Generalized Gibbs Ensemble Description of Real Space
Entanglement Spectra of (2+1)-dimensional Chiral Topological
Systems with $SU(2)$ Symmetry

Abstract

We provide a quantitative analysis of the splittings in low-lying numerical entanglement spectra (ES) of a number of quantum states that can be identified, based on “Li-Haldane state-counting”, as ground states of $(2 + 1)$-dimensional chiral topological phases with global $SU(2)$ symmetry. The ability to account for numerical ES splittings away from their “ideal” chiral conformal field theory (CFT) spectra, solely within the context of CFT, is an additional diagnostic of the underlying topological theory, of finer sensitivity than “state-counting”. We use the conformal boundary state description of the ES, which can be formulated as a quantum quench. In this language, the ES splittings arise from higher local conservation laws in the chiral CFT besides the energy, which we view as a Generalized Gibbs Ensemble (GGE). Global $SU(2)$ symmetry imposes strong constraints on the number of such conservation laws, so that only a small number of parameters can be responsible for the splittings. We work out these conservation laws for chiral $SU(2)$ Wess-Zumino-Witten CFTs at levels one and two, and for the latter we notably find that some of the conservation laws take the form of local integrals of operators of fractional dimension, as proposed by Cardy for quantum quenches [J. Stat. Mech.: Theory Exp. 2016, 023103 (2016)]. We analyze numerical ES from systems with $SU(2)$ symmetry including chiral spin-liquid ground states of local 2D Hamiltonians and two chiral Projected Entangled Pair States (PEPS) tensor networks, which exhibit the “state-counting” of the $SU(2)$-level-one and -level-two theories. We find that the low-lying ES splittings can be well understood by the lowest of our conservation laws, and we demonstrate the importance of accounting for the fractional conservation laws at level two. Thus the states we consider, including the PEPS, appear chiral also under our more sensitive diagnostic.

I. INTRODUCTION

Topological states of matter exhibit a new kind of robust “non-local” order that is of great interest to condensed matter physics. Some types of topological states in two dimensions, including fractional quantum Hall states, lack time-reversal symmetry and are known as chiral topological states, which possess gapless topologically-protected edge states at their boundaries with universal finite-size spectra governed by (1+1)D chiral conformal field theories (CFTs) particular to the specific bulk topological order. The searches for physical Hamiltonians that give rise to two-dimensional quantum states of this type, as well as investigations of the states themselves, are a very active area of research.

A useful method to help identify these states in numerical simulations is the entanglement spectrum (ES). Bipartitioning the Hilbert space into two disjoint halves $A$ and $\bar{A}$, we can compute the reduced density matrix of $A$ as $\rho_A = \text{Tr}_{\bar{A}} \rho$, where $\rho$ is the (global, pure-state) density matrix of the topological quantum state, and $\text{Tr}_{\bar{A}}$ indicates that we trace out the degrees of freedom associated to $\bar{A}$. Then we can define the entanglement Hamiltonian as $H_{\text{entanglement}} = -\log \rho_A$. Its spectrum will be the ES. If the bipartition corresponds to degrees of freedom in two regions of real space, we call this spectrum the real space entanglement spectrum (RSES), and we refer to the division (interface) between the two spatial regions $A$ and $\bar{A}$ as the entanglement cut. The crucial realization by Li and Haldane was that, for chiral topological systems, the low-energy states of the theory on a physical edge in real space, known to be described by CFT, are in a one-to-one correspondence with the low-lying eigenstates of the entanglement Hamiltonian computed across the entanglement cut placed at the same location as that physical edge.

This wonderful fact, judiciously applied, allows the ES to become a diagnostic for identifying the presence of chiral topological states in numerical simulations. Typically the entanglement spectrum is computed across the entanglement cut (e.g., for an entanglement cut that is a circle, appearing when the surface of a cylinder is cut into two parts, see Fig. 1), and for the low-energy part of the spectrum, the number of states at each momentum and of each type is counted and compared to the corresponding number in the relevant CFT. This agreement is taken as evidence that the correct topological state (or something similar to it) has been produced by the computation.

Numerical results at finite size, however, typically show splitting of the energy levels of
entanglement spectra at a given momentum (see e.g. Refs. 12, 14–19, among many others), energy levels that would be degenerate considering the corresponding CFT Hamiltonian alone. We would like to gain a more complete understanding of the detailed characteristics of these splittings in the low-energy levels for real space entanglement spectra, as these may provide information (going beyond the state-counting alone) about the underlying (2 + 1)-dimensional topological field theory, which is directly reflected in the structure of the resulting CFT, as well as the performance of the numerical methods used. In particular, regarding the former point, if the underlying (2 + 1)-dimensional bulk topological field theory has been correctly identified, it must be possible to account for the splittings in the ES entirely within the context of the resulting CFT, i.e. without recourse to any other principles. If this is not possible, then the nature of the bulk state was not correctly identified.

Various papers12,18,19 have successfully endeavored to study splittings in the entanglement spectra for Laughlin (or Pfaffian) quantum Hall states in a number of cases by, e.g., dispersive terms due to irrelevant operators, or composite fermion descriptions. We focus our attention on systematically investigating the ability of CFT to describe and characterize these splittings in a variety of different numerically generated chiral topological states (including Projected Entangled Pair States (PEPS)—see below). We use the conformal boundary state description10,20–22. Specifically, we consider chiral topological states where the bulk, and consequently also the edge theory (and therefore the chiral CFT describing the entanglement spectrum), possess global SU(2) symmetry, and in particular those where the topological properties of the bulk are described by SU(2)-level-k (SU(2)_k) Chern-Simons theory7, and thus a physical edge is described by a chiral SU(2)_k Wess-Zumino-Witten (WZW) CFT (reviewed in Section II), as is the case for some types of topological state.5 The Kalmeyer-Laughlin spin liquid23 is one example of a chiral topological state that hosts, at a physical edge, edge modes described by a chiral SU(2)_1 WZW CFT. In this work specifically, we consider both chiral SU(2)_1 and SU(2)_2 WZW theories, and we account for special features appearing in the half-integer spin sector of the SU(2)_2 theory. As compared to the quantum Hall states mentioned above, global SU(2) symmetry turns out to strongly constrain the number of parameters that can be responsible for the splittings. We additionally consider the effect of a discrete symmetry, the composition of spatial reflection and time reversal (RT), which further constrains the number of parameters responsible for the
splittings in some cases.

For chiral topological states, the splittings can be understood in terms of CFT, as outlined below, by considering certain conserved quantities in the chiral CFT describing the ES, which contribute to a Generalized Gibbs Ensemble (GGE) form for the reduced density matrix. Thus the entanglement Hamiltonian will incorporate not only the data of the CFT Hamiltonian itself, but also data on the locally conserved quantities of the theory of the CFT that obey the $SU(2)$ symmetry, as well as relevant discrete symmetries. These locally conserved quantities can be thought of as arising physically in the process\textsuperscript{10} of generating the reduced density matrix along the real-space entanglement cut and are a property of the underlying two-dimensional topological quantum state itself. (See below for a review of this process using the “conformal boundary state” formulation). Further, in Ref. 20, Cardy describes “semi-local” conserved quantities, integrals of operators with non-integer dimension, that should in general be present in the GGE. In sectors with twisted boundary conditions (such as, in a cylindrical geometry, those arising from threading the cylinder with topological flux, as shown in Fig. 1), these quantities take the form of integrals of local operators, commute with the Hamiltonian, and belong to the GGE along with other locally conserved quantities. We detail the contribution by these conserved quantities described by Cardy to the splittings in the half-integer spin sector of the chiral $SU(2)_2$ theory (which can be viewed as the Ramond sector of a theory with $N = 1$ supersymmetry). This is discussed in Sections III and IV.

We fit this description of the ES (which by construction is capable of describing the entanglement spectrum of any such chiral topological state) to numerically computed entanglement spectrum data of a variety of different states, all of which were observed to obey Li-Haldane counting, in Section V. What we find from these fits is that we can understand the numerical spectra very well using our approach, including the novel fractional dimension conserved quantities, which we show to be essential to the understanding of the entanglement spectra of chiral topological states described by the chiral $SU(2)_2$ WZW CFT. As mentioned above, this provides confirmation that the description of the bulk topological state by the corresponding topological field theory is correct for the systems considered, as the ES, \textit{including the splittings}, can be described entirely in terms of quantities of the CFT associated with that bulk topological field theory.

This approach also gives insight into the success of the various computational techniques
of the works considered here in capturing the chiral topological nature of the states in question. For instance, Refs. 14 and 15, whose work we discuss in Section V, use DMRG-based techniques, and we verify that they exhibit detailed splitting behavior in the entanglement spectrum that is consistent with the possibilities allowed by the construction of the entanglement Hamiltonian out of available terms in the GGE from the chiral CFT, thereby supporting the ability of these DMRG-based techniques to capture chiral topological behavior. The other two numerical entanglement spectra discussed in Section V, Refs. 16 and 17, are generated instead through the use of chiral projected entangled pair states (PEPS) tensor network techniques. There, too, our results support the ability of these (PEPS) techniques to capture chiral topological behavior.

PEPS tensor network techniques are a powerful general tool and the subject of considerable interest in their own right. Here, we consider in particular chiral interacting PEPS. However, non-interacting fermionic chiral topological PEPS (that is, non-interacting fermionic PEPS possessing a non-trivial Chern number) are known to obey a “no-go theorem”, stating that they cannot be ground states of local Hamiltonians gapped in the bulk. Thus, if a non-interacting fermionic chiral topological PEPS is the ground state of a local parent Hamiltonian, that Hamiltonian must be gapless in the bulk. Whether this “no-go theorem”, or a variation thereof, generalizes to interacting chiral topological PEPS is, to date, an open question. Our work can provide insight into this topic. For example, we consider the entanglement spectrum of the spin-1/2 PEPS investigated in Ref. 16 (shown, with our fit to the splittings, in Fig. 5). The observed finite size splittings of the entanglement spectrum can be very well understood by our approach, only using the information from the CFT. This analysis lends substantial support to the claim of chirality for the PEPS of Ref. 16, consistent with earlier work pointing toward chirality of this PEPS. Our approach also bolsters the evidence for chirality in the spin-1 PEPS of Ref. 17, where we find splittings characteristic of the non-Abelian chiral SU(2)2 theory, consistent with the observed Li-Haldane counting. In Ref. 17, as well as in other interacting PEPS that appear to be chiral based on Li-Haldane counting (including the PEPS of Ref. 25, which is similar to the PEPS found in Ref. 16, discussed above), it has been observed numerically that equal-time correlations of local operators in the PEPS quantum state appear to have long-range correlations. It is expected (see, e.g., Refs. 31,32) that this implies that local parent Hamiltonians of these PEPS would be gapless, which would be further evidence
FIG. 1. An infinite cylinder is bipartitioned into two sections $A$ and $\bar{A}$ by a circumferential (virtual) entanglement cut (in black). If the cylinder consists of a chiral topological bulk state, then by the result of Li and Haldane, the low-lying eigenstates of the entanglement Hamiltonian computed across the depicted entanglement cut are in a one-to-one correspondence with the low-energy states of the theory on the physical edge in real space that would be present if a physical, separating cut was made along the entanglement cut. An anyon flux of type $a$ is shown threaded through the cylinder.

in support of an interacting “no-go theorem”. Therefore, by providing additional evidence for chiral topological behavior in interacting PEPS, our approach shows the ability to help determine whether such a “no-go theorem” holds for interacting chiral topological PEPS.

