Abstract

We designed and performed a participatory sensing initiative to explore the reliability and effectiveness of a distributed network of citizen-operated smartphones in evaluating the impact of environmental noise in residential areas. We analyzed noise level measurement data collected by participants from home and correlated them with contextual information and subjective comfort ratings referring to different situations, times and environments. We show how to strengthen methods and procedures, particularly regarding the calibration of the devices, in order to make similar citizen-science efforts effective and useful at monitoring environmental noise as a contribution to planning long-term solutions to human well-being.
Introduction

Monitoring acoustic environments requires substantial dedicated human and material resources. Assembling a large number of densely sampled observations over the whole national territory is a difficult and expensive task. In fact, a single institution can acquire the hardware and perform proper calibrations up to few class 1 measuring devices. The use of smartphones has been proposed as a cost-effective method for assembling networks of environmental noise detectors. In the last decade several participatory sensing initiatives were launched to explore the possibility of exploiting the capillary diffusion of digital technologies and to empower citizens to collaborate with scientists.

NoiseTube was the first acquisition app developed together with a geo-localization platform meant for passive systematic monitoring to report daily noise data acquired by the users [1]. Several other apps and initiatives followed. The NoiseSpy app [2] allows collaborative collection and visualization of urban noise levels in real-time. The City-Sense [3] and Beyond The Noise [4] projects moved steps forward to a more comprehensive definition of soundscape and acoustic comfort in public places and the identification of quiet areas in an urban context. NoisePlanet (http://noise-planet.org) aims at collective sensing and modeling through a community of contributors. Data and maps collected with the NoiseCapture were made publicly available [5]. Large amounts of geolocalized data were also collected worldwide within EveryAware (http://www.everyaware.eu), a project meant to collect citizen-science initiatives in several different environmental fields. For extensive reviews on the topic see [6,7].

The reports of previous experiences show that participatory sensing campaigns are prone to weaknesses that must be taken into consideration and, possibly, minimized [8,9]. First, app retention is known to be low (the majority of participants performs only very few measurements), therefore projects relying on long term participation are unlikely to succeed. Also the lighter and easier to install the app is, the greater is the probability of download and use. Second, while the majority of people just perform at most one or two measurements,
very few participants tend to contribute a large number of measurements, i.e. there is a serious risk of biasing the results. Third, the hardware-software reliability is not trivial to keep under control, given the fast-paced development of smartphones, and the increasing variety of producers on the market. Last, performing environmental noise measurements is a deceptively simple task, also due to the large amount of inaccurate “dB measurement apps” available on the market [10]. Untrained participants may turn into a huge source of meaningless data if not properly instructed.

In our design we tried to minimize the impact of all of these issues. The campaign had a limited time span, and all of the measurements were taken from fixed locations (participants’ homes). This was a convenient choice, also considering that anti-pandemics restrictions severely affected mobility in Italy during 2020. Therefore we focused on measuring indoor noise affecting residential areas only. Since GPS localization would violate participants’ privacy we decided not to rely on existing networks, and we developed a new, less privacy-invasive, protocol, collecting, beside common information about sound sources, also specific information about the premises and their neighborhood. Giving up geolocalization has an impact on the spatial resolution of the data. Our initiative definitely did not aim at compiling noise maps, a goal that would require a much more detailed description of the locations. Fortunately, the median size of Italian municipalities is very low (around 2500 inhabitants), and the (few) large urban territories are partitioned by postal codes, therefore our resolution is the minimum territorial partition provided by either identifier. Usually it corresponds to the municipality territory. In our protocol neither the values, nor the location and subjective data are uploaded to a central server by the app. This feature completely disentangles participants’ sensitive information from the activity, and guarantees complete privacy. Adding an intermediate step, makes the procedure more prone to transcription errors. However, in the following we will show that this was just a minor issue in our campaign. Moreover, a detailed fact sheet was made available including a step-by-step guide for taking measurements and sending data and a series of specific insights to
contextualize the experiment (what is sound, how is it measured, what is noise pollution, what can be measured with smartphones and what are the limits of the instrument).

Participants were left free to make as many measurements as they wished at home to grasp the general features and dynamics of their local acoustical environment, but they were finally requested to send only two records representing extreme situations (i.e. the noisiest and the quietest in their environment). These choices avoided the complications of outdoor measurements, in which extra care must be taken to avoid spurious effects due to wind, reflections, refractions, etc..

Several authors investigated whether smartphones can be reliably employed as sound level meters. [11] reported mean square root errors in instantaneous measurements of urban noise less than $3 \text{dB}(A)$ when phones are calibrated with a constant correction. [12] assessed the effects of different apps, and found some to be appropriate for occupational noise measurements. [13] found that iOS platforms are superior to Android ones in a reverberation room test. [14] reported a measurement error standard deviation below 1.2 $\text{dB}(A)$ within a wide range of noise levels. [15] showed that a sound level meter app and an external microphone can achieve compliance with most of the requirements for Class 2 of IEC 61672/ANSI S1.4-2014 standard.

However the reliability of smartphones and related apps as sound measurement tools in an out-of-lab context depends on a variety of factors such as quality of hardware and software, operating system, age and condition. A smartphone can work as a Sound Level Meter (SLM), provided the proper software is installed, with inherent limitations due to the fact that the quantities of interest, such as LAeq, are obtained by computation from a sampling of the audio input. Smartphones are not designed for metering. They are optimized to output voice and possibly music in the best cost-effective way [16]. However, with the use of external microphones, a limited number of calibrated detectors equipped with effective logging software can be set up [17].

