-states, \(\omega_p\) and \(\omega_d\) the eigenfrequencies of \(p\)-band and \(d\)-band, respectively. Note that in a \(C_6\) symmetric system, only \(p\)-states (\(d\)-states) with the same spin direction can be coupled and Eq. (4) is similar to the electronic Hamiltonian in Bernevig-Hughes-Zhang (BHZ) model [24–26], where the two block matrices correspond to the massive Dirac equations with pseudo-spin-up and down, respectively. This pair of pseudo-spin pairs are interconnected by inversion symmetry operation, along with their disparate parities which ensures that the entire system satisfies pseudo TR symmetry. If the \(p\)-band is compared to the valence band and the \(d\)-band to the conduction band [cf. Fig. 2(c)] analogous to the BHZ model in the electronic system, Eq. (4) serves as a Hamiltonian matrix of PQSHE. Then the topological state of our system should be determined as follows [21]. When \(\omega_p > \omega_d\) the system corresponds to a topological non-trivial states; when \(\omega_p < \omega_d\), the system has parity inversion at the \(\Gamma\) point, which directly indicates the topological trivial state; when \(\omega_p = \omega_d\), at the \(\Gamma\) point there occurs a band of fourfold degeneracy, corresponding to the double Dirac point which marks the transition point of topological phases [11].

III. RESULTS AND DISCUSSION

In this work, COMSOL software based on the finite element method is used to calculate the PC dispersion and the electric field diagram [27, 28]. Considering the TM mode (\(\mathbf{E}_z, \mathbf{H}_x\) and \(\mathbf{H}_y\) components only), the band degeneracy and its breaking at \(\Gamma\) point is achieved by adjusting the rotation angle of hexagons in every unit. As shown in Fig. 2, when the rotation angle is 12°, the two degenerate bands split in proximity of \(\Gamma\) point.

Based on the above theory, two degenerate band eigenstates are analogous to the quantum electron wave functions for \(p\)-band and \(d\)-band [3, 20]. According to \(\mathbf{E}_z\) fields in Fig. 2(d) and (e), we recognize that the dipole electric field belongs to the \(p\)-band and the quadrupole one to the \(d\) band [30]. Therefore, the type of energy band can be determined according to \(\mathbf{E}_z\) fields.

In the enlarged view Fig. 1(b) of the hexagonal cluster, \(R\) is the length from the center of the hexagon to the center of the cylinder, and \(d\) is the diameter of the cylindrical pillars. For the rotation mechanism, Fig. 1(c) shows the arrangement of the supercell when the cylindrical pillars rotate simultaneously for an angle of \(\alpha = 9.4^\circ\), clockwise around the center of the hexagon.

In order to facilitate the description of the topological phase transition mechanism, we consider the behavior of the transverse magnetic (TM) mode in a Kekulé PC with \(C_6\) symmetry [8]. According to Maxwell’s equation, the propagation of time-harmonic TM waves in PC can be described by [3]:

\[
\frac{1}{\varepsilon(x)} \nabla \times \nabla \times \mathbf{E}_z(x) = \frac{\omega^2}{c^2} \mathbf{E}_z(x) \hat{z},
\]

where \(\varepsilon(x)\) is the dielectric parameter and \(c\) the speed of light. When \(\varepsilon(x)\) is periodic, Bloch theorem applies in form of EM waves.

For the representations \(\mathbf{E}_z\) field at \(\Gamma\) point, artificial atoms carry orbitals \(p_x(p_y)\) and \(d_{xy}(d_{x^2-y^2})\), in analogue to the electron orbitals for periodic array of atoms in a solid. Since the direct counterpart of spins do not occur naturally, two eigenvectors \(\mathbf{E}_1\) and \(\mathbf{E}_2\) can be constructed as: \([p_+, p_-]\) and \([d_+, d_-]\) (cf. Sec. I of Supplementary Material), in which

\[
p_\pm = \frac{p_x \pm ip_y}{\sqrt{2}},
\]

\[
d_\pm = \frac{d_{x^2-y^2} \pm id_{xy}}{\sqrt{2}}.
\]