II. STRUCTURE OF CHIRAL $SU(2)_k$ WESS-ZUMINO-WITTEN CFTS

The Hilbert space of a chiral $SU(2)_k$ WZW theory consists of $k + 1$ primary states and their descendants under the actions of elements of an affine $SU(2)$ current algebra. Each primary state and its descendants comprise a separate topological sector of the theory. Each descendant of a primary state has a particular level associated to it based on the elements of the current algebra used to specify the state. The descendant states, ordered by increasing level above the primary state, form “conformal towers” for each topological sector of the theory.

For $SU(2)_k$, we can denote each of the $k + 1$ primary states by its global $SU(2)$ spin
quantum number $j$, with the notation $|j = i/2\rangle$ for some integer $i = 0, \ldots, k$. The state $|j\rangle$ takes the form of the $(2j + 1)$-dimensional spin-$j$ representation of $SU(2)$. The descendant states in the conformal tower also obey the global $SU(2)$ symmetry, and we can therefore view all of them as $SU(2)$ multiplets of various dimensions. The pattern of multiplicities of these multiplets is characteristic of the theory. This structure is illustrated for the chiral $SU(2)_1$ WZW theory in Fig. 2. In the $SU(2)_1$ theory, there are two topological sectors, corresponding to $|j = 0\rangle$ and $|j = 1/2\rangle$ primary states, which are often referred to as the integer and half-integer sectors, respectively.

Our analysis will be done in a spatially circular geometry with fixed time coordinate, in which we take the affine $SU(2)$ currents $J^a(x)$ (where $a = 1, 2, 3$ is the index of the generator in the adjoint representation of $SU(2)$) to be periodic in the spatial coordinate $x$ around the circle: $J^a(x) = J^a(x + \ell)$, where $\ell$ is the circumference of the circle. The energy-momentum tensor $T(x)$ of the CFT can be related to the $J^a(x)$ by expressing $T(x)$ in the Sugawara form:

$$T(x) = \frac{1}{k + 2} \sum_{a=1}^{3} (J^a J^a)(x),$$

(2.1)

where we use $()$ around $J^a J^a$ to indicate normal ordering. We note that $T(x)$ will inherit the periodicity of $J^a(x)$: $T(x) = T(x + \ell)$. We can then write $T(x)$ in a mode expansion, as

$$T(x) = \left(\frac{2\pi}{\ell}\right)^2 \left(-\frac{c}{24} + \sum_{n=-\infty}^{\infty} L_{-n} e^{2\pi inx/\ell}\right),$$

(2.2)

where the central charge $c = \frac{3k}{k+2}$ for an $SU(2)_k$ WZW theory, and the $L_{-n}$ are the modes of $T(x)$. Thus we see that the Hamiltonian of this theory, which describes the left-moving states, will be

$$H_L = vp_L = \frac{v}{2\pi} \int_0^{\ell} T(x) dx = \frac{2\pi v}{\ell} \left(L_0 - \frac{c}{24}\right)$$

(2.3)

where $v$ is a (non-universal) velocity, $p_L$ is the left-moving momentum, and $L_0$ is the zero-mode of $T(x)$. From now on we will suppose $v = 1$ for simplicity, since the conclusions we draw will not depend on an overall scale factor. We can also write down a corresponding set of quantities for right-moving states: a Hamiltonian $H_R$ that is instead an integral of the conjugate energy-momentum tensor $\bar{T}(x)$, the right-moving momentum $p_R$, and $\bar{L}_0$ the zero-mode of $\bar{T}(x)$. The eigenvalue of $L_0$ (or $\bar{L}_0$) is the overall conformal dimension of the state on which it acts: the sum of the conformal dimension of the WZW primary state at the base of the relevant conformal tower and, if the state in question is a descendant of a
FIG. 2. A reproduction of the entanglement spectrum of Figure 4 from Bauer et al. (Ref. 14).

Two topological sectors are manifest, the integer in (a) and half-integer in (b), with conformal towers rooted respectively in the $|j = 0\rangle$ and $|j = 1/2\rangle$ primary states. Extending above these primary states in each blue-shaded subtower are their descendant states, all of which display $SU(2)$ symmetry across the indicated azimuthal quantum numbers written at the bottom of the subtowers. Within each subtower, indicated by vertical black lines up to the fourth descendant level, we have the 1-1-2-3-5 counting of states that are degenerate in momentum and under the pure CFT Hamiltonian. This state-counting pattern is characteristic of the Abelian chiral $SU(2)_1$ CFT.

Our Fig. 2 is taken from Figure 4 of the arXiv version: arXiv:1401.3017 [cond-mat.str-el].

WZW primary state, the level of that descendant state above the corresponding primary state. Therefore, all of the states in a given conformal tower at the same descendant level should be degenerate in energy under this CFT Hamiltonian, and since this is a conformal field theory, in momentum as well. The counts of these degeneracies are a characteristic marker of the CFT.

We can observe these degeneracies in numerical results. If this (1+1)D CFT on a circular spatial geometry is in fact the theory of each circular edge that arises from cutting, along
its circumference, an infinite cylinder home to a (2+1)D bulk topological quantum field theory, then the left- and right-moving momenta $p_L$ and $p_R$, and Hamiltonians $H_L$ and $H_R$, govern the left- and right-moving states along the respective edges created by that cut of the cylinder. The aforementioned degeneracies of the momenta and energy spectra will also be present.

The geometry of this setting is depicted in Fig. 1. As discussed in the introduction, the Li-Haldane correspondence means that these degeneracies will then appear in the low-lying (entanglement) energy levels of the real space entanglement spectrum computed with an infinite cylinder bipartitioned with a (virtual) entanglement cut in the same location as the physical cut determining the edge. Crucially, though, when this computation is done, as in the numerical work, for cylinders of finite circumference for the entanglement cut, the degeneracies in question appear only for momentum, but are split for the entanglement energies. To illustrate this with a particular example, we can consider Fig. 2, an entanglement spectrum exhibiting this characteristic pattern of degeneracies associated with the chiral $SU(2)_1$ WZW CFT. The degeneracies are present in momentum, but split in the entanglement energy levels of the spectrum. We will consider this particular entanglement spectrum in greater detail in Section V.

III. EXPLAINING ENTANGLEMENT SPECTRUM SPLITTING WITH LOCALLY CONSERVED QUANTITIES

As we saw in Fig. 2, in the real space entanglement spectra that we study, numerically computed at finite size, the states at the same descendant level are not all degenerate. Instead, we observe splitting of such states despite their common conformal dimension. Our goal is to gain control over the RSES, splittings and all. To do this, we need to re-examine the origin of the entanglement/edge correspondence that allows us to find the edge CFT data in the entanglement spectra in the first place.

Ref. 10 (as briefly summarized here below) understands the entanglement/edge correspondence in a bipartitioned cylindrical geometry (Fig. 1) from the point of view of a quantum quench, that for time $t > 0$ decouples the two Hamiltonians $H_L$ and $H_R$ of the
counter-propagating left- and right-moving physical edges produced by physically cutting
the cylinder along the entanglement cut. Then, the actual topological ground state $|G\rangle$ of
the system on the surface of the cylinder will serve as the $t = 0$ boundary condition of the
quench, i.e. the initial state. That short-range entangled (and short-range correlated) initial
state $|G\rangle$ can be represented as the state resulting from a coupling between the two counter-
propagating edges above (e.g., by relevant or marginally relevant operators), a process which
generates a gap. This initial state plays a dual role (see Refs. 10, 21, and 22): (i) on the one
hand, as described above, it can be viewed as the ground state of a CFT gapped by coupling
left- and right-movers, and (ii) it is at the same time a boundary condition on a gapless
CFT describing the initial state of the quantum quench after Wick-rotation to imaginary
time. That boundary condition itself undergoes a renormalization group (RG) flow, and is
controlled at large scales by a scale-invariant boundary fixed point. When formulated in the
language of a state in the Hilbert space of the bulk CFT, this fixed point is described by
what is known as a conformally invariant boundary state $|G_*\rangle$. That fixed point boundary
state is itself not immediately useful for representing the physical state $|G\rangle$ because, represent-
ing a fixed point, it turns out to be not normalizable. It can be given a finite norm by
slightly “deforming” this state by slightly moving away from the fixed point in the RG sense
by irrelevant boundary operators. The initial work by Cardy and Calabrese on quantum
quenches$^{34,35}$ made a particular (special) choice for this irrelevant boundary operator, which
they chose to be the energy momentum tensor of the CFT at the boundary; thus, they
represented the physical state $|G\rangle$ in terms of the fixed point conformally boundary state as

$$|G\rangle \propto e^{-\tau_0(H_L+H_R)}|G_*\rangle,$$

(3.1)

where $H_L$ and $H_R$ are the CFT Hamiltonians for left- and right-movers, which are precisely
the spatial integrals of the left- and right-moving energy-momentum tensors $T(x)$ and $\mathbf{T}(x)$,
respectively. The so-obtained state $|G\rangle$ turns out to be a purification of a thermal density
matrix (as reviewed below), where the “extrapolation length” $\tau_0$ plays the role of an in-
verse temperature, which sets the scale for the finite correlation length of all “equal time”
correlation functions of local operators in this state.$^{36}$

Furthermore, the topological sector of the theory on the surface of the cylinder depends on
the topological flux through the cylinder (Fig. 1). This will select as follows$^{10}$ a corresponding
sector in the entanglement spectrum we are interested in describing. In any so-called rational
CFT, such as those under consideration, all conformally invariant boundary states $|G_+\rangle$ turn out to be finite linear combinations of states $|G_+,a\rangle$, where $a$ denotes topological flux.\[37\] This leads to the obvious generalization of (3.1), namely $|G_+\rangle \propto e^{-\tau_0(H_L+H_R)}|G_+,a\rangle$, where $|G_+\rangle$ describes the ground state of the system in the topological flux sector $a$. We are interested in the reduced density matrix $\rho_{L,a}$ of the ground state $|G_+\rangle$ of the topological system in question where the half of the cylinder with the right-moving edge has been traced out. It turns out that under the assumption of (3.1), tracing out the half of the cylinder with the right-moving degrees of freedom yields\[10\]

$$\rho_{L,a} = \text{Tr}_R (|G_+\rangle\langle G_+|) \propto P_a e^{-4\tau_0 H_L} P_a,$$  