The calibration of professional SLMs is checked on the field by fitting the microphone to a calibration source. Plugging an external microphone in the analog input could work, but
it is not practical for everyday users. A method has been proposed [18] to calibrate the internal microphone using environmental noise as a source, but it requires a calibrated microphone as well, and requires sampling a certain amount of data in order to achieve proper averaging of the spectral response.

A common issue to all mobile crowd-sensing initiatives is that data collected by many users employing random devices and running different SLM softwares might turn out to be nearly useless due to poor reliability [19]. Here, we choose the open source SLM software OpeNoise, developed by one of the authors [17,20]. We focused in the first place on comparing different situations, thus giving more relevance to differential data, which are less affected by calibration issues. However the app itself allows to adjust a device-dependent single parameter gain; in post processing, a subset of data was corrected for the gain, when known. In this way data can be examined in “dual mode”, which offers the advantage of allowing cross-validation to some extent (see discussion below).

A citizen-science initiative such as this one offers several societal and educational benefits [21], such as: Impacting citizens’ perception of the value of scientific data by directly involving them in a scientific research project; contributing to education in STEM area by providing basic information about sound and its measurement and making people aware of the difficulties in making reliable measurements; spreading knowledge of the merits and limits of measuring sound with smartphones; contributing to alleviate negative effects of COVID-19 lockdown. Moreover, the involvement of pupils and teachers belonging to the compulsory education compartment is fundamental in ensuring equal opportunities for inclusion in the experiment of people from every social status, and, by the way, it avoids that the sample is biased, e.g., by people owning the most expensive smartphones, or living in privileged contexts. Last, but not least, the possibility of empowering citizens to take an active part in environmental issues, potentially affecting their health, is in line with EU directive 2003/35/EC.

It was decided to initially propose the experiment first in Bergamo, one of the provinces most affected by the first wave of COVID-19 in Italy. In collaboration with the
BergamoScienza science festival, between October 12 and 14 2020 the experiment was presented to a dozen schools with a live broadcast in which we explained the purpose of the experiment and provided instructions to participate. The feedback obtained from the first measurements were useful to fine tune the protocols before the national launch, which took place on October 19 with a live broadcast within the program of the National Geographics Science Festival in Rome and on the social channels of the Communication and Public Relations Unit of the Cnr. Data were collected from Oct 19 until Nov 15, during this period several social relaunches were made to involve more people to participate. About a month after the end of the experiment, a new live broadcast was organized to share some preliminary results with the public who participated in the campaign. Further details about the communication actions are provided in the Supplementary Information.

Materials and methods

The instructions, additional information and didactical materials for teachers and students were distributed through a dedicated website [22], where a Google form was made available to send the collected data. The terms and conditions of use of the form clearly stated that no personal data were being collected and that compiling and sending the form represented the user’s consent to use the data for research purposes only, as explained in the information material available on site. Furthermore the OpeNoise privacy statement clarifies that the app does not record or share any personal data, it does not record audio and does not acquire information about the localization of the smartphone. On the same page a browsable world map displayed all the collected measurements in real time, allowing people to navigate raw data. Particular care was put in the instructional material to stress factors that could render the measurements invalid. It was clearly explained how to handle the smartphone with extreme care, to properly identify and direct the microphone, to be aware of interfering noises both from the inside and the outside of the house, and it was recommended to reset and repeat the measurement in case something went wrong.
Performing the experiment required a smartphone, paper and pen, installing the OpeNoise app and following the instructions articulated in three phases (see Supplementary Text for the detailed protocol): **Phase I** (preparation and awareness): familiarizing with the app and becoming aware of the acoustical background in participants’ homes; **Phase II** (colloquially named “measuring noise”): performing indoor noise level measurements from an open window and recording the observations together with subjective comfort ratings. Then select two records corresponding to the subjective quietest and noisiest states experienced and send them via the online form. **Phase III** (optional, colloquially named “measuring silence”): perform an indoor measurement of the quietest background with all windows shut.

Considering the difficulties in performing an accurate calibration on the field we asked participants not to apply gain corrections to the OpeNoise app. The optional background measurement (Phase III) was performed by about half of the participants (247 records received). This fact allowed us to check the reliability of correcting ex post the smartphone gains, based on a previous calibration campaign performed in a lab controlled environment (see the discussion below).

**Results**

A total of 492 records containing 1258 measurements were received. 91% of the records were compiled by high-school students 14 to 18 years old.

Participants contributed data from 12 Italian regions (out of 20). 59% of the records originated from two northern regions (Emilia-Romagna and Lombardia) whose combined population is 24% of the total Italian population. The median population of the municipalities in which the participants declared to live was 17198. The largest cities contributing were Torino (over 887000 inhabitants, 46 records received) and Genova (about 586000 inhabitants, 43 records received). 49% of the participants declared to live in an area with high population density, 42% in an area with low population density, and 9% in isolated
premises (e.g. rural or mountain areas, etc.). Overall 73% of the measurements were performed from windows overlooking places open to the public such as public streets, squares, etc.; the remaining 27% overlooked inner spaces such as private backyards or gardens. 81% of the measurements were performed within the height of the second floor. 36% of the smartphones employed were made by Apple running iOS, the remaining 64% were from mixed brands running Android (33% Samsung, 16% Huawei, 10% Xiaomi, etc.). These figures approximately reflect the Italian smartphone market shares [23].

