Abstract

Using a bicycle for commuting is still uncommon in US cities, although it brings many benefits to both the cyclists and to society as a whole. Cycling has the potential to reduce traffic congestion and emissions, increase mobility, and improve public health. To convince people to commute by bike, the infrastructure plays an important role, since safety is one of the primary concerns of potential cyclists. This paper presents a method to find the best way to improve the safety of a bicycle network for a given budget and maximize the number of riders that could now choose bicycles for their commuting needs. This optimization problem is formalized as the Bicycle Network Improvement Problem (BNIP): it selects which roads to improve for a set of traveler origin-destination pairs, taking both safety and travel distance into account. The BNIP is modeled as a mixed-integer linear program that minimizes a piecewise linear penalty function of route deviations of travelers. The MIP is solved using Benders decomposition to scale to large instances. The paper also presents an in-depth case study for the Midtown area in Atlanta, GA, using actual transportation data. The results show that the Benders decomposition algorithm allows for solving realistic problem instances and that the network improvements may significantly increase the share of bicycles as the commuting mode.

1 Introduction

Using a bicycle for transportation is still uncommon in US cities, but it brings many benefits to both the cyclists and to society as a whole (Handy et al., 2014). Cycling has the potential to reduce traffic congestion and emissions, increase mobility, and improve public health (Northrop, 2011). Additionally, bikes can serve as an economical alternative to a car, especially for short trips (Ryu et al., 2018). The benefits of cycling as a mode of transportation have been recognized by policy makers, and more and more cities have started promoting bicycle usage. An example in Atlanta is the Walk, Bike, Thrive! plan, which provides a recipe for a more walkable and bikable city (Atlanta Regional Commission, 2020). Plans like this also benefit modes that are similar to bicycles, such as e-bikes and e-scooters, which have many of the same advantages and may also benefit larger population segments and urban settings.

The low number of cyclists is not due to a lack of interest. Dill and McNeil (2016) questioned 3,000 people in the 50 largest US metropolitan areas about their attitudes towards cycling, and they found that 56% of the population can be classified as interested but concerned. One of the key barriers for this group is traffic safety: while most feel comfortable riding on a protected bike lane that is part of a major street, only 16% would be somewhat comfortable without the bike lane. The willingness to cycle is also demonstrated by the surge in US bike ridership during the COVID-19 pandemic (Bryant, 2020). Many people have started cycling for recreation, but also as a socially-distant alternative to public transit. Policy makers hope that this trend continues and that these new cyclists start commuting by bike when they return to work after the pandemic.

To convince people to commute by bike, the infrastructure plays an important role. The study by Dill and Carr (2003) suggests that, if a city provides the proper infrastructure for cycling, commuters are likely to make use of it. Hull and O’Holleran (2014) study selected European cities to identify whether good design can encourage cycling. They found that the design may indeed have a significant impact on mode choice, and that safety, comfort, and continuity were the most influential factors. Another important factor, which was not explicitly considered in the previous study, is the proximity: the distance between the origin and the destination of the trip (Saelens et al., 2003). Wang et al. (2021) found that similar factors affect the choice to use shared bicycles. Risk perception was found to be a direct influence, as well as the mode’s relative advantage, and the compatibility with current travel habits. Although safety is especially important to cyclists, safety improvements in the last decades have often focused on motorized vehicles, as highlighted by CIVITAS Initiative (2020) for the European Union. This situation can be improved by investing in bicycle infrastructure, which additionally improves the safety for non-cycling road users (Walljasper, 2016).

This paper presents optimization models to find the best way to improve an existing bicycle network for a given budget. Policy makers may use this method to guide their investments in cycling infrastructure, and to obtain the advantages that come with it. The optimization problem is formalized as the Bicycle Network Improvement Problem (BNIP) that selects how best to spend a given budget for road improvement in order to minimize the total penalty for a set of traveler origin-destination pairs (ODs). The penalties are calculated from the distance deviations from travelers’ shortest paths. The optimization problem uses piecewise linear penalty functions, which are flexible enough to model different human preferences and numerous other factors.

This paper models the BNIP as a Mixed-Integer Linear Program (MIP), which is solved through Benders decomposition. The optimization method is then used to conduct an in-depth case study for the Midtown area in Atlanta, GA, based on real transportation data. As the 10th most congested city in the US, and with a bicycle infrastructure scored in the red category (Reed, 2019), Atlanta makes for an interesting test case. Compared to the city of Delft in the Netherlands, cyclists in Atlanta are over two times more likely (78% versus 32%) to report poor
road infrastructure as a cause of stress (Gadsby et al., 2021). Furthermore, a survey by the Atlanta Department of City Planning mentions that 70% of people in the city currently feel uncomfortable to ride a bike (Bottoms, 2018).

The paper contains four main contributions:

1. From a methodology standpoint, the paper formalizes the Bicycle Network Improvement Problem (BNIP) and shows that Benders decomposition is able to find optimal improvement plans for realistic instances, while the problem is computationally intractable for state-of-the-art black-box solvers.

2. From a case study standpoint, the paper shows that even small investments in infrastructure may allow many additional commuters to travel safely by bike.

3. At the intersection of methodology and case study, the paper demonstrates the value of optimization, which produces improvement plans that are significantly better than those obtained by heuristics. Moreover, and this is important for cities, the paper compares the benefits of optimal long-term plans with those obtained by upgrading the infrastructure incrementally. The paper shows that, on the case study, successive improvements using the BNIP lead to a network that is very close to optimal in the long term, which simplifies decision making.

4. From a computational perspective, this paper compares a wide range of different penalty functions, and reports consistent results across all of them.