(3.2)

where $P_a$ is a projector onto the sector $a$. That is, the reduced density matrix has a thermal form with effective inverse temperature $\beta = 4\tau_0$. Then we would have an entanglement Hamiltonian simply proportional to the Hamiltonian $H_L$ of the left-moving chiral edge CFT (2.3) projected onto the sector $a$. As previously noted, though, under this Hamiltonian, all the states of a given conformal dimension are degenerate, so there must be additional terms in the entanglement Hamiltonian. Cardy has more recently argued\[20\] in the context of quantum quenches that one can generalize the assumption of (3.1) to include also conservation laws which are integrals of irrelevant local boundary operators $\Phi_i$ and $\Phi_i^\dagger$ (left- and right-moving, respectively) other\[38\] than the energy-momentum tensors $T(x)$ and $\overline{T}(x)$, leading to a Generalized Gibbs Ensemble (GGE):

$$|G\rangle \propto e^{-(\beta/4)(H_L+H_R)} \prod_i e^{-(\beta_i/4)\int [\Phi_i(x) + \overline{\Phi}_i(x)] dx} |G_+\rangle$$  

(3.3)

That is to say, we now introduce a more fine-grained ansatz to guide $|G\rangle$ closer toward the actual topological ground state on the surface of the cylinder by deforming $|G_+\rangle$ with a more complete set of irrelevant boundary operators$^{39}$. When we calculate the reduced density matrix $\rho_L$ by tracing out the right-moving parts of the above expression, we obtain a GGE form for $\rho_L$,

$$\rho_{L,a} = \text{Tr}_R (|G,a\rangle\langle G,a|) \propto P_a e^{-\beta H_L} \prod_i e^{-\beta_i\int \Phi_i(x) dx} P_a,$$  

(3.4)

where $\Phi_i(x)$ can be viewed as operators acting only on the left-moving boundary$^{40}$. This clarifies the cause of the splittings: additional locally conserved quantities $H^{(i)} = \frac{1}{2\pi} \int_0^L \Phi_i(x) dx$ in the theory, besides just the Hamiltonian $H_L$, are entering into the form of the reduced
density matrices \( \rho_{L,a} \). These may include integrals of such irrelevant operators as powers of the energy-momentum tensor \( T(x) \), e.g. \( \frac{1}{2\pi} \int dx (TT)(x) \), a hierarchy of integrals of motion that can be written down for a wide range of CFTs.\(^{41,42}\) Integrals of other available local operators of even integer conformal dimension will come in as well, however, and for the case of the chiral \( SU(2)_2 \) theory (in the topological sector where the boundary conditions allow them) we will also have integrals of operators with half-integer conformal dimension, a case discussed in Ref. 20. One example of these is the integral \( G_0 = \frac{1}{2\pi} \int dx G(x) \) of a chiral superconformal current operator \( G(x) \), analogous to that included in the hierarchy of integrals of motion in an \( N = 1 \) superconformal field theory.\(^{43}\) We will find that this same conservation law can be written down in the chiral \( SU(2)_2 \) theory, since it is known\(^{44–46}\) to possess \( N = 1 \) superconformal invariance.

The entanglement Hamiltonian is then extended by the addition of these conserved quantities, and we have (within a given sector, so we can suppress the subscripts \( a \))

\[
H_{\text{entanglement}} = -\log \rho_L = \sum_{i}^{\infty} \beta_i H^{(i)} = \beta H_L + \sum_{i \neq 1}^{\infty} \beta_i H^{(i)},
\]

where \( \beta_i \) are parameters chosen to properly match the initial conditions of the quench, and we take \( \beta_1 = \beta \) and \( H^{(1)} = H_L \). Thus, we explain the splittings by some linear combination of the locally conserved quantities \( H^{(i)} \).

**IV. CHOOSING THE LOCALLY CONSERVED QUANTITIES**

A crucial question in this effort is how to properly choose the locally conserved quantities \( H^{(i)} \) that go into our parametrization (3.5) of the entanglement Hamiltonian. These quantities \( H^{(i)} \) must both commute with the Hamiltonian \( H_L \) of (2.3) and, crucially, must preserve both the \( SU(2) \) symmetry of the CFT and any applicable discrete symmetries. For the systems we consider, the principal discrete symmetry in question is the \( \mathcal{RT} \) symmetry of the \( (1+1)D \) theory found in the entanglement spectrum that results from the symmetry of the \( (2+1)D \) theory under the composition of a spatial reflection through a plane parallel to the axis of the cylinder and time reversal. Further, in the case of each of the PEPS we consider, the \( \mathcal{RT} \) symmetry has been built into the PEPS wavefunction by construction. The details of the \( \mathcal{RT} \) symmetry can be found in Appendix B. We will not require our conserved quantities to commute among themselves as long as they commute with \( H_L \). One might rightly
worry about the issue of non-commutativity of the $H^{(i)}$ among themselves when taking the logarithm of (3.4) to obtain (3.5), but since our list of $H^{(i)}$ will be exhaustive of quantities that commute with $H_L$ and preserve $SU(2)$ and $\mathcal{RT}$ symmetry, we can simply reassign the $\beta_i$ as needed to account for the commutators. The requirement of global $SU(2)$ symmetry serves as a strong constraint on the irrelevant local operators whose integrals we can use for the $H^{(i)}$.

To simplify our calculations and to avoid a surfeit of parameters, we only consider integrals of local operators up to conformal dimension $\Delta = 6$. (Operators of higher conformal dimension, more irrelevant, will have less significant contributions to the spectral splittings, and could of course be incorporated if necessary.) At a given conformal dimension $\Delta$, we consider the complete list of all the independent $SU(2)$-symmetric operators of dimension $\Delta$ in the theory. The operators of this type available will exactly correspond to the $SU(2)$ singlet descendants of the primary states of the theory. For the $SU(2)_1$ WZW theory, the number of operators in that list is the number of $SU(2)$ singlet descendants of the identity (equal to the number of singlet descendants of the primary state $|j = 0\rangle$) with dimension $\Delta$. Because in the Abelian $SU(2)_1$ theory these singlet descendants can be constructed from $|j = 0\rangle$ using only the Virasoro modes of the energy-momentum tensor, these operators will consist only of combinations of the energy-momentum tensor $T(x)$ and its derivatives. We do, however, exclude total derivatives from the list of operators we consider, as their spatial integrals will not contribute given the periodicity of the cylinder. In fact, more strongly, the $\mathcal{RT}$ symmetry requires that we only include operators with even dimension $\Delta$, as it can be observed that an odd number of derivatives (necessary to obtain an odd $\Delta$ in the $SU(2)_1$ theory) will be odd under $\mathcal{RT}$, while all factors of $T(x)$ are even under $\mathcal{RT}$. A list of the operators $\Phi_i(x)$ we consider for the $SU(2)_1$ theory can be found in the leftmost column of Table I.

For the $SU(2)_2$ WZW theory, the picture is somewhat more complex. In this case, the $SU(2)$ singlets come in two sets: descendants of the $|j = 0\rangle$ primary state and descendants of the $|j = 1\rangle$ primary state. Descendants of the $|j = 0\rangle$ primary state correspond to operators that have integer conformal dimension, and include as a subset the operators we considered for the $SU(2)_1$ theory. Descendants of the $|j = 1\rangle$ primary state, on the other hand, correspond to operators that have fractional (half-integer) conformal dimension, and as we will see, we will only need to consider their effects within the $|j = 1/2\rangle$ sector where
Another view of these two types of operators is found by expressing the chiral $SU(2)_2$ WZW theory as a theory of three free real Majorana fermions, which we will denote by $\psi^a(x)$ for $a = 1, 2, 3$. (See e.g. Ref. 48.) We can relate the 3-fermion theory to the chiral $SU(2)_2$ WZW theory as described in Section II by writing the $SU(2)$ current $J^a(x)$ as

$$J^a(x) = -\frac{i}{2} \epsilon_{abc} : \psi^b \psi^c : (x), \quad (4.1)$$

where the :: indicates normal ordering. The 3-fermion theory possesses $N = 1$ supersymmetry. The sectors of the $|j = 0\rangle$ and $|j = 1\rangle$ primary states of the chiral $SU(2)_2$ theory correspond to the Neveu-Schwarz sector of the 3-fermion theory, while the sector of the $|j = 1/2\rangle$ primary state corresponds to the Ramond sector. Integrals of fermionic operators will contribute in the Ramond sector, but not the Neveu-Schwarz sector, due to the anti-periodic boundary conditions for fermionic operators in the Neveu-Schwarz sector. Thus one only needs to consider the effect of the fermionic operators in the Ramond sector. We, however, will not work with the three fermions $\psi^a(x)$ per se, but rather with bosonic spin-1 operators $\phi^a(x)$ of conformal dimension $\Delta = 1/2$ that possess identical “anti-commutation
relations” within the chiral theory and satisfy
\[ J^a(x) = -\frac{i}{2} \epsilon_{abc} : \phi^b \phi^c : (x). \] (4.2)

We can then additionally write down a current operator \( G(x) \) in terms of the \( \phi^a(x) \) operators, which has the same operator product expansion relations within the chiral theory as the superconformal current operator \( G(x) \) in Ref. 44:
\[ G(x) = \frac{i}{6} \epsilon_{abc} : \phi^a \phi^b \phi^c : (x). \] (4.3)

\( G(x) \) has conformal dimension \( \Delta = 3/2 \) (as it is composed of three of the \( \Delta = 1/2 \) operators \( \phi^a(x) \)). Furthermore, \( G(x) \) is an \( SU(2) \) singlet. \( G(x) \) corresponds to the lowest-level \( SU(2) \) singlet descendant in the \( |j = 1\rangle \) primary sector, and is thus one of the fractional dimension operators available in \( SU(2)_2 \). \( T(x), G(x), \) and combinations of both and their derivatives will comprise the set of all of the operators we consider in the \( SU(2)_2 \) theory. These are explicitly written up to conformal dimension \( \Delta = 6 \) in all the columns of Table I. The left two columns comprise the integer dimensional operators, those which contain an even number of half-integer dimensional factors (\( G(x) \) or its derivatives) and hence are periodic in, and therefore found in, all sectors. The right column contains the half-integer dimensional operators, which contain an odd number of factors of \( G(x) \) or its derivatives, and are only available to us in the \( |j = 1/2\rangle \) sector as discussed above. Note that the \( RT \) symmetry requires that we again exclude all operators with odd integer dimension \( \Delta \), including total derivatives of even integer dimensional operators. However, it turns out that \( G(x) \) is invariant under \( RT \) in the Ramond sector. Thus of the half-integer dimensional operators we consider, only \( (T \partial G)(x) \), where an odd number of derivatives are not multiplied by an \( i \) (which will become \(-i\) under the anti-unitary \( RT \)), will actually be wholly excluded from the entanglement Hamiltonian. This is indicated in Table I by a shaded cell.