Road traffic noise was the most frequently cited source of noise overall (33%). However the frequency of occurrence is different in the subsets of measurements referring to noisy and quiet states. In quiet situations natural sounds are the most frequent (35%) followed by road traffic (27%), unidentified (14%) and outdoor anthropogenic (12%), while in noisy situations road noises are most frequently identified as the main source (40%), followed by outdoor anthropogenic (21%), natural (13%) and inner anthropogenic (11%). Other sources are mentioned in less than 6% of the records in both situations. The ratio of traffic/industrial to natural/undefined sources decreases from 5:1 in noisy states to almost 1:1 in quiet states (see Supplementary Figure S1).

The records were first screened for major inconsistencies. 33 records were discarded because they contained duplicated data or impossible measurements (such as $L_{A\text{min}} > L_{A\text{max}}$, $L_{A\text{eq}} < L_{A\text{min}}$, etc.). 14 records reported lower comfort ratings for the quiet state than for the noisy state, together with lower noise levels in the quiet state. These records are not necessarily wrong as a louder environment could be judged more comfortable than a quieter one under some circumstances, but not enough information was provided to investigate the reasons for these anomalies, so they were removed. In 70 cases (which contained valid data) the attribution to noisy and quiet states appeared to be inverted (i.e. both lower comfort rating and higher $L_{A\text{eq}}$ were attributed to the quiet state and vice versa). The labels for noisy and quiet states in these records were swapped. 16 records reported a suspiciously small time interval (\(\leq 1\) min) between the recording of the noisy and quiet states. However, since the inclusion of these records did not subvert the conclusions of this
work, we choose to keep them in the mix. An independent set of consistency checks was performed on the sound level values in both Phase II and Phase III (see discussion below). In sum 93% of the records were considered valid, which demonstrates a remarkable collaboration effort by participants.

Discussion

Analysis of comfort ratings

Comfort was rated on a scale from 1 (less comfortable) to 5 (more comfortable). The distribution of the overall ratings (Figure 1) is skewed towards high values (i.e. high comfort). 55% of the records rate comfort >= 4, 25% comfort = 3, and 20% comfort <= 2. The mean rating for quiet states is 4.2, and 72% of the ratings are >= 4. The mean rating for noisy states is 2.8 and 30% of the ratings are <= 2. The mean comfort score during daytime (3.4) is lower than at night (4.1) (see Supplementary Figure S2).

These data reassure us that situations of acoustical discomfort are way less frequent than situations of comfort, which is of course desirable in a residential context. Note that, while the attribution to noisy or quiet state only defines the two extreme states at the participant’s location, comfort ratings indicate the participant’s subjective perception of comfort. For a given location it’s very likely that the quiet state will be rated more comfortable than the noisy state, however it may happen that the two extreme states are perceived as both comfortable or both uncomfortable. The examination of the asymmetry in the ratings sheds light on this point.

While in quiet situations high comfort ratings are dominant (4 and 5 cover 84% of the data, 1 is never used), the ratings for noisy situations are much more variable: ratings 2, 3 and 4 are used with similar frequencies (25%, 36%, 22%), and even 5 is used in 4% of the cases (see Figure 1). This implies that noisy scenarios actually correspond to a variety of perceptions, not necessarily strongly associated with discomfort.
The mean comfort score for quiet states ($N = 445, M = 4.2, SD = 0.8$) is higher than that for noisy states ($N = 445, M = 2.8, SD = 1.1$).

Measurements referring to quiet states are more frequently performed from rooms facing private spaces than public places open to traffic (56% vs 48%). However the mean comfort ratings are very similar (3.6 vs 3.5), probably indicating that participants considered inner-facing rooms of their homes *a priori* more representative of quiet states.

**The mean comfort scores in both quiet and noisy states appear to be decreasing with increasing population density.** However, while the difference between mean comfort scores of isolated and highly populated places is always sizeable, places with a low population density are rated more acoustically comfortable than highly populated areas only in noisy situations (difference = 0.49), while they are almost equivalent in quiet
situations (difference = 0.1) (see Supplementary Figure S3). A more in-depth analysis about the sources of noise is therefore in order.

The distribution of the mean comfort scores by source (see Supplementary Figure S4) shows a very interesting feature: despite some sources (such as air traffic) being reported too rarely to be relevant, the order of sources ordered by decreasing comfort is almost exactly the same in both low and quiet states, with natural sources being associated to the highest comfort and industrial sources to the lowest one.

Having found how sources are associated with mean comfort, we can examine how often each source is mentioned in a given population density environment. We find (see Supplementary Figure S5) that the occurrence of road traffic noises increases monotonically with increasing population density. Natural sources show the opposite trend. Indoor anthropogenic sources are cited with similar frequency of occurrence in all environments. Noise from undefined sources is more frequently reported from low-density and Isolated places in quiet situations.

This body of data clarifies the similarities noted above between low-density and high-density places in noisy states as they contain an equal fraction of road traffic. In quiet states, on the other hand, low-density places and isolated places share an equal fraction of natural or unidentified sources, which are overall rated among the most comfortable.