Here antiunitary operator \(T = UK\) is proposed where \(U = -i \mathbf{\sigma}_y\), \(K\) is a complex conjugate operator [3, 15, 17]. Since \(U^2 = -1\) guarantees \(T^2 = -1\), \(T\) can be used as a pseudo-TR operator in our photonic system. Under the action of the \(T\) operator \([p_+, p_-]\) has the following transformations [17]:

\[
T^2 p_\pm = -p_\pm.
\]

Obviously, this pseudo-TR resulting from the crystal symmetry [3, 20, 22] plays the central role in our analogue QSH.
Fig. 2(a), when the pillars is unrotated $\alpha = 0^\circ$, there are two degenerate points in each band. By observing the eigenfrequencies of $E_z$ fields, we find that the p-band goes above the d-band across the band gap. Here in panel (a) our system is initially in a topological non-trivial state ($\omega_p > \omega_d$, represented by phase I). When the unit cell is rotated counterclockwise by $90^\circ$, the eigenfrequency $\omega_p = \omega_d$ at Dirac point $\Gamma$ in panel (b) [11]. When we continue to adjust the rotation angle to $\alpha = 12^\circ$, as shown in (c), the fourfold degeneracy point at $\Gamma$ point reopens. We then realize the band degeneracy and its breaking via a simple rotation of the unit cell. Panel (c) also indicates that p band goes under d band in contrast with (a) where the p and d bands are reversed at $\Gamma$ point, reducing it to a topologically trivial state ($\omega_p < \omega_d$, represented by phase II). The physical reason of topological phase switching results both from the band inversion due to broken spatial inversion symmetry and also from the parity inversion [11] [20].

The eigenfrequencies of the p- and d- bands within a period for 60 degrees changes along with rotation angle $\alpha$, as shown in Fig. 2(f). We find that the p- and d-bands reverse twice in one period of $\alpha$, which occur at both $\alpha = 9.4^\circ$ and $50.4^\circ$ as the topological phase transition points. Moreover, the complete band gap produced by the rotation mechanism increases to peak at $\alpha = 13^\circ$ and then becomes narrow along with increasing rotation angle, and vanish for $30^\circ$ eventually. Furthermore, the first topological phase transition angle monotonically decreases with the relative lattice constant $a_0/R$, shown as the solid curve in left panel (g). When $a_0/R$ reaches 2.6, the neighboring atoms become tangent, which hinders designers to tune $a_0/R$ further. In short, the rule of thumb for setup parameters to achieve topological phase indicates a range of $a_0/R > 3.0$ in the trivial phase II, any angle of rotation will not cause phase switching though a topologically-trivial band gap still occurs near $\Gamma$ point. Note that the rotation mechanism preserves the pseudo-TR of the system (cf. Sec. III of Supplementary Material), and eases the method to generate the topological band gap without using magnetic experimental setups [3] [15] [31].

The hallmark of topological bands is the scattering-free boundary states propagating on the interfaces between distinct topological matters [3] [15] [31]. To reveal the edge states explicitly in our QSHE system, we plot the projected band dispersion and electric field $E_z$ in a ribbon shaped supercell composed of two distinct PC, respectively $\alpha = 0^\circ$ and $\alpha = 12^\circ$ in Fig. 3. As the dispersion diagram in (a) shows, a pair of edge modes (represented by red and blue dots) are observed within the bandgap. This pair of edge states are topologically protected by pseudo-TR symmetry, which can be identified as the spin-up and down modes. Because the $C_6$ symmetry of the point group is not destroyed, the topological edge mode has no gaps in the frequency space (cf. Sec. IV of Supplementary Material). In left panel of (b) we plot the electric fields of the edge state for points A and B at $k_x = \pm 0.02 (2\pi/a_0)$ in (a). The field maps indicate the robust topologically-protected edge states along the interface. In the two zoom-ups in the right panel of (b), the two circular arrows (red and blue for clockwise and counterclockwise rotation) indicate time-averaged power flow directions of $S = \text{Re} [E \times \mathbf{H}^*/2$ for the edge states duo [22]. It demonstrates the helical edge states under spin-momentum locking explicitly.