The rest of the paper is organized as follows. Section 2 reviews prior work. Section 3 formally introduces the BNIP, and Section 4 describes a Benders decomposition algorithm to solve it. Section 5 discusses the current conditions in Midtown Atlanta, which also motivates this research. The Midtown Atlanta case study is presented in Section 6. Section 7 explores the use of different penalty functions, and Section 8 presents the conclusions and possible directions for future research.

2 Review of Prior Work

There are several studies that consider bicycle infrastructure improvement planning. Duthie and Unnikrishnan (2014) present a network design formulation to connect all OD (origin-destination) pairs with a lower bound on the bicycle level of service and an upper bound on the maximum travel length expressed as a function of the corresponding shortest path. Their objective and the BNIP objective are similar in that they limit the worst service for travelers with respect to the travel distances. There is, however, a fundamental difference between their work and the BNIP: the former mandates that all ODs admit feasible bicycle travels regardless of the improvement budget, while the BNIP has a limited budget to serve as many OD pairs as possible. The benefit of having a finite budget is that it abides by realistic scenarios, e.g., urban planners developing new bicycle infrastructure. Indeed, budgets for infrastructure improvements are almost always limited and their effective use is a key aspect for decision makers.

Mauttone et al. (2017) introduce another MIP model to minimize the overall travel cost of riders, where the cost primarily consists of travel distances. This formulation includes a budget constraint, but still requires all OD pairs to be served. This is made possible by allowing for bicycle trips that are not 100% safe, and penalizing the usage of unsafe roads. As safety is the primary concern for many potential cyclists, as argued in the introduction, the BNIP does not sacrifice the requirement for completely safe bicycle routes; rather it imposes limits on maximum travel distances to model realistic trips and provides an outside option for those riders who do not have a realistic safe route. It is also important to mention that Mauttone et al. (2017) only provide sub-optimal solutions in reasonable time for their real-life case studies, and they use
a heuristic to report results for large cases with more accuracy. The Benders decomposition algorithm proposed in this paper, however, solves the large Atlanta instances to optimality.

Liu et al. (2020) present a MIP model to plan bicycle networks using objectives for coverage and continuity of travels. They assume that the MIP model receives, as input, bicycle paths. Their adjacency-continuity utility function, which incorporates both safety and trip length, selects one of the pre-calculated paths to route each traveler while maximizing the utility of the network. Their work is similar to the BNIP as it improves both safety and proximity of the trips. The BNIP, however, has full flexibility in routing cyclists; this simplifies modeling for decision makers and may produce solutions of higher quality since the optimization can choose the best routes for riders and is not constrained by pre-selected paths.

In addition to the previous works, a number of studies incorporate more diverse characteristics in the problem modeling. For example, Lin and Yu (2013), Lin and Liao (2016), and Zhu and Zhu (2020) use multi-objective optimization to include various objectives such as road connections, accessibility, and service level. These formulations can model more customized bicycle experiences, but become more computationally intensive. The BNIP is a single-objective optimization problem with an objective that is flexible enough to model realistic applications. Most importantly, the proposed Benders decomposition algorithm is capable of performing studies in much larger instances and areas than those multi-objective programs. It is an interesting avenue for future research to study if the techniques in this paper can be generalized to multiple objectives.

A number of other studies rely on heuristic methods instead of mathematical optimization techniques. Bao et al. (2017) use large-scale bicycle trajectory data to define a flexible objective that combines the population covered by the network and the distances of their trajectories. It is solved with greedy-based heuristics that include steps to initiate road segments, expand the network, and terminate the improvement when the budget limit is met. Also, Hsu and Lin (2011) utilize shortest paths of ODs like those of Duthie and Unnikrishnan (2014) to evaluate the quality of the network. They use a variety of algorithms, some of which are greedy, to compare the shortest paths to bicycle routes.

3 The Bicycle Network Improvement Problem

This section introduces the Bicycle Network Improvement Problem (BNIP) to find the best improvement of an existing bicycle network within a given budget. Let the current road network be represented by a directed graph $G = (V, W)$ with nodes $V$ and arcs $W$. The arcs are referred to as ways. Ways are partitioned into two distinct sets $W = W_{\text{safe}} \cup W'$, with $W_{\text{safe}}$ the set of ways that are safe for cycling, and $W'$ the set of unsafe ways. Every way $(i, j) \in W$ has a length, given by the parameter $d_{ij} \geq 0$. The total length of ways that can be improved is limited by the budget $B$. The set of sample trips that travel through the network is given by $T$. Each OD $k \in T$ consists of an origin $o_k \in V$ and a destination $d_k \in V$. Additionally, let $s_k \geq 0$ be the length of the (possibly unsafe) shortest path between $o_k$ and $d_k$, and let $p_k \geq 1$ be the number of travelers completing this travel.

3.1 Modeling Bicycle Travel

Safety is critical to increase cyclist participation. Accordingly, two characteristics are taken into account when modeling bicycle trips. First, potential cyclists would like completely safe routes from origin to destination: if the safety requirement is met for a certain OD, then the route is labeled as safe. If the network cannot provide a safe route, the BNIP assumes that the potential rider will select another mode of transportation, which is referred to as the outside option. Second, the travel should not take much longer than the alternative transportation mode, e.g., driving by car. Hence, if there is no safe path of length smaller than $L_k$ (a parameter
for rider $k$), the BNIP assumes that rider $k$ will not travel by bicycle.