Analysis of differential noise levels

Raw (uncalibrated) data can be analyzed only as differences between noise levels measured with the same smartphone. Since each participant contributed two measurements per record sent (corresponding to the noisiest and quietest state at his/her location) we can study level differences neglecting calibration issues at first, assuming that the sources do not induce strong frequency-dependent nonlinearities in the responses.

The distribution of $\Delta L_{Aeq} = L_{Aeq}(quiet) - L_{Aeq}(noisy)$ for different values of $\Delta comfort = comfort(quiet) - comfort(noisy)$ quantifies the change in the perceived comfort between the two extreme states in each observer’s home (see Supplementary...
Figure S6). When there is no difference in the perceived comfort the median LAeq is correctly found to be not significantly different from 0 dB(A). This is a very good indicator of data consistency.

A linear model (see legend of Supplementary Figure S6) suggests that Delta LAeq decreases with increasing difference in the perceived comfort at a rate of 5.9 dB(A) per point of comfort loss 95% CI: [-6.7, -5.1] dB(A). This figure can be compared with calibrated values below as a validation that applied gains are correct.

Great care was taken in instructing participants about how to minimize extraneous noises originating from inside their own home, or due to smartphone mishandling, however, during a 1 min measurement, LAeq may be legitimately driven by sudden external events. This is reflected by Pearson’s correlation between LAeq and LAmax, which is 0.94 in our dataset, while LAeq and LAmi correlation are 0.64 in noisy and 0.74 in quiet states. Exploiting this fact the occurrence of disturbing events can be inferred by studying the distribution of LAeq - LAmi. The spread of this distribution (see Supplementary Figure S7) decreases monotonically with increasing comfort, confirming that disturbing events occur less frequently the quieter the environment is. Since LAmax and LAeq are strongly correlated, and LAmax - LAmi is an estimator of impulsive noise, these data show that the comfort rating is also directly affected by the annoyance of impulsive noise.

Gain corrections and measurements of the background

The measurement of the quietest background noise experienced indoors (in the quietest room, with windows shut) was proposed with a twofold aim: on one hand to explore the possibility of applying a simple calibration scheme prepared beforehand; on the other hand to identify possible unexpected behaviour in some models of smartphones.

Model-dependent additive constant gain corrections were applied to the raw LA values (see Supplementary Table S1). The corrections were obtained comparing the noise levels measured by the smartphone and a Class-1 sound level meter, using pink noise with sound levels in the range from 50 to 80 dB(A). Each value reported per producer/model is
referred to a single smartphone tested; the variability in the gain response between the same models has not been investigated, except for the iOS ones. Remarkably, it turns out that gain corrections for different iOS models are the same (within 1 dB) probably due to a strict standardized manufacturing process.

The inspection of the 267 resulting records showed a marked difference in the reliability at low noise levels between iOS and Android based smartphones. The minimum of the distribution of values for iOS-based smartphones is 26 $dB(A)$, with a very sharp mode at 28.6 $dB(A)$.

![Figure 2. Dispersion of calibrated LAeq for the quietest background. The values were obtained by adding to the raw LAeq the gains reported in Supplementary Table S1.](image-url)
Android smartphones behaved differently. Median and dispersion of Samsung smartphones (Md = 33.4, IQR = 16.2 dB(A)) are comparable to the ones of Apple smartphones (Md = 32.6, IQR = 12.9 dB(A)), even if 6 values are smaller than the Apple minimum. This probably indicates that the applied gain is incorrect for these models. The misalignment could be either due to a mistake in the model classification (some models come in several versions sharing the main name and differentiating by a suffix such as “Pro”, “Extra”, “Plus”, etc., that were neglected) or to a dependence of the gain on the specific version of the operating system (which was not tracked). Five records employing non-Samsung smartphones reported values < 20 dB(A) or even negative values. Either these are cases of mistyped values, or these smartphones are out of their linear operating range, and are unable to capture the noise level of an extremely quiet environment regardless of the gain correction. The measurements performed with these models were considered unreliable and discarded.

In contrast with measurements of Phase II (which are mostly louder than the quietest background) Pearson’s correlation between LAeq and LAmin in Phase III is very high (0.88). This fact indicates that the measurements were overall much less affected by sudden disturbing events than in Phase II. Nevertheless, even considering Apple smartphones only, it is clear from Figure 2 that about half of the background measurements were disturbed by sudden noises in Phase III, confirming that the measurement of a quiet background requires extra care to be performed. Nevertheless 75% of the values were < 41.4 dB(A).

Analysis of calibrated noise levels

With the information obtained from gain correction in Phase III we now turn back to calibrating noise measurements from Phase II. After discarding the records already considered unreliable in Phase III we corrected raw values of LAeq with the same calibration set employed above (Supplementary Table S1).
After calibration fewer extreme noise levels were left, being worth a closer look. Nine LAeq values were below 25 \textit{dB(A)}, which are incompatible with the results of Phase III, as we have seen that the lowest possible threshold in this dataset is 26 \textit{dB(A)}, considering sufficiently reliable the results obtained from iOS-based smartphones (see [13]). All of them refer to the same smartphone model, a circumstance that suggests that this is probably a case of wrong model classification, for which the applied calibration is just not appropriate. These values were removed from the dataset.