For each of these operators \( \Phi_i(x) \), we compute the mode-expanded form of \( \tilde{H}^{(i)} = \left( \frac{\ell}{2\pi} \right)^{\Delta_i - 1} H^{(i)} \), where \( \Delta_i \) is the conformal dimension of \( \Phi_i(x) \), and so \( \tilde{H}^{(i)} \) is the form of the corresponding integral where we have removed the dependence on system size \( \ell \). The mode-expanded forms of the \( \tilde{H}^{(i)} \) can be found in Table II of Appendix A. Using the mode-expanded forms for the \( \tilde{H}^{(i)} \), \( H_{\text{entanglement}} \) of (3.5) is diagonalized on the space of descendant states of each of the \( k+1 \) CFT primary states, as described in Appendix A. For each primary state, this gives a method for finding the corrections to the spectrum of the corresponding
sector of the CFT in terms of the set of parameters $\{\beta_i\}$ of (3.5). As can be seen from Table I, this will give 4 free parameters $\beta_i$ for the $SU(2)_1$ case and 11 free parameters $\beta_i$ for the $SU(2)_2$ case. To test the ability of this method to fit the RSES data, we use ordinary least-squares to find the set of parameters that lead to corrections that best fit the numerical data. Details on the fitting procedure are found in Appendix C. The results of this fitting procedure are shown for a number of data sets in the plots below in the next section. Precise values of the parameters and statistics of individual fits are found in Tables III and IV of Appendix D.

V. RESULTS

We present fits to four different sets of numerical entanglement spectrum data, of which the first three represent an Abelian $SU(2)_1$ WZW theory, while the last represents a non-Abelian $SU(2)_2$ WZW theory. In each case, we consider a certain number of low-lying descendant levels of the numerical entanglement spectrum data, as typically, numerical results may be less reliable as we get to higher entanglement energies.

A. Entanglement spectra containing an $SU(2)_1$ WZW theory

The first fit is to the numerical entanglement spectrum of the Kalmeyer-Laughlin chiral spin liquid found in a Mott insulator on the kagome lattice with broken time-reversal symmetry by Bauer et al. in Figure 4 of their 2014 paper, Ref. 14. Bauer et al. employed the method of Ref. 50 to compute their spectrum, using infinite DMRG to optimize a variational MPS state on a cylinder of circumference $\ell = 12$ sites. They found a chiral $SU(2)_1$ WZW theory in that spectrum, and the degeneracies and resulting $SU(2)$ symmetry of the spectrum were cited as proof of that fact.\textsuperscript{14} We additionally fit the splittings of the first five descendant levels of the spectrum, as seen in Fig. 3. For the Bauer et al. data set, the fits are performed independently in both the integer and half-integer sectors.\textsuperscript{51} On the whole, while not perfect, we see that the fits are fairly successful in explaining the 11 splittings between the 12 multiplets in those levels with the 4 parameters available by considering the coefficients of the integrals of the 4 operators up to dimension $\Delta = 6$ in the $SU(2)_1$ theory (see Table I). In particular, the fits match the relative positioning of the different multiplets.
within each descendant level of the spectrum.

The second fit is to the numerical entanglement spectrum of the chiral spin liquid found in a Haldane-Hubbard Mott Insulator on the honeycomb lattice by Hickey et al. in Figure 3 of their 2016 paper, Ref. 15. Hickey et al. used infinite DMRG as well, on a cylinder with a circumference of $\ell = 8$ sites. They found a chiral $SU(2)_1$ WZW theory in that spectrum, and again, the degeneracies and resulting $SU(2)$ symmetry of the spectrum were cited as proof of that fact.\textsuperscript{15} Our fit of the splittings of the first five descendant levels of this spectrum is seen in Fig. 4. For the Hickey et al. data set, we are able to very successfully fit both integer and half-integer sectors simultaneously, with one set of parameters. In particular, the fit captures the relative positioning of the multiplets within each descendant level of the spectrum, in both the integer and half-integer sectors. The 22 splittings of the 24 multiplets of the first five levels in both the integer and half-integer sectors are explained with the 4 parameters available by considering the coefficients of the integrals of the 4 operators up to dimension $\Delta = 6$ in the $SU(2)_1$ theory (see Table I).

The third fit is to the entanglement spectrum of a particular chiral PEPS on an infinite cylinder by Hackenbroich et al. in their 2018 paper, Ref. 16. We fit the spectrum found in their Figure 14. Hackenbroich et al. worked with a cylinder of circumference $\ell = 8$. In this spectrum they cited the degeneracies and relative computed conformal weight of the $|j = 0\rangle$ and $|j = 1/2\rangle$ primary states as evidence for a chiral $SU(2)_1$ WZW theory.\textsuperscript{16} Fig. 5 is our fit of the spectrum. We are able to fit both sectors of the Hackenbroich et al. dataset simultaneously with great success, though a relative scale factor between the two sectors is used due to their possibly differing velocities $v$ in (2.3).\textsuperscript{16} We thus end up using 5 parameters—the 4 parameters available by considering the coefficients of the integrals of the 4 operators up to dimension $\Delta = 6$ in the $SU(2)_1$ theory (see Table I), plus the relative scale factor, to fit the 22 differences between the multiplets in the first five descendant levels (with 12 multiplets each) in both the integer and half-integer sectors. The fit is quite good, and certainly captures the relative positioning of the multiplets within each descendant level of the spectrum in both sectors.

The power of our approach was demonstrated by one phenomenon in the Hackenbroich et al. data: the highest-energy multiplet in the highest descendant level that we fit in the half-integer sector is not simply the next higher doublet at the same value of momentum, as the Brillouin zone of the spectrum is “folded” in the half-integer sector (as compared
to the integer sector—momenta are multiples of $2\pi/4$ instead of $2\pi/8$). This leads data from higher descendant levels to overlap with the data of the level we are trying to fit. Yet, by fitting the integer sector, we were able to determine an estimate of the correct parameters for the half-integer sector, as well. These parameters predicted where the final highest-energy doublet could be found. Indeed, there was a doublet present at that point in the entanglement spectrum, and so we were able to show the success of our fit for the Hackenbroich et al. dataset.

FIG. 3. Our fit to the $SU(2)_1$ entanglement spectrum data of Bauer et al. (Ref. 14) is shown in (a) the integer sector ($|j = 0\rangle$ primary state and descendants) and (b) the half-integer sector ($|j = 1/2\rangle$ primary state and descendants). The original data is indicated by black +’s, while red ×’s mark the fit produced by our approach. The black boxes indicate states with the same momentum $K$ (and hence the same descendant level above the corresponding primary state), while $SU(2)$ multiplets are grouped within each box. We attempt to fit 11 differences between multiplets in the integer sector and 11 differences between multiplets in the half-integer sector. For each sector, our approach uses 4 parameters: 4 coefficients $\beta_i$ in (3.5) for the conserved quantities corresponding to the 4 distinct operators of $\Delta \leq 6$ available in $SU(2)_1$ found in the left column of Table I. The data was computed with a cylinder of circumference $\ell = 12$.  

14
FIG. 4. Our fit to the $SU(2)_1$ entanglement spectrum data of Hickey et al. (Ref. 15) is shown in (a) the integer sector (|$j = 0$⟩ primary state and descendants) and (b) the half-integer sector (|$j = 1/2$⟩ primary state and descendants). The original data is indicated by black +’s, while red ×’s mark the fit produced by our approach. The black boxes indicate states with the same momentum $K$ (and hence descendant level above the corresponding primary state), while $SU(2)$ multiplets are grouped within each box. We attempt to fit 11 differences between multiplets in the integer sector and 11 differences between multiplets in the half-integer sector, i.e. a total of 22 differences. Fitting both sectors simultaneously, our approach uses 4 parameters: 4 coefficients $\beta_i$ in (3.5) for the conserved quantities corresponding to the 4 distinct operators of $\Delta \leq 6$ available in $SU(2)_1$ found in the left column of Table I. The data was computed with a cylinder of circumference $\ell = 8$.15
FIG. 5. Our fit to the $SU(2)_1$ entanglement spectrum data of Hackenbroich et al. (Ref. 16) is shown in (a) the integer sector ($|j = 0\rangle$ primary state and descendants) and (b) the half-integer sector ($|j = 1/2\rangle$ primary state and descendants). The original data is indicated by black +’s, while red ×’s mark the fit produced by our approach. The black boxes indicate states with the same momentum $K$ (and hence descendant level above the corresponding primary state), while $SU(2)$ multiplets are grouped within each box. We attempt to fit 11 differences between multiplets in the integer sector and 11 differences between multiplets in the half-integer sector, i.e. a total of 22 differences. Fitting both sectors simultaneously up to a scale factor, our approach uses 5 parameters: 4 coefficients $\beta_i$ in (3.5) for conserved quantities corresponding to the 4 distinct operators of $\Delta \leq 6$ available in $SU(2)_1$ found in the left column of Table I, plus a relative scale factor between the two sectors. Also, note that the entanglement energy vertical axes of these plots should not be taken to represent the same scale. The data was computed with a cylinder of circumference $\ell = 8$.16

B. Entanglement spectra containing an $SU(2)_2$ WZW theory

The fourth and final set of fits is to the entanglement spectrum of a PEPS aimed at representing a spin-1 chiral Heisenberg antiferromagnet defined on a square lattice by Chen et al. in their 2018 paper, Ref. 17. The spectra we fit are those of their Figures 11cd, which display numerical entanglement spectra computed on a cylinder of circumference $\ell = 6$.17 They obtained degeneracies and multiplet content consistent with a chiral $SU(2)_2$ WZW theory. Recall from Section II that the chiral $SU(2)_2$ WZW theory will have three primary states, $|j = 0\rangle$, $|j = 1/2\rangle$, and $|j = 1\rangle$, each with an associated topological sector of
descendant states. The Chen et al. data does not contain a clear representation of the $|j = 1\rangle$ sector. We perform several fits to the Chen et al. data.

In the first pair of fits, depicted in Fig. 6, we illustrate the necessity of including the conserved quantities corresponding to the half-integer dimensional operators (found in the rightmost column of Table I) in the fit. To show this, we fit the three lowest descendant levels of the $|j = 1/2\rangle$ sector only by two different approaches. In one approach, shown in Fig. 6(a), we use the conserved quantities corresponding to the first three integer dimensional operators from Table I available in $SU(2)_2$, up to $\Delta = 4$ ($T(x)$, $(TT)(x)$, and $i(G\partial G)(x)$), to fit the numerical spectrum. In the other approach, shown in Fig. 6(b), we use the conserved quantities corresponding to the first three operators available of both integer and half-integer dimension, up to $\Delta = 7/2$ ($G(x)$, $T(x)$, and $(TG)(x)$), to fit the numerical spectrum. In both approaches, there are 3 parameters available corresponding to the coefficients of the conserved integrals of the operators in question, which are used to fit the 6 differences present in the data for the first three levels of the $|j = 1/2\rangle$ sector. Yet it is clear from Fig. 6 that the second approach, which makes use of the two half-integer dimensional operators, produces a far better fit.

