Abstract

Low lattice thermal conductivity is essential for high thermoelectric performance of a material. Lattice thermal conductivity is often computed based on density functional theory calculations, but such calculations carry a high computational cost and machine learning is therefore increasingly being used to estimate lattice thermal conductivity at a much lower computational expense. With the ability to assess larger sets of materials, machine learning could offer an effective procedure to identify low lattice thermal conductivity compounds. However, such compounds can be quite rare and distinct from typical compounds in a given training set. This can be problematic as standard machine learning methods lack the ability to precisely interpret properties of compounds with features differing significantly from those in the training set. By computing the lattice thermal conductivity of 122 half-Heusler compounds using the temperature dependent effective potential method, we generate a data set sufficient in span to explore this issue. We show that random forest regression can fail to identify low lattice thermal conductivity compounds with random selection of training data. However, if the choice of training data is instead guided using feature and principal component analysis, it can drastically improve the ability to identify low lattice thermal conductivity compounds as well as model performance.
1. Introduction

With their ability to convert heat to electricity, thermoelectrics find use in a number of niche technologies ranging from wine coolers, hiking stoves with mobile phone chargers, and radioisotope thermoelectric (TE) generators used to power e.g. the Curiosity Mars rover. Thermoelectrics also have a great potential to reduce global greenhouse gas emission through waste heat recovery, but their role is currently limited by the modest efficacy realized in devices [1, 2] and the fact that several state-of-the-art TE materials contain toxic or rare elements [3, 4]. Finding new TE materials has therefore gathered much scientific interest in recent years [5].

The efficiency of TE materials is conventionally given by the dimensionless figure of merit, which is expressed as $ZT = \frac{\sigma S^2}{\kappa_e + \kappa_\ell}$, where $\sigma$ is the electrical conductivity, $S$ is the Seebeck coefficient, $T$ is the absolute temperature, $\kappa_e$ is the electronic thermal conductivity, and $\kappa_\ell$ is the lattice thermal conductivity. A high $ZT$ requires both a high power factor, $P = \sigma S^2$, and simultaneously a low total thermal conductivity. In non-metals, $\kappa_\ell$ is typically significantly larger than $\kappa_e$, while in heavily doped semiconductors, $\kappa_\ell$ and $\kappa_e$ can be comparable in size [6, 7]; nonetheless, a low $\kappa_\ell$ is usually important for achieving high $ZT$.

High-throughput screening studies based on first-principle calculations have in recent years been used to discover new TE materials [8–14]. Some studies focus on electronic properties and use simple models or estimates of $\kappa_\ell$. This could be because calculations of $\kappa_\ell$ can become computationally expensive. The computational cost arises because accounting for the phonon-phonon interactions due to the anharmonicity of the lattice vibrations requires obtaining third-order force constants extracted from a large number of supercell-based density functional theory (DFT) calculations [15–17]. For this reason, machine learning (ML) methods are increasingly supplementing first-principles based calculations for predicting $\kappa_\ell$ [18–25], and pre-trained ML models have been used in a convenient web-based application [26].

Our study is based on 122 HH compounds for which $\kappa_\ell$ is computed explicitly using DFT. The compounds are based on a combination of dynamically stable HHs, 54 from groups 4-9-15 (Ti,Zr,Hf)(Co,Rh,Ir)(As,Sb,Bi), 4-10-14 (Ti,Zr,Hf)(Ni,Pd,Pt)(Ge,Sn,Pb), and 48 HHs from groups 5-8-15 (V,Nb,Ta)(Fe,Ru,Os)(As,Sb,Bi) and 5-9-14 (V,Nb,Ta)(Co,Rh,Ir)(Ge,Sn,Pb). The last 20

![Fig. 1: The HH crystal structure, displayed as the unit cell.](image-url)
HHs are the remaining stable compounds studied by Feng et al. [37], based on a revision of the 75 stable HHs identified by Carrete et al. [18].