In 19 cases LAeq was > 75 \textit{dB(A)}, with a median LA\text{max} of 93 \textit{dB(A)}. In some of them participants complemented the measurement with a comment that justifies such high values. For example: LAeq = 76.6 \textit{dB(A)}: “heavy property renovation in the neighbor’s apartment”; 76.7: “ambulance”; 77.7: “leaf blowing during road cleaning”; 79.7: “heavy traffic on the motorway”; 80.0: “car accident”. It is clear that these readings describe specific events. Some of them appear to be accidental, and are not particularly representative of the average acoustic environment, but in some other cases they might be recurring, thereby substantially contributing to the acoustical perceived wellness in the area where they were observed. In this experiment these cases cannot be further distinguished.

After applying calibration and removing unphysical readings below 26 \textit{dB(A)} a total of 432 measurements were left to be analyzed. Figure 3 shows the distribution of LAeq attributed to quiet and noisy states. The median gain-corrected LAeq are 49.1 \textit{dB(A)} in \textbf{noisy and 41.5 dB(A) quiet situations}. Interestingly, these values are very close to the threshold values below which "every effect" of noise is considered negligible by Italian regulations. In fact, according to the Ministerial Decree setting threshold values for noise pollution [24], if the noise level measured indoor with open windows does not exceed 40 \textit{dB(A)} at night or 50 \textit{dB(A)} during daytime, further analysis based on differential noise levels is not necessary.

Both distributions in Figure 3 have a peak centered at about 46 \textit{dB(A)}. Around this level about half of the measurements are attributed to a quiet state and half to a noisy state. Noises with LAeq sound levels greater than this threshold are more likely to be classified as
noisy than quiet. We interpret the ratio between noisy attribution to the total number of measurements per 3 dB(A) bin as the average probability that environmental noise is rated as annoying. Within a dynamic range in which calibrated smartphones appear to behave linearly (40 - 80 dB(A)) this relationship can be expressed as $P[\text{not quiet}] / \% = 1.08 \times \text{LAeq} / \text{dB(A)}$, with 95% CI: [0.98, 1.15] (see Supplementary Figure S8). This relation only provides averaged information over all of the different types of noise experienced in which the measurements were taken. It might also be thought as an estimation of annoyance, bearing in mind the caveat [25] that subjective annoyance also depends on temporal and spectral features of sound as well as on day-time or night-time.

**Figure 3.** Distribution of LAeq for noisy and quiet states. Thick black lines show median values. A few outliers are visible on the right side of the quiet state distribution. The outliers
below 26 dB were considered due to inappropriate calibration and were removed from the dataset.

The symmetry of the distributions in Figure 3 requires a comment. The shape for noisy states shows a heavier tail towards high LAeq, as expected, while the distribution for quiet states (aside from a few outliers, which represent sudden events), is clearly bimodal. Besides the peak in common with the noisy distribution around 46 dB(A), another dominant feature appears at 30 dB(A). Decomposing the plots further into their night and day projections clarifies the origin of this peculiar shape.

Actually the adequacy of the 50/40 dB(A) day/night thresholds can be put to a test by the data we collected. In Figure 4 the cumulative fraction of records reporting a high level of comfort (4 or 5) are plotted as a function of the corresponding measured LAeq. The fractions corresponding to the nominal threshold are highlighted. During day-time 82% of the reports are below 50 dB(A), and the curve shows a clear change in slope, confirming that this threshold is fully adequate. The fraction for night time is slightly lower (69%), and no pronounced change in the slope is visible at this value, suggesting that the night-time threshold could be more questionable, but the sample size at this time is quite lower, producing larger uncertainty, so no certain conclusion can be drawn at this stage.
Figure 4. Cumulative fraction of records reporting high comfort levels (4 or 5) as a function of the corresponding measured LAeq. Respectively 82% and 69% of the records refer to sound levels below thresholds of annoyance as established by Italian regulations (i.e. 50 dB(A) during day-time and 40 dB(A) at night). Error bars indicate 95% confidence intervals, which are [76%, 87%] for day-time and [56%, 81%] for night-time data. Sample sizes are N = 211 (daytime) and N = 51 (nighttime).

Factors affecting noise levels and annoyance

The median LAeq at night (37.6 dB(A)) is 8.9 dB(A) lower than the daytime median LAeq. However, median LAeq in quiet nights is 10.8 dB(A) lower than in noisy ones, and median LAeq in quiet daytime is 6.3 dB(A) lower than noisy daytime (see Supplementary Figure S9). This decomposition shows that the feature at 30 dB(A) only
appears on quiet nights while a large plateau of values between 30 and 50 $dB(A)$ appears on quiet days. Identifying the sources of noise helps understanding these features.

The analysis of LAeq distribution by sources in 3 $dB(A)$ bins shows (Figure 5) that road traffic explains about half of the peak around 46 $dB(A)$ in both quiet and noisy states (see also Supplementary Figure S10 for a split version of this plot). The other half in quiet states mostly comes from natural sounds, while in noisy states it has mixed origins. Road traffic has a much larger level spread in noisy states than in quiet states. Together with outdoor anthropogenic sources it is the main contributor at all LAeq levels.