In the second fit, depicted in Fig. 7, we consider the first three descendant levels of both (in Fig. 7(a)) the $|j = 0\rangle$ and (in Fig. 7(b)) the $|j = 1/2\rangle$ sectors in tandem. We employ the conserved integrals of all integer and half-integer dimensional operators in the $SU(2)_2$ theory (all three columns of Table I) up to $\Delta = 4$ to fit the numerical spectra. The 2 half-integer dimensional operators will contribute to the fit in the $|j = 1/2\rangle$ sector only, while the 3 integer dimensional operators will contribute in both sectors. We thus fit the 4 differences between the multiplets of the first three levels of the $|j = 0\rangle$ sector and the 6 differences between the multiplets of the first three levels of the $|j = 1/2\rangle$ sector, for a total of 10 differences, with the 6 parameters available by considering the coefficients of conserved integrals of the 5 operators up to dimension $\Delta = 4$ in Table I, plus an additional relative scale factor between the two sectors. The fit is quite good in both sectors and correctly captures the relative positioning of multiplets within each level of both sectors.

In the third and final fit, found in Fig. 8, we consider a simultaneous fit of both (in Fig. 8(a)) the $|j = 0\rangle$ and (in Fig. 8(b)) the $|j = 1/2\rangle$ sector with all 11 unshaded operators of Table I (up to $\Delta = 6$). As before, the half-integer dimensional operators, of which there are now 4, will contribute in the $|j = 1/2\rangle$ sector only, while the 7 integer dimensional
operators will contribute to the fit in both sectors. This fit attempts to account for 9 differences between multiplets in the \( |j = 0\rangle \) sector and 14 differences between multiplets in the \( |j = 1/2\rangle \) sector, for a total of 23 differences between multiplets, using the 12 parameters available by considering the coefficients of conserved integrals of the 11 included operators up to dimension \( \Delta = 6 \) in Table I, plus an additional relative scale factor between the two sectors. The resulting fit is reasonable, especially in the lower levels. In each of the sectors, though, there are instances where the relative ordering of the multiplets has been changed in a few places in the higher levels.

That this occurs despite the use of all 11 operators with \( \Delta \leq 6 \) indicates that, at higher entanglement energies, the numerical entanglement spectrum for the particular system of Chen et al. begins to differ slightly from our expectations for a topological state with an entanglement spectrum exhibiting the chiral \( SU(2)_2 \) WZW theory. We did also perform a slight modification of this last fit that included the integral of \((T \partial G)(x)\) (the operator from Table I otherwise excluded due to the \( RT \) symmetry). The inclusion of this additional integral did not result in a significant improvement of the quality of the fit, consistent with the fact that the integral ought to be excluded.
FIG. 6. Two fits to the $SU(2)_2$ entanglement spectrum data of Chen et al. (Ref. 17) in the sector of the $|j = 1/2\rangle$ primary state and descendants are shown. The original data is indicated by black +’s, while red ×’s mark the fits produced by our approach. The black boxes indicate states with the same descendant level $K$ above the corresponding primary state, while states in the same $SU(2)$ multiplet are grouped within each box. We attempt to fit the 6 differences between multiplets in the 3 depicted levels of the $|j = 1/2\rangle$ sector, up to $K = 2$. The fits use 3 parameters corresponding to the coefficients $\beta_i$ in (3.5) for the conserved quantities corresponding to, in (a), the 3 integer dimensional operators with $\Delta \leq 4$ available in $SU(2)_2$ ($T(x)$, $(TT)(x)$, and $i(G\partial G)(x)$), and, in (b), the 3 integer and half-integer dimensional operators with $\Delta \leq 7/2$ available in $SU(2)_2$ ($G(x)$, $T(x)$, and $(TG)(x)$). (See Table I.)
FIG. 7. A fit to the $SU(2)_2$ entanglement spectrum data of Chen et al. (Ref. 17) is shown for the first three levels (up to $K = 2$) in (a) the sector of the $|j = 0\rangle$ primary state and descendants and (b) the sector of the $|j = 1/2\rangle$ primary state and descendants. The original data is indicated by black +’s, while red ×’s mark the fit produced by our approach. The black boxes indicate states with the same descendant level $K$ above the corresponding primary state, while $SU(2)$ multiplets are grouped within each box. We attempt to fit 4 differences in the $|j = 0\rangle$ sector and 6 differences in the $|j = 1/2\rangle$ sector. Fitting both sectors simultaneously up to a relative scale factor, our approach uses 6 parameters: 5 coefficients $\beta_i$ in (3.5) for conserved quantities corresponding to the 5 distinct operators of $\Delta \leq 4$ available in $SU(2)_2$ (see Table I), plus a scale factor, which corresponds to the relative scale of the two sectors. Also, note that the entanglement energy vertical axes of these plots should not be taken to represent the same scale.
FIG. 8. A fit to the $SU(2)_2$ entanglement spectrum data of Chen et al. (Ref. 17) is shown for the first four levels (up to $K = 3$) in (a) the sector of the $|j = 0\rangle$ primary state and descendants and (b) the sector of the $|j = 1/2\rangle$ primary state and descendants. The original data is indicated by black +’s, while red ×’s mark the fit produced by our approach. The black boxes indicate states with the same descendant level $K$ above the corresponding primary state, while $SU(2)$ multiplets are grouped within each box. We attempt to fit 9 differences in the $|j = 0\rangle$ sector and 14 differences in the $|j = 1/2\rangle$ sector. Fitting both sectors simultaneously up to a relative scale factor, our approach uses 12 parameters: 11 coefficients $\beta_i$ in (3.5) for included conserved quantities corresponding to the 11 distinct operators of $\Delta \leq 6$ available in $SU(2)_2$ (see Table I), plus a scale factor, which corresponds to the relative scale of the two sectors. Also, note that the entanglement energy vertical axes of these plots should not be taken to represent the same scale.

VI. CONCLUSION AND OUTLOOK

The results of Section V demonstrate the success of our approach to quantitatively understanding splittings in low-lying numerical entanglement spectra entirely within the framework of CFT, and thereby further support the chiral nature of the considered quantum states. We also note that such a success of the fits applies even more so to the chiral topological PEPS data of Hackenbroich et al. (Fig. 5). The results for the PEPS data from Chen et al., as well, are close to what we expect (Figs. 7 and 8), and these, as well as the results of Fig. 6, clearly illustrate the necessity of including the integrals of the half-integer dimensional operators of Table I. Because we are able to reproduce the splittings of the respective entanglement spectra at low energies, we are able to confirm, with more confidence
than based on the characteristic Li-Haldane countings of the chiral $SU(2)_1$ or $SU(2)_2$ WZW theory alone, that the PEPS entanglement spectra of Hackenbroich et al. and Chen et al., as well as the non-PEPS entanglement spectra we consider from Bauer et al. and Hickey et al., reflect the presence of an underlying (2+1)-dimensional chiral topological theory. Where the PEPS we considered are concerned, our analysis thus provides substantial support to the claim of the chiral topological nature of the corresponding PEPS wavefunctions. As mentioned, our analysis and approach also show the ability to help determine whether a “no-go theorem” holds for interacting topological PEPS.

As numerical methods for calculating the entanglement spectra of chiral topological states develop further, more data will become amenable to analysis by the approach developed in this work. The next target could perhaps be the chiral $SU(2)_3$ spin-liquid state, known to possess non-Abelian anyonic excitations capable of supporting universal quantum computation\textsuperscript{5,52}. This system will require the understanding of generalizations of the conserved quantities in this work, including those of half-integer dimension introduced in the context of $SU(2)_2$. The CFT of $SU(2)_3$, however, is known to possess fractional conservation laws\textsuperscript{53} (also referred to as “fractional supersymmetry”) which are a direct generalization of the (actual, non-fractional) $N = 1$ supersymmetry used in the present work to handle the $SU(2)_2$ case. Based on the present work, it is presumably to be expected that these more unusual fractional conservation laws will be needed to explain the splittings in the entanglement spectrum of the chiral topological $SU(2)_3$ spin-liquid. We leave the discussion of this to future work. Beyond that, it may also become worthwhile to extend this to more general $SU(N)_k$ spin-liquids such as those with $N > 2$, or $SU(2)_k$ spin-liquids with $k > 3$. Most such extensions will also require understanding generalizations of the conserved quantities discussed here, including those of fractional dimension, and potentially again including those found in Ref. 53.

**ACKNOWLEDGMENTS**

We thank Bela Bauer for useful discussions regarding the application of our method to chiral PEPS, as well as Norbert Schuch and Didier Poilblanc for interesting discussions regarding the spectra. We thank the authors of Refs. 15–17 for permitting us to use the relevant numerical entanglement spectra presented in their work for the analysis of those
spectra performed in this paper. This work was supported in part by the National Science
Foundation under Grant No. DMR-1309667 (AWWL).

Appendix A: Calculation of the Conserved Quantities

To compute the values of the conserved quantities we will use in the GGE, we first write
them in terms of the modes $L_n$ of $T(x)$ defined by (2.2), and the modes $G_n$ defined by a
similar mode expansion for the superconformal currents $G(x)$ of (4.3):

$$G(x) = \left(\frac{2\pi}{\ell}\right)^{3/2} \sum_{m=-\infty}^{\infty} G_{-m} e^{2\pi i m x/\ell}, \quad (A1)$$

where we will choose $m \in \mathbb{Z} + 1/2$ if the conserved quantity is to be used in the Neveu-
Schwarz sector (the sector of descendants of the $|j = 0\rangle$ and $|j = 1\rangle$ primary states),
and $m \in \mathbb{Z}$ if the conserved quantity is to be used in the Ramond sector (the sector of
descendants of the $|j = 1/2\rangle$ primary state). The expressions we get are collected in Table
II. For completeness, the table includes $\tilde{H}^{(5)}$, which is excluded from the entanglement
Hamiltonian by $\mathcal{RT}$ symmetry (indicated by the shading of the row), but we take the the
associated coefficient $\beta_5 = 0$ in the expression of the entanglement Hamiltonian as a linear
combination of conserved quantities in (3.5).