2. METHODS

2.1. Lattice thermal conductivity

DFT calculations in this work are done with the VASP [44–46] software package using the revision of Perdew-Burke-Ernzerhof generalized gradient approximation for solids (PBEsol) [47, 48]. The plane-wave energy cutoff is set to 600 eV. For the relaxations, we use an $11 \times 11 \times 11$ k-point sampling of the Brillouin zone, while the electronic self-consistent loop is iterated to an energy difference of $10^{-6}$ eV, and ionic positions are relaxed until forces fall below 1 meV/Å. The lattice thermal conductivity, $\kappa_\ell$, is calculated with the temperature dependent effective potential (TDEP) method [16, 49], taking into account three-phonon and isotope-phonon scattering [50, 51]. Fifty configurations based on $3 \times 3 \times 3$ repetitions of the primitive cell are used to obtain second- and third-order force constants. The atomic configurations are taken from a fixed-temperature canonical ensemble at 300 K, where the zero-point motion of the phonons is matched with the Debye temperature [52]. The Debye temperature is obtained from the Voigt approximation of the bulk and shear moduli [53]. A $3 \times 3 \times 3$ k-point grid is used for the supercell DFT force calculations. We employ a cutoff for second-order pair-interactions of 7 Å while for third-order pair-interactions, the cutoff is set slightly larger than half the width of the supercell (i.e. 6.1 Å for NbCoGe). For the calculation of $\kappa_\ell$, the reciprocal space is discretized on a $35 \times 35 \times 35$ q-point grid. In a detailed convergence study for NbCoGe, we find this choice of parameters to give a numerical error of $\kappa_\ell$ less than 3 %.

2.2. Machine learning model

Random forest (RF) regression is a non-linear ML method used in industry and academia alike [54]. An RF model is based on an ensemble of decision trees, where each tree is trained on a subset of randomly chosen features and training samples. This randomness makes RF less prone to overfitting. RF has been shown to perform well in earlier ML studies involving the lattice thermal conductivity [23]. In the RF regression, a given input sample is sorted in each of the decision trees based on its features, so that in a given tree, the sample is assigned to a $\kappa_\ell^{(i-)}$ in the training set. Finally, the predicted outcome is given by the mean $\langle \kappa_\ell^{(i-)} \rangle$ of the predictions of the ensemble of decision trees.

In ML, failing to identify key features can result in overfitting and reduce method interpretability [55, 56]. Feature selection is here performed using exhaustive feature selection (EFS) in combination with RF regression. EFS is a brute-force scheme to assess the predictive performance of every possible combination of extracted features. This is computationally costly when a large number of features is involved, but in our study this cost is small compared to that of computing $\kappa_\ell$. The EFS model finds the subset of features that gives the best outcome of a chosen performance metric using cross-validation with the training data. The optimal features for a training set is here chosen as the subset of features that gives the highest Spearman rank correlation between predicted and calculated $\kappa_\ell$ in a five-fold cross-validation process. The EFS scheme is done with the MLxtend [57] code, while RF regression is done using Scikit-learn [58]. Note that in each case when a set of features is evaluated, the hyperparameters of the RF model are optimized independently with a hyperparameter grid search.

Fig. 2 outlines the construction of the baseline model.

Fig. 2: Flowchart for building the baseline model.
essment. By semi-randomly, we refer to that the five lowest $\kappa_\ell$ compounds are in the test set. We make this choice to emulate a not too improbable scenario that could easily arise for larger material classes when only modest size training sets are used. From the training pool, 10 unique training sets of 40 compounds are selected randomly. EFS using RF regression is then done for each of the training sets. The models are then retrained based on the features obtained with EFS. Our baseline model predictions is given by the average of the predictions of these 10 RF models.

In the alternative active sampling model, we use principal component analysis (PCA) with the HOGGORM [59] package to identify compounds possessing combinations of feature values that make them distinct from those in the training pool. PCA takes into account correlations between features and provides orthogonal principal components (PC) as linear combinations of feature vectors in feature space. The PCs are oriented in the direction of maximum variance in feature space. In the procedure the features are centered and scaled to unit variance. The PCA analysis is based on all compounds in the study. Using PCA, we identify three compounds that are needed to cover the feature space mapped out by the first four PCs. These three are subsequently included in the training sets from the baseline model, such that the 10 training sets for the active sampling model contain 43 compounds which are used with RF and EFS.

Our study is based on 14 features, out of which the following nine are tabulated features: the ratio between the lightest and heaviest atoms in the primitive cell $m_r$, the average atomic mass, $m_a$, the standard deviation of the atomic masses, $m_s = \frac{1}{3} \left( \sum_{i=X,Y,Z} (m_i - m_a)^2 \right)^{1/2}$, as well as corresponding features for the electronegativity $\chi$, and covalent atomic radius $r$. An additional five features is based on standard output of low-cost DFT calculations. These include the following: the volume of relaxed primitive unit cell, $V$, and mass density, $\rho$. We also include the lattice thermal conductivity of the Slack model $\kappa_s$, Debye temperature, $\theta_D$, and bulk modulus, $B$, which are related to the elastic tensor [64]. In other works, several higher-order features have been shown to be linked to scattering of phonons, such as the three-phonon scattering phase space, effective spring constants, and first moment frequencies from the phonon density of states [18, 37, 65]. Using such features can improve the predictions of the ML model, but we here limit the features to those that are based on properties one can expect to be continuously added in large material databases such as the MATERIALS PROJECT [66]. Therefore, using such simple features supports a methodology which can later be adopted for screening of larger material databases, and the features can be assessed for other material classes.