Natural noise is largely dominant in quiet states. Unidentified background noise is basically only present in quiet states, and is the main contribution to the peak at 30 $dB(A)$. To find the reason why noise from unidentified sources at low LAeq is so frequently reported we must examine how noise levels are distributed by population density.
Analyzing levels by population density (Supplementary Figure S11) clarifies two aspects. First, it turns out that the huge peak at 30 dB(A), which we have determined to be characteristic of quiet nights, is only observed in low-density places. This is reasonable, since, in quiet nights, those places are most likely reached by noise not made locally (e.g. noise coming from faraway roads, industrial plants, human activities, etc.). A further explanation of this peak could be related to the intrinsic limits of most smartphones which, in practice, cannot measure lower levels. Second, it unravels the role of road traffic noise in different contexts.

Road traffic is present both in low and high-density areas, however the level distribution is quite different. A high volume of road traffic in low-density places produces

**Figure 5.** Distribution of LAeq in low and high comfort states. The color code indicates the sources in each 3 dB(A) wide bin.
lower median noise levels ($46.2 \text{ dB}(A)$) than in high-density ones ($51.1 \text{ dB}(A)$). On the contrary, a low volume of road traffic, in low-density places produces higher median noise levels ($46.1 \text{ dB}(A)$) than in high-density ones ($43.4 \text{ dB}(A)$). Outdoor anthropogenic noise shows a similar trend.

**Association between noise levels and comfort ratings**

We have already seen that a direct relationship between differential noise levels and differences in comfort ratings is demonstrated by the collected data. Studying calibrated values we can also show that a similar association exists between absolute LAeq and absolute comfort ratings.

Figure 6 shows that the median LAeq decreases monotonically as a function of the comfort rating. The extreme values of the median LAeq are $61.5 \text{ dB}(A)$ for the lowest comfort score, and $39.1 \text{ dB}(A)$ for the highest comfort score. The association between measured LAeq and the absolute comfort rating is statistically significant ($F_{(1,434)} = 126, p < 0.001$, $R^2 = 0.24$) under the linear relation $\text{LAeq in dB}(A) = 67.1 - 5.6 \times \text{comfort}$, with 95% CI for the slope coefficient: [-6.5, -4.7] $\text{dB}(A)/\text{comfort point}$. This figure is very close to the value obtained to describe the variation of LAeq as a function of the variation of comfort, confirming that the trend is robust with respect to calibration. Obviously this fit is not meant to be predictive of individual values, which are also associated with other factors and to clustering of the observations. It rather describes an average trend in the whole dataset. The slope for night data is comparable to the one for day data: 95% CI: day [-6.3, -4.3]; night [-7.5, -2.3].

The data do not show statistically significant differences in LAeq among different days of the week. Calibrated data by hour are too few to make any quantitative analysis possible.

After Nov 11 stricter restrictions were enforced by the authorities to contrast the Covid pandemic. In particular, circulation was prohibited later than 10 pm. Half of the
measurements were performed after Nov 11. However, in this experiment we could not identify any significant change in the measured noise levels or in the reported comfort ratings before and after the restrictions were introduced. The reason is most probably that 89% of the measurements were performed during daytime, mostly in the afternoon, when no major restrictions to the circulation were effective. Also, the restrictions were overall less tight than the ones adopted during Spring 2020. Several studies report changes in LAeq [26,27] and in the soundscape [28] associated with COVID-19 restrictions to the circulation with variable impact depending on the nature of the urban area examined.

Several (optional) comments were attached to the data records. 7 express general appreciation for the initiative. 10 comments just confirm that the time chosen to perform the measurements is indeed representative of the nominal environment of the participant’s home (7 confirm quiet states, 3 noisy states). 9 report anomalies in quiet states (typically sudden events such as ambulances or cars passing by). Many comments specify the main identified source of noise: 11 outdoor anthropogenic (barking dogs, bells, loud people outdoors), 5 road traffic, 3 indoor anthropogenic (TV or loud people indoors), 2 mixed sources (notably one indicates very loud birds singing on top of external voices), 1 rail traffic. 2 mention that the measurements were taken in a particularly quiet situation attributed to anti-Covid restrictions.
Figure 6. LAeq by comfort rating. Thick black lines indicate the median values; the box limits the first and third quartile.

Conclusions and Perspectives

We have shown that collecting detailed and reliable data from a distributed network of high-school pupils on a national scale is indeed a feasible task. We conclude that initiatives such as this one allow the scientific community to assemble valid and useful data and, if routinely performed, would allow a cheap, yet reliable form of noise monitoring over large territories. They also carry the important added-value of making participants acknowledged with their sound environment, and potentially active part in environmental policy making.
The campaign was most popular among students and teachers, for whom dedicated didactical material was prepared. The consistency of the collected data was remarkably high, considered the heterogeneity of the contributions. We focused on spreading as much as possible the measurements in space, while, also based on previous experiences, we did not mean to perform a continuous time monitoring. As a consequence night-time measurements are a minority in our sample.

We have identified two main human-related difficulties and sources of errors. The first is the two-step process consisting in separately collecting data on paper first, and then manually selecting and sending them via a web interface. In this procedure the main mistakes concerned mistyped values and accidental swap of data belonging to quiet and noisy states. The simplification of this process, e.g. by allowing the app to automatically upload data, would help limiting this kind of errors, but would imply more privacy invasive terms of use of the app. The second source of outliers is due to some participants performing measurements in correspondence of extraordinary events, instead of restraining to situations more representative of their normal environment. Adding a dedicated flag to the online form could help avoid this problem.