To find the spectral levels with our approach, we diagonalize the expression (3.5) using
these mode representations. This requires finding a basis to represent the descendant states
in each level of the conformal tower. We can define modes $J_{-n}^a$ of the affine $SU(2)$ current
$J^a(x)$ as well, writing

$$J^a(x) = \frac{2\pi}{\ell} \sum_{n=-\infty}^{\infty} J_{-n}^a e^{2\pi i n x/\ell}. \quad (A2)$$

For the Abelian $SU(2)_1$ case, in particular, we can then represent the central $j^z = 0$ or
$j^z = 1/2$ (depending on the sector) state of every descendant multiplet by a unique linear
combination of states with the form

$$J_{-n_1}^3 \cdots J_{-n_\ell}^3 |j, +j\rangle \quad (A3)$$

where $|j, +j\rangle$ is the highest-weight state in the $|j = 0\rangle$ or $|j = 1/2\rangle$ primary $SU(2)$ multiplets,
for some choice of positive integers $n_1 \leq \ldots \leq n_\ell$. The eigenvalue of $L_0$ on the state (A3)
will be equal to $h_j + \sum_{i=1}^\ell n_i$, where $h_j$ is the eigenvalue of $L_0$ on the primary state $|j, +j\rangle$. 28
\[ \tilde{H}^{(i)} \propto \int \Phi_i(x)dx \]

**TABLE II.** Expressions for the size-independent parts \(\tilde{H}^{(i)}\) of the corresponding locally conserved quantities \(H^{(i)}\) in terms of the Fourier modes \(L_n\) and \(G_n\) of the energy-momentum tensor \(T(x)\) and the superconformal currents \(G(x)\), respectively. The shaded row indicates that we will exclude \(\tilde{H}^{(5)}\) from fits on the basis of the \(\mathcal{RT}\) symmetry. The index \(i\) denotes the quantity the parameter \(\beta_i\) refers to, useful for comparison to Tables III and IV. \(\Delta_i\) indicates the conformal dimension of the operator \(\Phi_i(x)\) which is integrated to give \(H^{(i)}\). The symbols :: in the \(i = 6\) row indicate normal ordering by increasing subscripts \(n_1, n_2, n_3\). \(c\) is the central charge: \(c = 1\) for \(SU(2)_1\), while \(c = 3/2\) for \(SU(2)_2\). Note that while \(\tilde{H}^{(i)}\) with associated half-integer \(\Delta_i\) occur only in the Ramond \((|j| = 1/2)\) primary) sector, leading to modes \(G_m\) with integer \(m\), the \(\tilde{H}^{(i)}\) with associated integer \(\Delta_i\) can occur in both the Neveu-Schwarz \((|j| = 0)\) and \(|j| = 1\) primary) and Ramond sectors, leading to modes \(G_m\) with half-integer \(m\) in the Neveu-Schwarz sector and integers in the Ramond sector. Indices that are always integers have been denoted by \(n\) (or \(n_1\), etc.) above, while indices that vary between integers and half-integers depending on the sector have been denoted by \(m\).
(h_0 = 0, while h_{1/2} = 1/4.) The descendant level of the state is then given by just the sum \( \sum_{i=1}^{\ell} n_i \). We then use the Virasoro and affine Lie commutation relations along with the Sugawara form for \( L_n \) (the mode-expanded form of (2.1)) to evaluate the mode expressions of Table II corresponding to the integrals of the operators of the leftmost column of Table I on the basis of states (A3). This is possible because these mode expressions \( \tilde{H}^{(i)} \) are exactly those in Table II that include only Virasoro modes \( L_n \). The primary states of the chiral \( SU(2)_1 \) WZW theory are also Virasoro primary, in the sense that \( L_n|j, +j\rangle = 0 \) for all \( n > 0 \), which simplifies this process greatly. Diagonalizing an arbitrary linear combination of the \( \tilde{H}^{(i)} \) evaluated in that basis, we obtain an expression for the corrections to the \( SU(2)_1 \) conformal tower that we can fit to entanglement spectra.

It remains to identify each eigenvalue of the combined operator with a particular dimension of multiplet in the conformal tower. In the Abelian case, we take advantage of the symmetry of the conformal tower, and the fact that the mode expressions we use are expressed solely in terms of Virasoro modes. It turns out that in the \( SU(2)_1 \) theory, in addition to the WZW primary states, the lowest-level descendant \( SU(2) \) multiplet of a given dimension is also a Virasoro primary state.\(^{56}\) We can then write down an additional basis similar to (A3) for the states of descendant multiplets that have \( j^z = j + i \), for an integer \( i \geq 0 \):

\[
J_{-n_1}^3 \cdots J_{-n_r}^3 |j + i, j + i\rangle,
\]

where the notation \( |j + i, j + i\rangle \) now denotes the \( SU(2) \) highest-weight state in the lowest-level descendant spin-(\( j + i \)) multiplet. Because the \( |j + i, j + i\rangle \) states are Virasoro primary, acting on the elements of this basis with the mode expressions of the conserved quantities we need to evaluate in the \( SU(2)_1 \) theory (composed solely of Virasoro modes) does not require knowledge of the explicit form of the \( |j + i, j + i\rangle \) state in terms of the modes of the affine \( SU(2) \) current acting on the underlying WZW primary state \( |j\rangle \). Each basis (A4) at fixed \( i \) spans a section of the full \( SU(2)_1 \) conformal tower with fixed \( j^z = j + i \). For \( i = 0 \), \( j^z = j \), so the basis (A4) is simply the original Abelian basis (A3). The number of such bases at fixed \( i \) in which an eigenvalue of the conserved quantities occurs then determines the dimension of the \( SU(2) \) multiplet associated to that eigenvalue: if the eigenvalue occurs in \( s \) such bases in addition to (A3), the multiplet is a spin-\( s \) multiplet.

For the calculation in the non-Abelian \( SU(2)_2 \) theory, we can no longer use the Abelian basis (A3). Instead of building a similar non-Abelian basis from the modes \( J_n^a \), we take the
3-fermion theory point of view, though instead making use of the $\phi^a(x)$ of (4.2). We can define modes $\phi^a_{-m}$ by

$$\phi^a(x) = \left(\frac{2\pi}{\ell}\right)^{1/2} \sum_{m=-\infty}^{\infty} \phi^a_{-m} e^{2\pi i m x/\ell}. \tag{A5}$$

One non-Abelian basis is then

$$\phi^{a_{i_1}}_{-m_1} \cdots \phi^{a_{i_{\ell}}}_{-m_{\ell}} |\sigma\rangle, \tag{A6}$$

where $\sigma \in \{\text{NS}, \text{R}\}$ corresponds to the ground state of the Neveu-Schwarz or Ramond sectors, respectively. If $\sigma = \text{NS}$, $m_i \in \mathbb{Z} + 1/2$, whereas if $\sigma = \text{R}$, $m_i \in \mathbb{Z}$. In either case, $a_i \in \{1, 2, 3\}$. The Neveu-Schwarz sector of this theory corresponds to the $|j = 0\rangle$ and $|j = 1\rangle$ primary sectors of the $SU(2)_2$ WZW theory: states with an even number of $\phi^a_{-m}$ represent the descendants (by action of the affine current algebra) of the $|j = 0\rangle$ primary state, while states with an odd number of $\phi^a_{-m}$ represent the descendants of the $|j = 1\rangle$ primary state. The Ramond sector corresponds to the descendants of the $|j = 1/2\rangle$ primary state. The eigenvalue of $L_0$ on a state in the basis (A6) is given by $h_\sigma + \sum_{i=1}^{\ell} m_i$, where $h_\sigma = 0$ for $\sigma = \text{NS}$, and $h_\sigma = 3/16$ for $\sigma = \text{R}$. The descendant level of that state is then found by subtracting off the eigenvalue $h_j$ of $L_0$ of the corresponding primary state $|j\rangle$. For states in the $|j = 0\rangle$ and $|j = 1/2\rangle$ primary state sectors, this is simply $\sum_{i=1}^{\ell} m_i$, since $h_0 = h_{\text{NS}}$ and $h_{1/2} = h_{\text{R}}$. For the $|j = 1\rangle$ primary state sector, we have $h_1 = 1/2 = h_{\text{NS}} + 1/2$, so the level of the descendant state is given by $\sum_{i=1}^{\ell} m_i - 1/2$.

To obtain a basis that more directly reflects the multiplet structure of the theory, however, we diagonalize the operator $J_0^3$ (which can be expressed in terms of $\phi^a_m$ modes by the relation (4.2)) on the basis (A6) and use those eigenstates as the basis. The eigenvalues of $J_0^3$ can be thought of as $j^z$ quantum numbers. We can then diagonalize linear combinations (3.5) of the conserved quantities corresponding to the mode representations of Table II (which can be algorithmically re-written in terms of the $\phi^a_m$ modes) in each of the fixed-$j^z$ sectors formed by that basis. The presence of a given eigenvalue across $2s + 1$ fixed-$j^z$ sectors is used to associate that eigenvalue with a spin-$s$ multiplet.
Appendix B: $\mathcal{RT}$ Symmetry Mechanism

We consider a chiral topological state arranged in the cylindrical geometry of Fig. 9. The infinite cylinder is bipartitioned into two regions $A$ and $\bar{A}$, with an entanglement cut between them. The coordinate $x_1$ is the compactified spatial coordinate around the cylinder, which has circumference $\ell$, while the coordinate $x_2$ denotes spatial position along the cylinder. The region $A$ is thus the half-cylinder $x_2 \geq 0$, while the region $\bar{A}$ is the half-cylinder $x_2 < 0$. The entanglement cut lies along $x_2 = 0$. We can then define an orientation-reversing spatial transformation that preserves the position of the entanglement cut:

$$\mathcal{R} : (x_1, x_2) \mapsto (-x_1, x_2)$$

$\mathcal{R}$ reflects the cylinder about the violet plane in Fig. 9, mapping region $A$ into region $A$ and region $\bar{A}$ into region $\bar{A}$.

This reflection reverses the orientation of the cylinder, so it inverts the chirality of the chiral topological state, in the sense that, among other things, the associated chiral edge modes, if one were to physically cut the cylinder along the entanglement cut, would reverse their direction of flow. We can restore the system to its original state if we follow spatial
reflection with a time-reversal transformation $\mathcal{T}$, which will also reverse the direction of flow of the chiral edge modes. This gives rise to the discrete symmetry we will consider, $\mathcal{RT}$, under which we consider our system to be invariant.

2. The $\mathcal{RT}$ Symmetry in the PEPS

At the level of the square-lattice PEPS wavefunctions we consider in the $SU(2)_1$ (Ref. 16) and $SU(2)_2$ (Ref. 17) cases, we can see the $\mathcal{RT}$ invariance explicitly. The projectors onto the PEPS, which are the building blocks of the PEPS wavefunctions, take the form of either $A_1 + iA_2$ or $B_1 + iB_2$, where $A_1$, $A_2$, $B_1$, and $B_2$ are linear combinations of projectors that transform like the $A_1$, $A_2$, $B_1$, and $B_2$ irreducible representations, respectively, under the actions of the elements of $C_{4v}$ point group of the square lattice. The consequence of this is that under the action of $\mathcal{R}$, we have

$$A_1 \mapsto A_1, \quad A_2 \mapsto -A_2, \quad B_1 \mapsto B_1, \quad B_2 \mapsto -B_2. \quad (B2)$$

At the same time, $A_1$, $A_2$, $B_1$, and $B_2$ are all real, and therefore invariant under $\mathcal{T}$. Thus the only effect of the antiunitary $\mathcal{T}$ is to conjugate the $i$ in $A_1 + iA_2$ or $B_1 + iB_2$:

$$A_1 + iA_2 \mapsto A_1 - iA_2, \quad B_1 + iB_2 \mapsto B_1 - iB_2. \quad (B3)$$

Thus $A_1 + iA_2$ and $B_1 + iB_2$ are both invariant under $\mathcal{RT}$.