To further validate the robust one-way propagation of topological helical edge states subject to PC defects [10] [16], we use the helicity feature, i.e. the direction of the pseudo-spins, of the edge states to control the propagation of electromagnetic waves. The pseudo-spin-up (pseudo-spin-down) mode is selectively excited by using a positive (negative) circular polarization excitation source $S_+ (S_-)$ [3]. On the interface of two kinds of photonic crystals with distinct topological phases, we observe the EM propagation mostly along the edge. In
FIG. 3. (a) Projected band diagram of a one-dimensional supercell, composed of both topologically non-trivial phase I ($\alpha = 0^\circ$) and topologically trivial phase region II ($\alpha = 12^\circ$). A (red dots) and B (blue dot) correspond to the clockwise spiral and counterclockwise helical edge states, respectively. (b) Left panel: electric field distribution $E_z(x,y)$ around the edge. Right panel: zoom-ups for electric field $E_z$. The arrows represent the average Poynting vector directions and magnitude to corresponding to point A and B for $k_x = \pm 0.02 \cdot 2\pi/a_0$ and circular thick arrows in red and blue are used to guide the eyes.

the waveguide design, we make use of the wider common bandgap to excite the topological edge state selectively. For the topological non-trivial (I) part parameters are kept the same as Fig. 3, while for trivial phase (II) part, parameters $a_0/R = 3$, $\alpha = 12^\circ$ are chosen with other parameters unchanged. When the eigenfrequency $\omega/(2\pi c/a_0)$ is chosen as 0.49, the in-line waveguide excites EM waves by the pseudo-spin source $S_+$. Simulation shows that these edge states can transmit EM waves well in the selected rightward direction as shown in Fig. 4(a). To verify the defect immunity characteristics of the topological edge state, an in-line waveguide with defects is designed as shown in Fig. 4(b). Simulation also verifies that EM waves are still able to transmit around the disordered region to localize at the topological interface. Furthermore, to validate the backscattering immunity characteristics of edge states, a Z-shaped waveguide with sharp bends is shown in Fig. 4(c). The EM wave excited from $S_+$ propagates along the Z-shaped interface between the topological distinct phases (II/I) can travel around geometric bends without significant loss. In order to represent the energy flow in the waveguide excited by different chiral excitation sources, Poynting vector distribution of the in-line waveguide and the defective waveguide are plotted in panels (d), (e), which is distributed in one-way transverse vortex during its propagation. By calculating the transmission efficiency of the three waveguides in panels (a-c), as shown in Fig. 4(f), we confirm that the energy transmission of the waveguides around the band gaps I and II is with negligible loss. In order to further verify the topological feature of the edge-state propagation, two boundary types of waveguides are designed, in which the zigzag boundary is used in Fig. 3 and the armchair-type boundary state also demonstrates backscattering suppression and null-interference properties (cf. Sec. V of Supplementary Material). Our results confirm that the boundary states induced by our rotation-induced phase transition are a truly analog of QSHE states, which are robust one-way reflection-less travelling eigenwaves against defects [3, 15].

IV. CONCLUSIONS

In summary, based on the pure-dielectric Kekulé lattice, we use the synchronized rotation of the unit cells to induce a topological phase transition on a PC platform. The pseudo-TR symmetry is constructed based on the $C_6$ symmetry of the Kekulé lattice in design, topological phase transition in the rotation mechanism maintains the pseudo-TR inversion. Our model exploits the rotational freedom of the pillars to break the mirror symmetry of the crystal lattice, thereby reducing the manufacture re-
requirements to manipulate Dirac points. The synchronized rotation of unit cells directly opens the bandgap, providing an additional degree of freedom for the generation of the topological gap without magnetic experimental setups. Electromagnetic wave simulation verifies that topological edge states emerge within a band gap due to synchronized rotation of unit cells. Other than already-known platforms [21-25,36], we hope that this work provides a design possibility for scrutinizing the optical QSHE system.