To model the appeal of short bicycle trips for rider $k$, the BNIP uses a penalty function $f_k$ that is non-decreasing and satisfies $f_k(0) = 0$. For an OD pair $k$ and a path of length $l_k$, the penalty is given by $f_k(u_k)$ where $u_k = l_k - s_k$ denotes the deviation from the (potentially unsafe) shortest path. If rider $k$ cannot be provided a short trip, the outside option is used, and the penalty is the objective function is defined as $L_k - s_k$. As such, this trip is assigned the same penalty as a path of length $L_k$, which is the tipping point at which the rider starts preferring the outside option.

3.2 Mathematical Formulation

The mathematical model for the BNIP is depicted in Figure 1. For every way $(i,j) \in W'$, variable $y_{ij} \in \mathbb{B}$ indicates whether $(i,j)$ is upgraded to safe conditions (value one), or remains unchanged (value zero). The shortest safe path for every OD is determined by variables $x$ and $z$: variable $x_{ij}^k \in \mathbb{B}$ represents whether trip $k \in T$ uses way $(i,j)$. Variable $z_k \in \mathbb{B}$ indicates whether trip $k \in T$ uses the outside option. As explained in the previous section, the variable $u_k$ represents the argument of the penalty function for every trip $k \in T$.

Objective (1a) minimizes the total penalty of the riders $\sum_{k \in T} p_k f_k(u_k)$ on the network. The penalties for cyclists are computed in terms of the deviation from the shortest-path distance. Riders who are not cycling or have safe paths that are too long incur the penalty associated with a path of length $l_k = L_k$, as will become clear shortly. Constraint (1b) limits the budget for improving the network. Constraints (1c) impose the path conservation conditions: each OD has either a unit flow (if $z_k = 0$), in which case the $x$-variable describes the path, or uses the outside option (if $z_k = 1$). Constraints (1d) make sure that unsafe ways can only be used if upgraded. Constraints (1e) compute the deviation. Note that, if the shortest path for trip $k$ exceeds length $L_k$, it is optimal to set $z_k$ to 1, i.e., trip $k$ uses the outside option. Infeasible trips are also assigned the penalty associated with a path of length $L_k$. Constraints (1f)-(1h) capture the integrality conditions.

Figure 1: The MIP Model for the BNIP.

An optimization model that purely maximizes the number of cyclists is also presented in the paper.
\[
\min \sum_{k \in T} p_k f_k(u_k), \quad \text{(2a)}
\]
\[
\Phi_k(y) = \min \sum_{(i,j) \in W} d_{ij} x_{ij}^k + L_k z_k - s_k, \quad \text{(3)}
\]
\[
u_k \geq \Phi_k(y) \quad \forall k \in T. \quad \text{(2b)}
\]

Figure 2: The Master Problem of the BNIP.

Figure 3: The Subproblem of the BNIP.

4 Solution Methods for the BNIP

Solving the BNIP directly with a MIP solver, such as CPLEX or Gurobi, is computationally intractable for the scale of the case study considered in this paper. Observe however that, for a given design (i.e., when the \(y\)-variables are fixed), the formulation reduces to a set of independent minimum-cost flow problems, one for each OD. By total unimodularity, this implies that the integrality conditions (1g)-(1h) can be relaxed. This makes the problem ideally suited for Benders decomposition (Benders, 1962).

4.1 Benders Decomposition

The Benders decomposition for the BNIP has a master problem to determine how to upgrade the network, and subproblems to return the safe path or the outside option for each rider for a given upgraded network. The master problem generates a network design, and the subproblems find the paths in the proposed network for each trip. The optimal solutions of the subproblems are then used to derive the Benders cuts that are added to the master problem. These two steps are iterated until no more violated Benders cuts are generated by the subproblems, at which point the network is optimal.

**The Benders Master Problem** The master problem is presented by Figure 2. Its Objective (2a) is the same objective as in Formulation (1). Constraints (1b) and (1f) ensure that the network improvement plan is within budget and valid. When solving the master problem, Constraints (2b), where \(\Phi_k(y)\) is the minimum objective value for trip \(k\) given a design \(y\), are replaced by the Benders cuts generated from the solutions to the subproblems.

**Benders Subproblem** The subproblem for a trip \(k\) generates Benders cuts for each network produced by the master problem. The \(z\)-variables (the outside option) ensure complete recourse: the subproblem is feasible for any network, because ODs can always use the outside option. This implies that the optimality cuts (2b) are sufficient and no feasibility cuts are needed.

For a given network, the subproblem decomposes into many independent subproblems, and Figure 3 defines the subproblem of the BNIP for each \(k \in T\). Since the subproblem is a standard minimum-cost flow problem, it is totally unimodular and can be solved by linear programming. This implies that the Benders subproblem can be solved by optimizing many small and independent linear programs, which is the prime reason why the Benders decomposition provides a significant computational benefit.

Figure 4 presents the dual subproblem, with dual variables \(\lambda\) and \(\mu\) associated with Constraints (1c) and (1d) respectively. The Benders cuts are obtained as

\[
u_k \geq \bar{\lambda}_{o_k} - \bar{\lambda}_{d_k} - \sum_{(i,j) \in W'} \bar{\mu}_{ij} y_{ij} - s_k, \quad \text{(5)}
\]

where \(\bar{\lambda}\) and \(\bar{\mu}\) are optimal dual values for the corresponding trips.
\[ \Phi_k(y) = \max \lambda_k^o - \lambda_k^d - \sum_{(i,j) \in W'} \mu_{ij}^k y_{ij} - s_k, \]  
\[ \text{s.t.} \quad \lambda_i^k - \lambda_j^k \leq d_{ij} \quad \forall (i, j) \in W^{safe}, \]  
\[ \lambda_i^k - \lambda_j^k - \mu_{ij}^k \leq d_{ij} \quad \forall (i, j) \in W', \]  
\[ \lambda_k^o - \lambda_k^d \leq L_k, \]  
\[ \lambda_i^k \in \mathbb{R} \quad \forall i \in V, \]  
\[ \mu_{ij}^k \geq 0 \quad \forall (i, j) \in W'. \]  