3. RESULTS AND DISCUSSION

3.1. Lattice thermal conductivity of half-Heusler compounds

Fig. 3 compares the lattice thermal conductivity calculated with the TDEP method, $\kappa_{TDEP}^{\ell}$, at 300 K, 500 K, and 700 K for the 122 HHs. Table A.1, Appendix A, reports $\kappa_{TDEP}^{\ell}$ at 500 K. The span of $\kappa_{TDEP}^{\ell}$ goes from 0.85 W/mK (LaPtSb) to 23.45 W/mK (LiBSi) at 500 K, revealing that the chemical composition affects thermal transport notably. Compounds with heavy atoms on the X- or Z-site, such as La, Ba, Bi, and Pb, or with high average mass, typically have lower $\kappa_{TDEP}^{\ell}$. The correlation between lattice thermal conductivity and the average mass has been observed for experimental lattice thermal conductivity with compounds across different spacegroups [20]. The ordering of the five lowest $\kappa_{TDEP}^{\ell}$ materials from low to high $\kappa_{TDEP}^{\ell}$ is consistent with what was found by Feng et al. [37]. The vanadium-containing compounds VRuBi, VFeBi, VIrPb, VOsBi, VRhPb, and VCoPb are found to have negative phonon frequencies and are not studied further. The two latter have previously been found to have favorable decomposition into elemental phases [67].

In the following, the ML models are based on $\kappa_{TDEP}^{\ell}$ at 500 K, which also would be indicative of low lattice thermal conductivity at 300 and 700 K.
Fig. 3: $\kappa_{\ell}^{\text{TDEP}}$ for the HHs at 300 K (blue bars), 500 K (turquoise bars), and 700 K (red bars).
lattice thermal conductivity. Higher $B$ can also be related to stiffer atomic bonds and increased phonon velocities. This is in line with the Spearman correlation of $-0.69$ between $\kappa_{TDEP}^l$ and $V$ and $0.58$ between $\kappa_{TDEP}^l$ and $B$ for the compounds in the training pool. The plot shows that some of the compounds in the test set fall outside the convex hull spanned by $V$ and $B$ of the compounds in the training pool. By including such outliers in the training sets, we can possibly diversify the ML models. However, as $B$ and $V$ also have a sizeable Spearman correlation of $-0.51$, —i.e. higher $V$ tend to be related to less stiff bonds and thus lower $B$ — solely relying on these two features carries a risk of missing important compounds and correlations. This motivates the use of PCA, which offers a more systematic procedure to take all features and their correlations into consideration.

To facilitate ML interpolation, we identify three additional compounds that are included in the training sets of the active sampling model. These compounds are highlighted with red circles in Fig. 4. The specific compounds to be included are determined iteratively by identifying the compounds in the test set with the largest euclidean distance in the PC space to those in the current training pool, until a marked drop in distance arises. This procedure identifies that the three additional compounds BaBiK, LiZnSb, and LaPtSb should be included in the training set.

---

When the two PCs are mapped back to the original feature space, the cumulative explained variances of $V$ and $B$ are 78.6 % and 77.2 %, showing that the PCs retain most of the information for these features.
3.3. Exhaustive feature selection analysis

Fig. 5 compares the selection frequency of a given feature in the EFS for the 10 RF models used in the baseline (blue bars) and active sampling (orange bars) ML models. The baseline and active sampling models use on average 5.7 and 6.3 features out of the 14 potential features, respectively. The relatively few features used is in line with the recent results of Miyazaki et al. [70] showing that using a limited feature subset gives the best ML performance, as overfitting can arise with redundant features. In both the baseline and active sampling models, B and V are the most frequently selected features, which agrees with their high Spearman correlation with $\kappa_{\ell}^{\text{TDEP}}$ as discussed in the previous section. However, while both these features are simultaneously selected despite a relatively high inter-correlation, this is not the case for all features. For instance, in the active sampling model, only one of the 10 models select both V and $\kappa_s$ at the same time, with a correlation of -0.79, whereas six include both B and $\kappa_s$, which have a correlation of 0.34.