Regarding gain corrections, we have shown that the analysis of differences between couples of uncalibrated values already provides a fair amount of information. By examining differential data only we could unambiguously link the variation of noise levels to the variation of comfort rating. However, if absolute levels are desired, gain corrections are necessary. In this case differential data can be employed as a further validation of gain adjusted values.

We have shown that applying a frequency-independent gain per smartphone model is a good starting point, the bottleneck being the continuous injection of new models on the market, which, in turn, requires that the calibration database is updated regularly if the experience is repeated over time. Few models for which the calibration was unreliable were easily spotted thanks to the measurement of the background noise, which indicates that Phase III actually is a key part of the protocol. From our data a scenario of moderate comfort
appears also in situations considered noisy by the observers. The median sound levels are ordered increasingly from quiet-night to noisy-night, quiet-day, noisy-day. LAeq in quiet situations are less dispersed than in noisy situations, however in both cases few outliers appear due to sudden disturbing events. The body of measured LAeq values correlates well with the reported comfort ratings. Larger contributions of natural and undefined sound sources are found in quiet situations, and the comfort ratings follow a general trend, common to all situations, with natural sound rated the most comfortable and industrial sound the least comfortable. Different sources contribute different distributions of LAeq, with characteristic shapes. All this information was employed to explain the overall shape of LAeq distributions. Differences between places having different population densities also emerge both in terms of LAeq and in terms of sources.

As a perspective, the possibility of collecting spectral data is surely appealing, as it would definitely enable more in depth examinations of statistical sound level as annoyance indicators and the possibility of re-tuning the initiative in the direction of soundscape description, however the latter aspect is critically limited by the poor reliability of data collected by smartphones at frequencies <200-250 Hz. Finally experiments like the one we performed could also be employed to further select, among the participants, a subset of the most interested and active contributors, in order to organize a more focused campaign to refine the dataset, the general compromise being the optimal balance between the number of observations and the possibility of training individuals to comply to more standardized procedures.

**Author contributions**

C.A.R., F.F., L.B., S.M. devised the project; C.A.R., F.F., J.F. designed the experimental methodology; L.B., D.G., J.F. implemented the software; C.A.R., F.F., J.F. D.G. performed data analysis; L.B, S.M. planned and performed the communication campaign; C.A.R. wrote the original draft; all authors contributed to review and editing of the draft.

Measurement protocol

**Phase I**: preparation.
5. Install the OpeNoise app.
6. Skip the calibration;
7. become aware of the acoustic environment of the participant’s home and acquaint yourself with the app by performing casual measurements at day and night-time;
8. identify locations and times at which most often the maximum and minimum acoustic comfort is experienced.

**Phase II**: “measuring noise”
29. For each situation (i.e. time and location) identified during Phase I perform an indoor sound level measurement according to the protocol described below.

**Phase III** (optional): “measuring silence”.
Identify the home’s most quiet location and time (typically a bedroom at night with windows shut);
perform a 1 min measurement of the background noise.

**Measurement protocol** for each chosen location/time:
1. Position yourself indoor at 1 m from an open window in the chosen room;
2. disable automatic screen switch-off and enable do-not-disturb mode;
3. silence indoor noise sources (TV, animals, voices, music, etc.);
4. identify the smartphone mic and point it towards the window (enable in app reverse screen mode, if convenient);
5. repeat the following sequence :
   a. stay quiet throughout the measurement;
   b. press reset and record for at least 1 minute (max 2 minutes);
   c. read and record the values of LAmin, LAeq(t) and LAmx;
   d. in case of undesired noise repeat from 5a;
6. annotate all the fields in the provided table including measured values, information about the location and time, a subjective rating of sound comfort during the measurement in a scale from 1 (less comfortable) to 5 (more comfortable) and comments;
7. when a sufficient number of observations were collected, select the two corresponding to the most comfortable and least comfortable states (hereby simply named “noisy” and “quiet” states) experienced and send the data via the provided google form.

Citizen science initiatives at Cnr
The initiative is part of a larger project called “Scienza sul balcone” (science on the balcony) [1] born in Italy in the spring of 2020 from an idea by Alessandro Farini (National
Institute of Optics of the National Council of Research of Italy) and Luca Perri (astrophysicist and science communicator), during the national COVID19 lockdown - which lasted from 11 March to 3 May 2020. In that period, flash mobs - born spontaneously and quickly spread throughout Italy through social networks and instant messaging services - were organized several times, in which citizens gathered at their windows or on their balconies to realize together with simple actions. One of these events required pointing the flash light of the smartphone towards the sky in the evening with the aim of illuminating the night sky and being photographed by one satellite. In the following days images of extraordinarily illuminated Italy photographed by satellite were also shared on social networks, but in reality the brightness of the flash light of a smartphone cannot be detected by a satellite, and the images were normal nighttime satellite images retouched to make the Italian peninsula unusually illuminated. This unusual flash mob, however, gave an idea to Farini and Perri, who decided to propose a new flash mob, a scientific experiment concerned with measuring the intrusive light that enters homes at night using the smartphone's brightness sensor but also to sensitize the population to pay attention to the scientific truthfulness of the news disseminated through social networks. This first experiment had great media coverage, both nationally and internationally [2]. The present initiative is the second experiment in the series, and more are being organized on different topics.