Figure 4: The Dual Subproblem of the BNIP.

\[ \max \lambda_k^o - \lambda_k^d - \sum_{(i,j) \in W'} \mu_{ij}^k y_{ij}' - s_k, \]  
\[ \text{s.t.} \quad \lambda_i^k - \lambda_j^k \leq d_{ij} \quad \forall (i, j) \in W^{safe}, \]  
\[ \lambda_i^k - \lambda_j^k - \mu_{ij}^k \leq d_{ij} \quad \forall (i, j) \in W', \]  
\[ \Phi_k(y) = \lambda_k^o - \lambda_k^d - \sum_{(i,j) \in W'} \mu_{ij}^k y_{ij}' - s_k. \]  

Figure 5: The Pareto Subproblem for the BNIP.

**Pareto-Optimal Cuts** It is well-known that network flow problems often suffer from dual degeneracy. Magnanti and Wong (1981) addressed this issue by generating Pareto-optimal cuts that are not dominated by any other Benders cut. This requires solving a Pareto subproblem that uses the result from the standard subproblem. Pareto-optimal cuts need a core point, i.e., a point in the relative interior of the feasible region of the master variables. For the BNIP, the following point \( y' \) is selected as the core point.

\[ y_{ij}' = \frac{1}{2} \min \left\{ \frac{B}{|W'|d_{ij}}, 1 \right\} \quad \forall (i, j) \in W' \]  

(6)

The point \( y' \) is in the relative interior, as \( y_{ij}' \in (0, 1) \) and \( \sum_{(i,j) \in W'} d_{ij} y_{ij}' \leq \sum_{(i,j) \in W'} d_{ij} \frac{B}{|W'|d_{ij}} = \frac{B}{2} < B \), which strictly satisfies budget constraint (1b).

Using the core point \( y' \), Figure 5 presents the Pareto subproblem. To use Pareto-optimal cuts, each Benders iteration is changed as follows. For every trip, the value of \( \Phi_k(y) \) is calculated by solving the subproblem (Figure 4). Next, the Pareto subproblem (Figure 5) is solved to produce new optimal dual values \( \bar{\lambda} \) and \( \bar{\mu} \), and those variables are used to generate cuts as in Equation (5).

**Two-Phase Benders** McDaniel and Devine (1977) observe that it is not necessary to solve the master problem to optimality at every iteration to obtain valid Benders cuts. They propose to apply Benders decomposition in two phases. In phase one, Benders decomposition is applied to the relaxed master problem. For the BNIP, this amounts to relaxing the integrality conditions (1f) in the master problem, and solving the subproblems for fractional values of \( y \). In phase two, the integrality conditions are reinstated, and the Benders decomposition algorithm continues with the original master problem. The Benders cuts that are added in phase one are maintained, which ensures a better starting lower bound, which often improves the overall performance of the algorithm. Moving from phase one to phase two is possible at any point, and this paper switches over when the relaxed problem is solved, or when a time limit is reached.
4.2 Greedy Heuristic

This section also introduces a greedy heuristic that only relies on the ability to solve shortest paths to demonstrate the value of optimization. The heuristic greedily computes the next way to upgrade in the network. For every OD, it computes a shortest path that minimizes the total distance on unsafe roads, i.e., the costs for traveling safe or unsafe way \((i,j) \in W\) is 0 or \(d_{ij}\) respectively. Only the shortest paths with a distance of at most \(L_k\) are considered for all \(k \in T\). The relative importance of an unsafe way is determined by counting the total number of riders whose shortest paths include this way. The greedy heuristic selects the most “important” way to upgrade and repeats the process until the budget is exhausted.

5 Cycling in Midtown Atlanta

This paper is motivated by improving bicycle travel conditions in the Midtown area in Atlanta, GA. Midtown is a neighborhood of Atlanta that consists of a commercial core and a residential neighborhood. The Midtown core is characterized by high-rise buildings and functions as a major employment center, including offices of large companies such as NCR, Google, Equifax, and Honeywell. The commercial core has around 28k residents, and 70k people per day travel to the area for work (Midtown Alliance, 2019). The residential neighborhood is to the east of the business district, and mainly consists of single-family residences. Every workday, a large number of commuters drive to Midtown, and cause a significant amount of traffic congestion. To better this situation, the case study aims at improving the bicycle infrastructure to provide these commuters safe and short cycling trips as an alternative to commuting by car.

5.1 Travel Data

To gain insight into current commuting behaviors, this paper uses travel data provided by the Atlanta Regional Commission (ARC). The ARC used an activity-based model, calibrated with survey data collected in 2007-2011, to simulate trips at the individual level (Atlanta Regional Commission, 2017). The data reveals a low share of cyclists among commuters to Midtown (about 0.7%), but also a significant potential for improvement: many of the trips to Midtown are short, and over 70% of commutes are completed by people driving alone, who could potentially switch to cycling if the infrastructure is improved.

The case study focuses on one particularly interesting group: the group of white-collar workers coming in from Virginia-Highland, an affluent neighborhood immediately to the east of Midtown. Figure 6 shows the daily number of trips originating from Virginia-Highland for both cyclists and solo drivers, categorized by trip purpose. Many trips are taken by white-collar commuters but, despite the close proximity of Virginia-Highland to Midtown, the number of cyclists is less than 5% that of the number of solo drivers.