3. The Action of $\mathcal{RT}$ Symmetry on the Conserved Quantities of the Entanglement Hamiltonian

We thus see that whether we think of an abstract chiral topological state or the concrete PEPS we are working with, we will have invariance of the overall density matrix $\rho$ under $\mathcal{RT}$. Since the $\mathcal{RT}$ symmetry preserves $\rho$ and maps $A \mapsto A$ and $\tilde{A} \mapsto \tilde{A}$, we can see that the reduced density matrix $\rho_A = \text{Tr}_A \rho$, which may be compared to (3.4), will be preserved under $\mathcal{RT}$. Hence, the entanglement Hamiltonian $H_{\text{entanglement}} = -\ln \rho_A$, (3.5) in our case, should likewise be invariant under $\mathcal{RT}$. As a consequence, we demand that the $H^{(i)}$ of (3.5) satisfy

$$(\mathcal{RT}) H^{(i)} (\mathcal{RT})^{-1} = H^{(i)}. \quad (B4)$$
We can deduce the action of $\mathcal{RT}$ on the $H^{(i)}$ by considering its action on the modes of the various operators. First, we consider the effect of $\mathcal{RT}$ on the left-moving energy-momentum tensor $T(t, x)$, the energy-momentum tensor of our chiral theory, expressed as a function of the time coordinate $t$ and compact spatial coordinate $x$ ($x_1$ in the notation of Fig. 9, since $T(t, x)$ is an operator in the $(1 + 1)$-dimensional theory along the cut). Conjugating by spatial reflection $\mathcal{R}$ alone, we have that

$$\mathcal{RT}(t, x)\mathcal{R}^{-1} = T(t, \ell - x) = T(t, -x)$$  \hspace{1cm} (B5)

$$\mathcal{RT}(t, x)\mathcal{R}^{-1} = T(t, \ell - x) = T(t, -x),$$  \hspace{1cm} (B6)

where $T(t, x)$ indicates the energy-momentum tensor of the right-moving theory, and we have used the spatial periodicity of $T(t, x)$ and $T(t, x)$ around the cylinder in the last equality. Likewise, time reversal gives

$$\mathcal{T}T(t, x)\mathcal{T}^{-1} = \overline{T}(-t, x)$$  \hspace{1cm} (B7)

$$\mathcal{T}\overline{T}(t, x)\mathcal{T}^{-1} = T(-t, x).$$  \hspace{1cm} (B8)

We can then use the scaling property of the $\Delta = 2$ operator $T(t, x)$ to see that

$$(\mathcal{RT})T(t, x)(\mathcal{RT})^{-1} = T(-t, -x) = (-1)^2 T(t, x) = T(t, x)$$  \hspace{1cm} (B9)

$$(\mathcal{RT})\overline{T}(t, x)(\mathcal{RT})^{-1} = \overline{T}(-t, -x) = (-1)^2 \overline{T}(t, x) = \overline{T}(t, x).$$  \hspace{1cm} (B10)

Thus $T(t, x)$, and hence the $T(x)$ we have considered at fixed time, remains invariant under conjugation by $\mathcal{RT}$. By similar logic, we have for the affine $SU(2)$ currents $J^a(t, x)$ that

$$(\mathcal{RT})J^a(t, x)(\mathcal{RT})^{-1} = J^a(-t, -x) = (-1)^1 J^a(t, x) = -J^a(t, x)$$  \hspace{1cm} (B11)

$$(\mathcal{RT})\overline{J}^a(t, x)(\mathcal{RT})^{-1} = \overline{J}^a(-t, -x) = (-1)^1 \overline{J}^a(t, x) = -\overline{J}^a(t, x),$$  \hspace{1cm} (B12)

where in the last equalities of (B11) and (B12) we have used the scaling property of the $\Delta = 1$ operator $J^a(t, x)$. Now the invariance of $T(x)$ extends to its modes, and so we have

$$(\mathcal{RT}) L_n(\mathcal{RT})^{-1} = L_n.$$  \hspace{1cm} (B13)

From (B11) we can likewise conclude that the modes $J^a_n$ of (A2) will obey

$$(\mathcal{RT})J^a_n(\mathcal{RT})^{-1} = -J^a_n$$  \hspace{1cm} (B14)
under conjugation by $\mathcal{RT}$.

We observe that (B13) and (B14) are consistent with the commutation relations\(^{33}\) of the $J_n^a$,

\[ [J_n^a, J_m^b] = i \epsilon_{abc} J_{n+m}^c + \frac{k}{2} n \delta_{n+m,0}, \quad (B15) \]

and the Sugawara relation (2.1). (2.1) and (B13) require that we must have one of $(\mathcal{RT}) J_n^a (\mathcal{RT})^{-1} = \pm J_n^a$, but only the minus sign of (B14) is also consistent with (B15). This is due to the anti-unitarity of $\mathcal{RT}$, which causes $(\mathcal{RT})^i (\mathcal{RT})^{-1} = -i$ to flip the sign of the $i$ upon conjugation of both sides of (B15) by $\mathcal{RT}$. In the $|j = 1/2\rangle$ primary sector, $J_0^a$ acts\(^{33}\) on the $|j = 1/2\rangle$ doublet like $\sigma^a/2$, where $\sigma^a$ is the $a$th Pauli matrix,\(^{59}\) and we have

\[ J_0^a |j = 1/2\rangle^\alpha = \frac{\sigma^a_\alpha}{2} |j = 1/2\rangle^\beta, \quad (B16) \]

where $|j = 1/2\rangle^\alpha$, for $\alpha = \pm$, indicates the $|1/2, \pm 1/2\rangle$ state (in the notation of (A3)) within the $|j = 1/2\rangle$ doublet.

We now examine the effect of $\mathcal{RT}$ on the $\phi_0^a$ modes. Group theory guarantees that the $\phi_0^a$ modes act\(^{33}\) on the $|j = 1/2\rangle$ primary state as $\sigma^a/\sqrt{2}$.\(^{60}\) Up to normalization, this is the same as (B16), and so we see that we must also have

\[ (\mathcal{RT}) \phi_0^a (\mathcal{RT})^{-1} = -\phi_0^a, \quad (B17) \]

since the $J_0^a$ obey (B14). The $\phi_0^a$ satisfy commutation relations with the modes $L_n$ of the energy-momentum tensor,

\[ [L_n, \phi_m^a] = -\left( \frac{n}{2} + m \right) \phi_{n+m}^a. \quad (B18) \]

When $m = 0$, this becomes

\[ [L_n, \phi_0^a] = -\frac{n}{2} \phi_n^a. \quad (B19) \]

From (B13) and (B17), we know how the left hand side of (B19) transforms, and therefore it follows that for integer indices $n$,

\[ (\mathcal{RT}) \phi_n^a (\mathcal{RT})^{-1} = -\phi_n^a, \quad (n \in \mathbb{Z}). \quad (B20) \]

Note that the derivation of (B20) relies upon $n \in \mathbb{Z}$, i.e. that we are in the $|j = 1/2\rangle$ primary sector, which is the Ramond sector for the $\phi_n^a$. This is because the indices of the $L_n$ in (B19) can only take integer values. In the $|j = 0\rangle$ and $|j = 1\rangle$ primary sectors, which are the Neveu-Schwarz sector for the $\phi_n^a$, the indices of the $\phi_n^a$ will instead take half-integer
values. There the fractional dimension operators will be anti-periodic in space, and so the conjugation by $\mathcal{R}$ will have the opposite sign. Thus we instead obtain

\[(\mathcal{RT})\phi_n^a(\mathcal{RT})^{-1} = \phi_n^a, \ (n \in \mathbb{Z} + 1/2). \quad (B21)\]

From (4.3), (B20), and (B21), we thus deduce that the superconformal current modes $G_n$ satisfy

\[(\mathcal{RT})G_n(\mathcal{RT})^{-1} = G_n, \ (n \in \mathbb{Z}) \quad (B22)\]

\[(\mathcal{RT})G_n(\mathcal{RT})^{-1} = -G_n, \ (n \in \mathbb{Z} + 1/2), \quad (B23)\]

in the Ramond and Neveu-Schwarz sectors, respectively.

Taking (B13) and (B22) into account, we can see that of the conserved quantities in Table II, only $H^{(5)}$ (considered, of necessity, in the Ramond sector) will fail to satisfy (B4), due to the effect of the anti-unitarity of $\mathcal{RT}$ on the imaginary coefficient. This analysis is done in terms of the modes, useful for considering the conserved quantities themselves, but the translation to the corresponding local operators of which they are the integrals (i.e. the contents of Table I) is straightforward.

**Appendix C: Discussion of Fitting Algorithm**

Above, we have discussed how we compute the splittings of entanglement spectra of chiral topological states that feature an $SU(2)_1$ or $SU(2)_2$ WZW theory in the entanglement spectrum by incorporating the linear combination of terms with conserved integrals of irrelevant local operators (3.5). We now discuss how we determine the optimal values of the parameters $\beta_i$ in that linear combination.

For a given set of numerical entanglement spectrum data, we choose the GGE parameters $\beta_i$ that best fit that spectrum. Within each topological sector of the entanglement spectrum, we calculate the eigenvalues of the linear combination of operators as a function of the $\beta_i$ and order those eigenvalues in increasing order of, first, descendant level, then multiplet dimension, and finally value. We write the $\ell$th element of that ordered list as $\xi_{\ell}^{\text{fit}}(\{\beta_i\})$. We order the actual entanglement spectrum data by the same criteria, and write the $\ell$th element of that ordered list as $\xi_{\ell}^{\text{data}}$. We can then write a fitting function of the chosen GGE
parameters in the $|j\rangle$ primary sector:

$$R_j (\{\beta_i\}) = \sum_\ell \left[ \xi_{\ell}^{\text{data}} - \xi_{\ell}^{\text{fit}} (\{\beta_i\}) \right]^2 W_\ell, \quad \text{(C1)}$$

where $W_\ell$ is a weight associated to the $\xi_{\ell}$. We set the weights $W_\ell$ so that the states at each descendant level have, collectively, the same weight in the fit, with $W_\ell \propto \frac{1}{N_\Delta}$, where $N_\Delta$ is the number of states at descendant level $\Delta$, and $\Delta_\ell$ is the descendant level of the $\ell$th state from the spectral data. The weights $W_\ell$ are normalized, however, so that $\sum_\ell W_\ell = 1$.

We then minimize either the individual $R_j (\{\beta_i\})$ for each sector of descendants of each primary state $|j\rangle$, or, in the case of a simultaneous fit of multiple sectors, the sum $\sum_j R_j (\{\beta_i\})$ of the $R_j (\{\beta_i\})$ over all the relevant sectors. The method used for minimization is Mathematica’s \texttt{NMinimize} function. The results of this minimization are the plotted results of Section V, Figs. 3-8. The corresponding values of the $\tilde{\beta}_i$ can be found in Tables III-IV of Appendix D.