There are some notable differences between the EFS for the active sampling model compared to the baseline model. In particular, the selection frequency of $m_s$ increases from 0.3 to 0.6 for the active sampling model. This result reflects that the variation of masses in the primitive cell is linked to low lattice thermal conductivity, such as the case of BaBiK. The selection frequency for $\kappa_s$ and B also sees an increase for this model.

3.4. Enhanced machine learning performance with active sampling

Fig. 6 (a) compares the predictions made by the baseline model and the active sampling model using the logarithmic scale used in the training. The error bars indicate the standard deviation in the prediction of the 10 models. It shows that the active sampling method has a superior ability to identify the compounds with low $\kappa_{\ell}^{\text{TDEP}}$. The three compounds found with PCA, highlighted with red circles, are not predicted by the active sampling model, as they are included in the training process. Fig. 6 (b) shows the corresponding comparison with a linear scale. In this case, the compounds are sorted according to $\kappa_{\ell}^{\text{TDEP}}$. In most of the cases, the predictions of the active sampling method, $\kappa_{\ell}^{\text{AS}}$, is higher than $\kappa_{\ell}^{\text{TDEP}}$ for low $\kappa_{\ell}^{\text{TDEP}}$ compounds, and vice versa for high $\kappa_{\ell}^{\text{TDEP}}$ compounds. This is also seen with the logarithmic view of Fig. 6 (a). Even if the numerical precision of the active sampling model for the low $\kappa_{\ell}^{\text{TDEP}}$ compounds remains quite modest, which can be linked to a limited sampling in this region of feature space, the method clearly identifies the compounds with the lowest $\kappa_{\ell}^{\text{TDEP}}$.

target in this study, we first discuss the Spearman correlation. The baseline model predictions, \( \log(\kappa_{BL}^T) \), has a Spearman correlation of 0.77 with \( \log(\kappa_{TDEP}^T) \), which is larger than the correlation of Carrete et al. [18] of 0.74. Their model is based on few training samples, but with more complex features. However, even though the Spearman correlation metric is fair and the low \( \kappa_{TDEP}^T \) compounds do tend to be in the lower end of the spectrum of \( \log(\kappa_{BL}^T) \), the model fails to differentiate between the truly low lattice thermal conductivity compounds and the rest. The active sampling model has a superior ability to identify such compounds, but also has superior predictivity for most other compounds, as reflected in the improvement of the other performance metrics.

While the performance gain when using more complex features and larger training sets has been demonstrated in earlier studies [20–23, 70–73], this work clearly shows that rather modest training set sizes and low feature complexity can still give reliable predictions with the use of active sample selection. Finally, we note that the use of a semi-random selection, rather than one that is truly random do accentuate the performance gains of the active sampling model. Nonetheless, we find that only including some of the low lattice thermal conductivity compounds in the model significantly reduces performance compared to including all three. Performance with a truly random model could also be very sensitive to exactly which training samples are selected. In any case, a key advantage of PCA is that when used in the process to include additional half-Heusler compounds, we have a procedure to identify whether the properties of a given compound can be predicted reliably.

### 4. Summary and conclusion

This study has explored strategies for using machine learning for finding low lattice thermal conductivity compounds using a limited number of training samples. Moreover, rather simple features was used, which can found directly in material databases or computed straightforwardly. The exploration was made possible by computing lattice thermal conductivity with the temperature dependent effective potential method for 122 half-Heusler compounds. We first demonstrated how a model based on a semi-random pool of materials (i.e. assumed "bad luck" in the training set) was unable to separate the truly low lattice thermal conductivity compounds in the test set from the rest. To improve the model, we used active sample selection based on principal component analysis. This approach suggested three com-
pounds to be included in the training process. The subsequent inclusions resulted in a substantial improvement of the model performance, in particular the ability to identify the remaining low lattice thermal conductivity compounds in the test set. Our study demonstrates how active sampling can improve the ability to accurately predict properties of compounds dissimilar from the typical ones in a material class. More narrowly, we expect the procedure outlined here to be adopted to study broader classes of materials to systematically identify new low lattice thermal conductivity compounds.

5. Data Availability

The lattice thermal conductivities for the HH compounds calculated with the TDEP method are available in Appendix A Table A.1.