To study how improving the bicycle network affects travelers, a sample of travels is generated to represent the white-collar commuters from Virginia-Highland. The eight Traffic Analysis Zones (TAZs) that cover Virginia-Highland are selected as the departure zones, and 72 TAZs that cover Midtown and Virginia-Highland are chosen as the destination zones. Destinations in Virginia-Highland are included, as these trips may benefit from the same infrastructure improvements. The ARC provides travel data between the TAZs, and to obtain a more realistic sample, the origins and destinations are randomly assigned to the centers of the smaller census blocks, weighted by the population counts. Five samples are generated for every OD pair, and samples that do not connect to the existent road network are filtered out. The result is a set of 1039 representative trips, covering 110 origins and 256 destinations, presented by Figure 7. The origins on the map are in Virginia-Highland in the East, and most destinations are in the business area in the West. The center of the map shows Piedmont Park, with the Midtown residential neighborhood to its South.
5.2 Current Bicycle Network

The current road network in the case study area was retrieved from OpenStreetMap (OpenStreetMap, 2020). The network consists of 5815 nodes and 11,329 directed ways. The ways make up 667 roads, and have a total length of 212 miles. The roads are classified into three types: roads with a dedicated bike lane, residential roads, and unsafe roads, where dedicated and residential roads are assumed to be safe for cyclists.

Figure 8 shows the current bicycle network in the case study region, where blue, red, and gray roads describe dedicated, unsafe, and residential roads, respectively. Unsafe roads do not have the proper infrastructure for cyclists, and are the target for conversion to dedicated roads. There are 450 bicycle-unsafe roads, with a total length of 113 miles. The conditions on the unsafe roads are assumed to be similar throughout the area, and the cost to realize dedicated bike lanes is assumed to be the same per unit length everywhere. Among the sampled ODs, only 170 trips (16%) have bicycle-safe routes that are completely safe. Moreover, many of them require a significant detour to complete those safe paths. For example, only 89 ODs (9%) have access to a bicycle path with a detour of less than 10% of the shortest path.
6 Experimental Results

This section presents experimental results on the case study. It first shows that the Benders decomposition algorithm allows for solving the BNIP to optimality for realistic instances that cover a whole neighborhood. It also analyzes the effectiveness of the optimal improvement plans to provide safe and short cycling trips to commuters and demonstrates the benefits of optimization by comparing the optimal improvement plans to those obtained with the greedy heuristic.

6.1 Experimental Settings

The experimental results use the case study region, the existing network, and the 1039 sample trips from Section 5. For each sample, the number of passengers \( p_k = 1 \), as the case study targets solo drivers that commute to their work places. The budget \( B \) ranges from 4 miles up to 28 miles of improvements, in 4 mile increments. For the case study, it is useful to consider network improvements on the road level, rather than on the way level, and to improve both directions at the same time. These solutions are more practical to implement, and also contribute to safe return trips. In total, 450 roads are identified. To improve all ways of a road at the same time, additional constraints are added to the BNIP: if \((i, j) \in W'\) and \((p, q) \in W'\) are part of the same road, then \( y_{ij} = y_{pq} \). These constraints are added to the Benders master problem, without changing the main steps of the algorithm. For the greedy heuristic, the relative importance of a road is calculated by averaging the usage counts for the individual ways.

The core experimental results use a linear penalty function with \( f_k(u_k) = u_k \), i.e., the objective maximizes the number of cyclists and minimizes the overall average distance over the shortest paths. The threshold \( L_k \) is computed in terms of a deviation factor \( R \geq 1 \), i.e., \( L_k = s_k R \). The resulting BNIP is denoted as BNIP-L. The full Benders algorithm is implemented in Python, and Gurobi 9.0.2 is used to solve the master problem and the subproblems. All computations are performed with an Intel Core i7-8565U CPU and 16GB of RAM.

6.2 Efficiency of the Benders Algorithm

This section compares three Benders decomposition algorithms: the traditional Benders decomposition algorithm (TB), the algorithm that uses Magnanti and Wong Pareto-optimal optimal cuts (MW), and the algorithm that uses both Pareto-optimal cuts and the McDaniel and Devine two-phase strategy (MW-McD). In the MW-McD experiments, phase one is limited to 20 minutes.

Figure 9 reports the experimental results for various budgets and \( R = 1.2 \). The left charts show the optimality gap, i.e., the difference between the best feasible solution and the lower bound over time, and the right charts show how the upper and lower bounds approach each other until the optimal solution is found. The three rows correspond to the TB, MW, and MW-McD strategy, respectively. In the MW-McD case, the vertical dashed line indicates the switch from phase one to phase two.

The first observation is that TB is significantly outperformed by MW and MW-McD. When fractional cuts are added prior to integral cuts (MW-McD), the initial optimality gap is much smaller and the number of iterations is significantly reduced compared to MW. Table 1 compares MW and MW-McD on the number of Benders iteration to reach optimality. MW solves each BNIP instance optimally in under 150 minutes, where MW-McD only takes around an hour per instance. Figure 10 verifies that the good performance of MW-McD is consistent for different budgets \( B \) and for different distance thresholds \( R \). Overall, the solution time of at most five hours is short for creating an improvement plan for months or years into the future. This contrasts with the MIP model that cannot solve the instances in reasonable time. Note that the difficulty comes from the size of the problem: the network consists of \(|W| = 11,329\) arcs, and

the BNIP introduces a flow variable for each arc and for each of the 1039 ODs, resulting in a MIP with over 10 million variables. The Benders decomposition exploits the problem structure and solves a significantly smaller problem for each OD at every step.