We note that the \texttt{NMinimize} function may not always find the exact global minimum of the function that we attempt to minimize. We believe, however, that the minimizing sets of $\tilde{\beta}_i$ reported here reflect local minima which are representative, in the sense that the globally minimal fits would not be substantial improvements in fitting the data. In cases where we do obtain very good fits, this is necessarily true. But even in the more difficult case of the $SU(2)_2$ data from Chen et al., e.g. in Fig. 8, the consistency of our results with the exact $\mathcal{RT}$ symmetry, as described at the end of Section V B, gives us confidence in this conclusion.

**Appendix D: Fitting Parameter Data**

Tables III and IV exhibit the numerical values of the parameters that were actually used in our approach to generate the best-fit results of the figures of Section V. Since our calculations on the CFT Hilbert space are done using the integrals of motion with size-dependence divided out $H^{(i)} = \left( \frac{\ell}{2\pi} \right)^{\Delta_i-1} H^{(i)}$, we end up computing corresponding size-dependent parameters $\tilde{\beta}_i = \left( \frac{2\pi}{\ell} \right)^{\Delta_i-1} \beta_i$. Essentially, we rewrite (3.5) as

$$H_{\text{entanglement}} = \tilde{\beta} \tilde{H}^{(1)} + \sum_{i \neq 1} \tilde{\beta}_i \tilde{H}^{(i)}. \quad \text{(D1)}$$

To remove arbitrary factors of scale, the $\tilde{\beta}_i$, which determine the splitting within a descendant level, have been normalized by dividing by $\tilde{\beta}$, which is the parameter that determines
the distance between descendant levels as the coefficient of $\tilde{H}^{(1)} = \frac{\ell}{2\pi} H_L$ in (D1). Tables III and IV also note the value of the corresponding fitting function $R_j (\{\beta_i\})$ of (C1) for the best fit that was achieved for the given data. Since $R_j (\{\beta_i\})$ is a sum of the squares of the distances between the data and our fit, we have normalized $R_j (\{\beta_i\})$ by dividing by $\tilde{\beta}^2$.

TABLE III. The values of the fitting function $R_j (\{\beta_i\})$, along with the associated normalized numerical values of the $\tilde{\beta}_i$ (where $\tilde{\beta}_i$ is the parameter corresponding to the $i$th conserved quantity of Table II) that were calculated for the best fits to the $SU(2)_1$ data of Section V A. The fits to the data of Hickey et al. and Hackenbroich et al. were performed simultaneously in both sectors, minimizing the sum of the $R_j (\{\beta_i\})$, and so the parameter values of the $\tilde{\beta}_i$ are the same in both sectors for those fits.
We set $\tilde{\beta}_5 = 0$ due to the exclusion of $\tilde{\mathcal{H}}^{(5)}$ by the $\mathcal{RT}$ symmetry.

$^a$ We set $\tilde{\beta}_5 = 0$ due to the exclusion of $\tilde{\mathcal{H}}^{(5)}$ by the $\mathcal{RT}$ symmetry.

**TABLE IV.** The values of the fitting function $R_j (\{\tilde{\beta}_i\})$, along with the associated normalized numerical values of the $\tilde{\beta}_i$ (where $\tilde{\beta}_i$ is the parameter corresponding to the $i$th conserved quantity of Table II) that were calculated for the best fits to the $SU(2)_2$ data of Section V B. Note the substantial improvement in $R_j (\{\tilde{\beta}_i\})$ of Fig. 6(b) relative to Fig. 6(a) that was achieved by fitting with the half-integer dimensional conserved quantities $\tilde{\mathcal{H}}_0$ and $\tilde{\mathcal{H}}_2$ instead of the integer dimensional conserved quantities $\tilde{\mathcal{H}}_3$ and $\tilde{\mathcal{H}}_4$. The fits of Figs. 7 and 8 were performed simultaneously in both sectors, minimizing the sum of the $R_j (\{\tilde{\beta}_i\})$, and so the parameter values of the $\tilde{\beta}_i$ corresponding to integer dimensional conserved quantities are the same in both sectors for those fits. Half-integer dimensional conserved quantities were only used for the $|j = 1/2\rangle$ sector, so the corresponding $\tilde{\beta}_i$ are marked by — in the $|j = 0\rangle$ sector. The data is from Chen et al. (Ref. 17), with size $\ell = 6$.

28 Ref. 62 sees a gapless chiral entanglement spectrum in the thermodynamic limit ("dispersion law"), as depicted in their Figure 27.
That correlation length goes to zero as the fixed point is approached when \( \tau_0 \to 0 \), in line with the expectation of the absence of a scale at a fixed point.

These states are maximally entangled states between the left- and the right-moving descendants of a primary in the bulk CFT Hilbert space\(^{63}\).

The additional boundary operators should be such that they are boundary limits of purely chiral (holomorphic or anti-holomorphic) bulk operators.

The actual ground state on the surface of the cylinder of any such two-dimensional chiral topological system can be fully represented in this manner, upon inclusion of a sufficient number of operators \( \Phi_i(x) \) and \( \bar{\Phi}_i(x) \).

As an aside, we remark that in the usual quantum quench problem one wishes to describe the expectation value of a product of a finite number of bulk operators of the CFT, each of which consists of a left- and a right-moving part, after waiting a sufficiently long (real) time. Such information is contained in the reduced density matrix for a bipartition of position space into a compact spatial interval \( A \) containing the locations of the finite number of operators, and its complement \( \bar{A} \). Under (real) time-evolution, such a density matrix relaxes\(^{20,64}\) into the thermal density matrix or GGE density matrix on the interval \( A \). The bipartition in the situation we consider here, in contrast, is that between left- and right-moving degrees of freedom, and the reduced density matrix in our (3.2) and (3.4) is obtained by performing a trace over the right-moving degrees of freedom. This density matrix reflects the left-right entanglement of the boundary state \( \left| G_a \right\rangle \).

In contrast to the \( \psi^a(x) \) and their antichiral counterparts \( \bar{\psi}^a(x) \), which anticommute with each other, \( \phi^a(x) \) and \( \bar{\phi}^a(x) \) actually commute with each other. Within the chiral (antichiral) theory,
though, \( \phi^a(x) \) and \( \psi^a(x) \) (\( \bar{\phi}^a(x) \) and \( \bar{\psi}^a(x) \)) will behave the same way in correlation functions (see, e.g., Ref. 65.).

51. Attempts to fit both sectors simultaneously resulted in some of the very highest-energy multiplets in the highest descendant level considered not according with our expectations based on the set of parameters that successfully fit the low-energy part of the spectrum.

54. Strictly, we ignore the constant terms in the expressions of Table II, which would only amount to an overall shift in the spectrum, and diagonalize a linear combination with respect to parameters that multiply each set of (possibly repeated) terms that occur in Table II. A simple linear transformation, however, relates these parameters to the \( \beta_i \) of (3.5).

56. We can see this by considering the effect of acting with any Virasoro mode \( L_n \) for \( n > 0 \) on a state \( |\phi\rangle \) of the multiplet. Because the mode \( L_n \) is a singlet under \( SU(2) \), \( L_n|\phi\rangle \) must be a state with the same \( j^z \) quantum number in a multiplet of the same dimension, but at a lower level. As there is no such state, it must be the case that \( L_n|\phi\rangle = 0 \). In the \( SU(2)_1 \) theory, the 1-1-2-3-5 counting of states in the subtowers of the highest-weight states of these Virasoro primary multiplets and their descendants also guarantees the uniqueness of such multiplets within the descendant levels in which they appear (see e.g. Fig. 2.).

58. Expanding (B9) in terms of modes, we obtain \( \sum_{n=-\infty}^{\infty} (\mathcal{R}\mathcal{T})L_n(\mathcal{R}\mathcal{T})^{-1}e^{2\pi inx/\ell} = \sum_{n=-\infty}^{\infty} L_ne^{2\pi inx/\ell} \), and since \( (\mathcal{R}\mathcal{T})e^{2\pi inx/\ell}(\mathcal{R}\mathcal{T})^{-1} = e^{2\pi inx/\ell} \), this means that \( (\mathcal{R}\mathcal{T})L_n(\mathcal{R}\mathcal{T})^{-1} = L_n \).

59. The normalization can be found by comparing the commutation relations of the Pauli matrices \( \sigma^a, [\sigma^a, \sigma^b] = 2i\epsilon_{abc}\sigma^c \), with (B15).

60. The \( \phi_n^a \) modes must satisfy the anti-commutation relations \( \{\phi_n^a, \phi_m^a\} = \delta_{n+m,0} \). The normalization of the action of the \( \phi_0^a \) modes on the \( |j = 1/2\) primary state may be found by comparison with the Pauli anti-commutation relations \( \{\sigma^a, \sigma^b\} = 2\delta_{ab}I \).
In terms of the operators \( \phi^a(x) \), we have \( R\phi^a(x)R^{-1} = \bar{\phi}^a(\ell - x) \) and \( R\bar{\phi}^a(x)R^{-1} = \phi^a(\ell - x) \), analogous to (B5). In the Ramond sector, where \( \phi^a(x) = \phi^a(\ell + x) \) and \( \bar{\phi}^a(x) = \bar{\phi}^a(\ell + x) \) are periodic, this works out to \( R\phi^a(x)R^{-1} = \bar{\phi}^a(-x) \) and \( R\bar{\phi}^a(x)R^{-1} = \phi^a(-x) \), as in (B5). In the Neveu-Schwarz case, on the other hand, \( \phi^a(x) = -\phi^a(\ell + x) \) and \( \bar{\phi}^a(x) = -\bar{\phi}^a(\ell + x) \) are anti-periodic, so \( R\phi^a(x)R^{-1} = -\bar{\phi}^a(-x) \) and \( R\bar{\phi}^a(x)R^{-1} = -\phi^a(-x) \), leading to the relative minus sign of (B21).

---

61 In terms of the operators \( \phi^a(x) \), we have \( R\phi^a(x)R^{-1} = \bar{\phi}^a(\ell - x) \) and \( R\bar{\phi}^a(x)R^{-1} = \phi^a(\ell - x) \), analogous to (B5). In the Ramond sector, where \( \phi^a(x) = \phi^a(\ell + x) \) and \( \bar{\phi}^a(x) = \bar{\phi}^a(\ell + x) \) are periodic, this works out to \( R\phi^a(x)R^{-1} = \bar{\phi}^a(-x) \) and \( R\bar{\phi}^a(x)R^{-1} = \phi^a(-x) \), as in (B5). In the Neveu-Schwarz case, on the other hand, \( \phi^a(x) = -\phi^a(\ell + x) \) and \( \bar{\phi}^a(x) = -\bar{\phi}^a(\ell + x) \) are anti-periodic, so \( R\phi^a(x)R^{-1} = -\bar{\phi}^a(-x) \) and \( R\bar{\phi}^a(x)R^{-1} = -\phi^a(-x) \), leading to the relative minus sign of (B21).