Communication campaign

Thanks to the involvement of the Cnr Communication and Public Relations Unit - which for the first time collaborated with the scientific network to carry out a citizen science project of this magnitude on the national territory - a targeted communication campaign was prepared, summarized briefly by points below:
- naming: a representative and easily identifiable name was chosen through a hashtag, which immediately went viral on social networks and in general news;
- slogan: to highlight the shared component of the experiment, an engaging and participatory slogan was chosen: "Have you ever participated in a scientific experiment directly from your home?";
- graphics: a simple and minimal logo was chosen, simple images suitable for sharing via social networks;
- web page: it was decided to create a simple web page in which the data collection system of the experiment was inserted without privacy problems and containing instructions, a series of insights and a map of the measurements entered;
- identification of communication tools suitable for the purpose: social channels (FB, YT, IG), promotion on the institutional website of the Cnr institutes involved and the communication portal, involvement of the media through press releases, collaboration with important Italian scientific festivals.

As a result, there have been numerous releases in the media (TV, radio, print media and online newspapers). During the year, citizen science was mentioned several times in the newspapers and there was talk of #scienzasulbalcone. Interactions in the official and social pages of the Communication and Public Relations Unit of the Cnr increased during the periods in which experiments were carried out. The live broadcasts made to present the experiments were among the most visible videos of the year in the YouTube channel and on the Facebook page of the Unit.
Figure S1. Main sources of noise in the low and high comfort states. In the high comfort state less traffic, industrial and anthropogenic sources are reported, while the number of observations related to natural and unidentified sources increases.
Figure S2. Comfort ratings during night (10pm-6am) and day time (6am-10pm). The colors indicate the number of records reporting a high comfort or low comfort state. Black lines and labels show the mean value of the scores. The mean comfort during day-time ($N = 787, M = 3.4, SD = 1.2$) is lower than the mean comfort at night ($N = 103, M = 4.1, SD = 0.9$).
**Figure S3.** Mean values (thick lines) and 95% confidence interval (boxes) of comfort ratings by population density and comfort state. A linear mixed effect model with state and population density as fixed effect and participants as random effect shows that comfort depends both on the state and the population density. The isolated places mean comfort rating is lowered by 0.32 in low density places and by 0.62 in high density places (both with standard error 0.12). The mean difference between quiet and noisy comfort is 1.41 ± 0.06 (standard error). Mann-Whitney U tests show that the distributions of isolated and highly populated places always significantly differ ($p < 0.001$ quiet, $p = 0.002$ noisy). The mean comfort of low-density places instead does not differ significantly from the one of high-density ones in noisy states ($p = 0.3$). It does not differ significantly from the one of isolated places in quiet states ($p = 0.1$).
Figure S4. Mean comfort ratings (thick lines) and standard errors (boxes) by source and comfort state. The lowest mean comfort score is always attributed to industrial sources ($N = 13, M = 1.9$ for noisy states and $N = 3, M = 3.7$ for the quiet states). The highest is always attributed to natural sources ($N = 60, M = 3.7$ for noisy states and $N = 160, M = 4.5$ for quiet states).
Figure S5. Differences in the frequencies of main sources of noise among places with different population density. The frequencies of road traffic related noise increases monotonically with the population density in the neighborhood of the measurement place both in noisy and quiet situations. Natural sources show the opposite trend. Indoor anthropogenic sources are cited with almost constant frequencies in all environments and situations. Noise of undefined source is more frequently reported from low-density and isolated places in quiet situations.
Figure S6. Distribution of $\Delta L_{Aeq} = L_{Aeq[quiet]} - L_{Aeq[noisy]}$ registered by each participant at different values of Delta comfort (difference of subjective comfort ratings between quiet and noisy states felt by each participant). Black lines indicate median values. A linear model yields $\Delta L_{Aeq\,dB} = -1.54 - 5.91 \times \Delta \text{comfort (F}_{1,443} = 214, p < 0.001, R^2 = 0.325)$. 
Figure S7. Distribution densities of $LA_{eq} - L_{Amin}$ at different comfort levels. Black lines indicate median values of the distributions. Both median and interquartile range decrease with increasing comfort from a maximum of 13.7 and 16.5 $dB(A)$ respectively to a minimum of 3.6 and 7.0 $dB(A)$ respectively.
Figure S8. Fraction of measurements referring to noisy or quiet states as a function of LAeq in 3 dB(A) wide bins. The dot size indicates the number of observations per bin. The blue line indicates the linear relationship \( P[\text{not quiet}] \% = 1.08 \cdot \text{LAeq} \) obtained by a linear model \( (F_{(1,11)} = 738, p < 0.001, R^2 = 0.985) \) with the number of observations per bin as weights. The shaded area indicates the 95% confidence interval of the linear estimator. Below LAeq = 46 dB(A) more measurements are referred to quiet states than to noisy states; above this threshold more measurements are referred to noisy states.
Figure S9. Distributions of LAeq by night/daylight phases and noisy/quiet states. Vertical black lines and the numeric labels indicate LAeq median values.
Figure S10. Distribution of LAeq by states (columns) and source (rows). Only the sources with the largest number of reports are included. Black lines and numeric labels point at median values.
Figure S11. Distribution of LAeq by states (columns) and population density (rows). Isolated places are not shown since their number is negligible. The colors indicate the sources of noise in each 3 dB(A) wide bin.