6.3 Impact of Bicycle Network Improvement Plans

It is interesting to study the type of improvements produced by optimal plans. Figures 27-30 in Appendix A present the full series of improvement plans for the different settings of $B$ and $R$; this section discusses the most important observations. The experiments are conducted with $R = 1.1, 1.2, 1.3$, and $1.5$.

Plan Characteristics The bicycle network improvement plans show several notable trends. First, the problem searches for sub-regions that can be served with minimum improvements by maximizing the usage of pre-existing infrastructure. The left map of Figure 11 shows the optimal plan when only 4 miles of road can be improved. Two crucial improvements (circled in yellow) were selected: a short segment that links the park and Virginia-Highland to the East, and roads Northwest of the park that connect to the business area. These connections are essential to allow the commuters from Virginia-Highland to commute to their workplaces.

A second observation is that the optimal plans do not waste budget to improve multiple roads that serve a similar purpose. For instance, consider the short discontinuity of safe roads between the park and the roundabout located north of the park. The optimization algorithm does not remove this discontinuity, because the short segment connecting Virginia-Highland to the park serves the same purpose. Plans generated by the greedy heuristic (Figure 31 in Appendix A) do not recognize this. This is the value of optimization that provides globally optimal plans. This will have the consequence that some trips are better served on the heuristic network, but overall the optimization will produce significantly better plans.
A third observation concerns increased budgets: here the BNIP prioritizes the improvement of the backbone of the network, rather than providing sporadic developments. The 12-mile map in Figure 11 shows the investments on Monroe Drive (a hook-like vertical road) to provide safe North-South travel, and on missing segments of Ponce De Leon Avenue (a horizontal road located southwest), that may connect all Southern demands.

The order in which the backbone is constructed depends on the deviation factor. For instance, Figure 14, which includes 24 miles improvement plans with four deviation factors, shows that North Highland Avenue (a vertical road located east) has not been improved for $R = 1.5$, unlike three other plans of shorter distance thresholds. That is because the longer deviation allowance permits to serve origins located on the east with residential roads despite causing some detour, and improves more roads in the western business area to complete more last miles of the ODs.

Although the order of its construction may be different, the backbone of the network converges as $B$ increases. To follow up on the above case, the 28 miles plan for $R = 1.5$ (Figure 30 in Appendix A) improves North Highland Avenue and exhibits practically identical road improvements regardless of different travel length allowance.

**Effectiveness** Figure 12 shows the effectiveness of the optimal improvement plans for different parameters. For each $R$, the percentage of potential cyclists grows as the budget and the average trip distance over the shortest paths decreases. Potential cyclists are those riders with a safe bicycle trip whose length does not exceed the maximum distance (i.e, $L_k$ for trip $k$). The number of people that benefit from the improvements is similar for all values of $R$. Improving only 4 miles of bicycle lanes already doubles the amount of potential cyclists at the minimum. Moreover, the number of potential cyclists increases almost linearly with the budget, indicating that further investments in bicycle infrastructure deliver similar value and keep attracting new potential cyclists.

Figure 13 presents an example of how the cycling path can change as the bicycle network is extended. The corresponding OD has a shortest path length of 4,250 meters (2.64 miles, $s_k$), and the maximum allowed length for a bicycle safe path is 6,375 meters (3.96 miles, $L_k = 1.5s_k$). On the current network, there does not exist a safe bicycle path that is sufficiently short. However, the OD achieves a safe bicycle path of 6,009 meters (3.73 miles, $1.41s_k$) when $B = 8$ miles of roads are improved. Increasing the budget further to 12 miles provides a shorter bicycle path of 4,976 meters (3.09 miles, $1.17s_k$).

#### 6.4 The Benefit of Optimization

This section compares the optimal improvement plans (OPT) to those obtained with the greedy heuristic (HEU). For instance, Figure 15, which includes 24 miles HEU plans of four deviation factors, demonstrates that heuristic improvements focus less on constructing the backbone, compared to Figure 14, and often unnecessarily provide multiple connections that serve a similar purpose. The optimal and heuristic plans are compared on the percentage of potential cyclists and the average additional trip distance. An example set of heuristic solutions for $R = 1.1$ is presented by Figure 31 in Appendix A.

**Individual Travel Comparison**  By definition, a heuristic plan cannot be better than the optimal plan, but the heuristic may improve some trips more than the optimal plan. For example, Table 2 counts the number of travels with a smaller trip distance when $R = 1.1$: it shows that, for all budgets, the optimal plans produces shorter routes more often than the heuristic.

Figure 16 shows a single OD that is evaluated both on the heuristic plan and the optimal plan. The corresponding OD has a shortest path length of 3,784 meters (2.35 miles, $s_k$), and the maximum allowed length for a bicycle safe path is $L_k = 1.3s_k$. The optimal plan provides a short route of 3,973 meters (2.47 miles, 1.05$s_k$) that is below the threshold distance. The heuristic also produces a safe path; however, the path length is 5,286 meters (3.28 miles, 1.39$s_k$), which exceeds the threshold, so the heuristic plan still requires the outside option to serve the OD.
Potential Cyclists  Figure 17 compares the heuristic plans and the optimal plans in terms of the number of potential cyclists. The results demonstrate that the optimal plans produce significant benefits in the number of potential cyclists. This is consistent over all budget values, and the difference may be more than 20%. This is a compelling demonstration of the value of sophisticated optimization for infrastructure improvement.

Average Additional Trip Distance  Figure 18 compares the average additional trip distance of the optimal and the heuristic plans for different values of $B$ and $R$. Again, the optimal plans produce significant benefits compared to the heuristics for all budget values. They parallel the improvements in potential cyclists and demonstrate the significant value of optimization for the BNIP.

Figure 19 shows the distribution of additional trip distances of safe routes for the optimal and heuristic plans under two example settings. Among the safe routes, the heuristic plans tend to produce fewer trips with smaller additional trip distances. In contrast, the optimization plans, which optimize both the number of potential cyclists and the average additional trip distances, have more trips with smaller additional trip distances as well as have more feasible bicycle travels.
6.5 Sequential Incremental Improvements

In practice, policy makers cannot necessarily predict future availability of budget or other resources for the infrastructure development. Therefore, the improvement plans may be prepared over time and not in advance. Furthermore, there may be an incentive to implement solutions that are optimal in the short term, but may not necessarily be good in the long run. To investigate the effect of small myopic improvements, it is interesting to study the cumulative effect of a succession of individual improvement plans that optimally extend the bicycle infrastructure by 4 miles at a time. Figure 20 presents one example of these plans, which illustrates how the sequential approach progressively produces the same overall structure as the optimal plan using $R = 1.1$.

Figure 21 shows that for all $R$, the additional average trip distances in the sequential approach is essentially similar to the overall optimal plans. This is of great practical importance, as it indicates that incrementally improving the network over time is practically identical to a strategic planning approach.

Table 3 provides more details on the differences between the plans. The largest difference

Table 3: Strategic Planning versus Incremental Improvements: Average Additional Trip Distance (m), $R = 1.1$.

of additional trip distances between an optimal and a myopic plan is only 4950 meters in total, or 5 meters per travel on average. The optimal plans and the myopic plans do not lead to the same networks, but the difference in penalty is very small, especially as the network is improved further over time.

7 Alternative Penalty Functions

The results in the case study were generated with a linear penalty function, but other choices may lead to different bicycle network improvement plans. This section considers two alternative models aimed at minimizing the penalty of lost travelers, and maximizing the number of cyclists, respectively. The former results in a piecewise linear penalty function, and the latter requires a modification of the program formulation.

7.1 Minimizing the Penalty of Lost Cyclists

This section presents a model that minimizes the penalty incurred by the travelers who choose not to use the improved bicycle network. Compared to the linear penalty functions, the new model specifically focuses on potential cyclists that are lost to the system, rather than on the average additional trip distance.

The model assumes that potential cyclists have a probability to drop out that increases with the deviation $u_k$ from the shortest safe trip. For short deviations $u_k \leq 0.2s_k$, the probability is assumed to be zero, and no penalty is incurred. After that, the dropout probability increases linearly until the maximum trip length of $L_k = 1.5s_k$ is reached, at which point all travelers choose the outside option. The expected penalty for lost travelers at deviation $u_k \in [0.2s_k, 0.5s_k]$
Table 4: Network Improvement Comparison of BNIP-P and BNIP-L ($R = 1.5$).

follows from multiplying the dropout penalty of $u_k = L_k - s_k$ by the probability of dropping out. This results in the following penalty function:

$$f_k^P(u_k) = \begin{cases} 
0 & \text{if } u_k \leq 0.2s_k, \\
\frac{5}{3}u_k - \frac{1}{3}s_k & \text{if } 0.2s_k \leq u_k \leq 0.5s_k.
\end{cases}$$

(8)

Note that $f_k^P$ is piecewise linear and convex. The endpoint $f_k^P(0.5s_k) = 0.5s_k$ corresponds to a 100% dropout rate and penalty $L_k - s_k = 0.5s_k$.

To use $f_k^P$ in the Benders decomposition algorithm, the master problem defines continuous $v$-variables, uses $f_k^P(v_k) = v_k$ in the objective, and includes the following two additional constraints:

$$v_k \geq 0 \quad \forall k \in T,$$

(9)

$$v_k \geq \frac{5}{3}u_k - \frac{1}{3}s_k \quad \forall k \in T.$$  

(10)

The optimization with piecewise linear penalty function $f_k^P$ is labeled BNIP-P, and Figure 32 in Appendix A presents the full series of the BNIP-P improvement plans.

**Improvement Results** The BNIP-P improvement plans are compared with the BNIP-L plans for $R = 1.5$, which have equal travel distance thresholds. Table 4 summarizes the improvements using each model. The two penalty functions produce very similar improvement plans; the percentage of network difference - a sum of percentages of unique improvement lengths on each improvement plan - shows that the two plans converge as more budgets are allowed.

The deviation of an individual traveler is shorter for the BNIP-L, which is anticipated as the BNIP-P assigns equal penalty for short routes and focuses more on increasing the probability of bicycle participation. However, the difference in cyclist percentages between the two optimized networks is very small. This is an important observation, as it shows that the linear objective does not forfeit the advantage of the piecewise objective.

### 7.2 Maximizing the Number of Cyclists

Rather than assuming a probabilistic model for cyclists dropping out, it is also possible to directly maximize the number of potential cyclists, i.e., to maximize the number of ODs with a short and safe trip, or equivalently, minimize the use of the outside option $z_k$. Figure 22 presents the modifications needed for this model, which is labeled as BNIP-Z.

Objective (11a) minimizes the use of the outside option on the network. A binary variable $f_k$ is introduced for every trip $k \in T$ to ensure complete recourse, and the $f$-variables replace
\begin{align}
\text{min} & \quad \sum_{k \in T} p_k z_k, \quad (11a) \\
\text{s.t.} & \quad \sum_{(i,j) \in W'} d_{ij} y_{ij} \leq B, \quad (11b) \\
& \quad \sum_{(i,j) \in W} x_{ij}^k - \sum_{(j,i) \in W} x_{ji}^k = \begin{cases} 1 - f_k & \text{if } i = o_k \\ f_k - 1 & \text{if } i = d_k \\ 0 & \text{otherwise} \end{cases} \quad \forall k \in T, i \in V, \quad (11c) \\
& \quad x_{ij}^k \leq y_{ij} \quad \forall k \in T, (i,j) \in W', \quad (11d) \\
& \quad \sum_{(i,j) \in W} d_{ij} x_{ij}^k + (L_k + M_k) f_k \leq L_k + M_k z_k \quad \forall k \in T, \quad (11e) \\
& \quad y_{ij} \in \mathbb{B} \quad \forall (i,j) \in W', \quad (11f) \\
& \quad x_{ij}^k \in \mathbb{B} \quad \forall k \in T, (i,j) \in W, \quad (11g) \\
& \quad f_k \in \mathbb{B} \quad \forall k \in T, \quad (11h) \\
& \quad z_k \in \mathbb{B} \quad \forall k \in T. \quad (11i) 
\end{align}

Figure 22: The MIP Model for the BNIP-Z.

\begin{align}
\text{min} & \quad (11a), \\
\text{s.t.} & \quad (11b), (11f), (11i), \\
& \quad \Psi_k(y) \leq L_k + M_k z_k \quad \forall k \in T. \quad (12) \\
& \quad \Psi_k(y) = \min \sum_{(i,j) \in W} d_{ij} x_{ij}^k + (L_k + M_k) f_k, \quad (13) \\
\text{s.t.} & \quad (11c), (11d), (11g), (11h). 
\end{align}

Figure 23: The Master Problem of the BNIP-Z. Figure 24: The Subproblem of the BNIP-Z.

the z-variables in Constraints (11c). That is, if no safe bicycle path exists, f_k can be set to one instead. Constraints (11e) use the constant M_k > 0 to ensure that the outside-option variables z_k are set correctly: preferably, the outside option is not used (z_k = 0), which implies that f_k = 0 and that the z-variables represent a safe and short bicycle path. If the outside option is used, setting f_k = 1 removes this requirement. As a result, BNIP-Z indeed minimizes the use of the outside option. Finally, Constraints (11h) define the newly added variables.

It is notable that the Benders decomposition solution method can be used for the BNIP-Z. Figures 23 and 24 present the modified master and subproblem, respectively. The new function calculating the shortest path, \( \Psi_k(y) \), is introduced by the modified subproblem. The master problem now includes the z-variables for the minimization of Objective (11a). The subproblem can be solved by linear programming as it is a standard minimum-cost flow problem. Pareto-optimal cuts and two-phase Benders can be used in the same way as before, and both y and z-variables may be relaxed in phase one.

Figure 33 in Appendix A presents the full series of the BNIP-Z improvement plans using \( L_k = 1.5s_k \).

**Improvement Results** Due to their objectives, the BNIP-L produces shorter deviations in average in its routes, and the BNIP-Z collects more potential cyclists. Nevertheless, Figure 25 illustrates that the difference of performances between the two programs is inconsequential. This shows that the use of the linear penalty, which examines both travel safety and proximity,
Figure 25: Performances of the BNIP-L and BNIP-Z.

does not sacrifice cyclists count to provide shorter deviation for riders.

7.3 Efficiency of Alternative Models

To evaluate the methodological efficiency of the three BNIP formulations, the optimality gap and the upper and lower bounds of the Benders solutions are compared over time. Using algorithm MW-McD, the BNIP-Z has the fastest computation times in many cases as shown in Figure 26. The BNIP-L also exhibits fast convergence to a small optimality gap for most cases. This is noteworthy as BNIP-L considers both traveler safety and deviation.

All three formulations reach optimality within a reasonable time, and they are shown to produce equally attractive improvement plans. Recall the BNIP-Z disregards travel distances, and the BNIP-P has a piecewise linear objective that is harder to interpret. The linear objective of the the BNIP-L reports the quality of the network in distance values, allowing for a more direct and meaningful evaluation of the network.

8 Conclusion

Cycling brings many benefits to both the cyclists and to society as a whole, and the emergence of e-bikes may make this transportation mode attractive for a larger population segment. However, safety is a critical issue faced by commuters when deciding their transportation mode. This paper considered the problem of improving the bicycle infrastructure to allow more people to travel by bicycle. It presented the Bicycle Network Improvement Problem (BNIP) that jointly optimizes safety and trip length, and whose solution provides the best improvement within a given budget. Solving the BNIP directly is computationally intractable for large instances, so the paper presented a Benders decomposition to remedy this issue by exploiting the problem structure and considering each rider independently in the subproblems.

The paper demonstrated the effectiveness of the method on an in-depth case study for Midtown Atlanta, based on real transportation data of white-collar commuters from Virginia-Highland. The computational results show that the proposed Benders decomposition algorithm with Pareto-optimal cuts and two-phase Benders is very effective in solving the realistic case study instances. Further analysis revealed that the optimal bicycle network improvement plans for Midtown Atlanta are very powerful in providing access to safe and short bicycle routes. The increase in potential adoption is almost linear in the available budget, indicating that more investments in bicycle infrastructure may keep attracting additional commuters to switch to cycling. The Benders decomposition method was compared to a greedy heuristic, and shown to lead to significantly better plans. The paper also showed that repeated myopic extensions of the
network leads to an almost optimal result in the long run. This is of great practical importance, as it indicates that myopically improving the network over time is practically identical to in-advance planning. In addition, the paper demonstrates that the results are robust with respect to different objective functions.

Current work is investigating how to extend these ideas to multi-modal transit systems, where the goal is not necessary to offer a bicycle path for the complete trip, but to let bicycles play a role in addressing the ubiquitous first/last mile problem.
