THE EAS APPROACH TO VARIABLE SELECTION FOR MULTIVARIATE RESPONSE DATA IN HIGH-DIMENSIONAL SETTINGS

BY SALIL KONER¹ AND JONATHAN P WILLIAMS¹

¹Department of Statistics, North Carolina State University, skoner@ncsu.edu; jwilli27@ncsu.edu

In this paper, we extend the epsilon admissible subsets (EAS) model selection approach, from its original construction in the high-dimensional linear regression setting, to an EAS framework for performing group variable selection in the high-dimensional multivariate regression setting. Assuming a matrix-Normal linear model we show that the EAS strategy is asymptotically consistent if there exists a sparse, true data generating set of predictors. Nonetheless, our EAS strategy is designed to estimate a posterior-like, generalized fiducial distribution over a parsimonious class of models in the setting of correlated predictors and/or in the absence of a sparsity assumption. The effectiveness of our approach, to this end, is demonstrated empirically in simulation studies, and is compared to other state-of-the-art model/variable selection procedures.

1. Introduction. With the advent of modern data collection technologies, in many real-life applications multiple responses are simultaneously collected that are characterized by a set of explanatory variables. Data of this structure falls under the scope of the multivariate regression. Examples arise in chemometrics (Frank and Friedman, 1993), genome-wide association study (GWAS) (Boulesteix and Strimmer, 2005), etc. More often than not, the number of predictors, say $p$, is much larger than the number of observed multivariate response vectors, say $n$. Parsimoniously modeling the variability in the response without overfitting is necessary to enhance the prediction accuracy. For example, in GWAS, identification of key genetic markers out of millions that are associated with a univariate or multivariate phenotype is of scientific interest (Vounou et al., 2010). Model/variable selection is a statistical framework that has been widely popular in this context. A naive way to approach this multivariate problem is model the components of the response as separate univariate regressions on the predictors, and to employ existing selection techniques available in the univariate setting. However, since the multiple responses for each subject are often correlated, prediction error can be minimized substantially if one uses the inherent association between the responses effectively (Breiman and Friedman, 1997). Finding the best model in the context of multivariate linear regression (MLR) without ignoring the correlation between the responses, especially in a high-dimensional setting is a challenging task and has received much attention in the literature over the last decade.

In this direction, we develop an EAS procedure for group variable selection in the high-dimensional MLR setting. The EAS procedure was originally developed in a high-dimensional univariate regression setting by Williams et al. (2019), and has been extended to the vector auto-regression setting by Williams, Xie and Hannig (2019). However, an EAS procedure has not been constructed for the multivariate regression setting, nor has there been built a group selection mechanism for EAS selection. Analogous to Bayesian model selection approaches, we consider a generalized fiducial inference (GFI) approach (Hannig et al., 2016) that explicitly estimates the generalized fiducial (GF) distribution over the class of all

Keywords and phrases: Bayesian model selection, generalized fiducial inference, model selection consistency, regularized regression.
subsets of predictors; whereas frequentist and most Bayesian approaches exclusively focus on coefficient estimation to perform variable selection. In a high-dimensional setting, it is very problematic for a variable selection procedure to over-rely on the magnitude of the estimated regression coefficients because they lack identifiability and are numerically unstable. Moreover, most variable selection procedures for multivariate regression do not consider the correlation structure of the multivariate responses. Our multivariate group EAS procedure is designed to inherently accommodate the arbitrary covariance structure of the response. As explained in Lee and Liu (2012), accounting for the correlation is important because, for example, in the case of the least absolute shrinkage and selection operator (LASSO) estimator the shrinkage criterion is effected by the magnitude and sign of the correlation between the responses.

Mathematically, under a standard sparsity and Gaussian errors assumption we prove that our proposed EAS procedure achieves strong model selection consistency, as defined in Narisetty et al. (2014). That is, we show that, over the class of all \( \epsilon \)-admissible subsets of the predictors/groups, the GF probability of a true sparse model converges to one in probability as the sample size goes to infinity, and the number of predictors/groups is allowed to grow sub-exponentially as a function of the sample size. Additionally, as a next paper in the series of papers to investigate EAS model selection strategies in various settings, the algorithm we propose improves on the computational efficiency and stability of the algorithms proposed in Williams et al. (2019); Williams, Xie and Hannig (2019). We provide user-friendly R software to implement our EAS procedure, available at \( \text{https://salilkoner.wordpress.ncsu.edu/research/} \).

Under sparsity assumptions, Obozinski et al. (2011) proved support union recovery for high-dimensional multivariate group LASSO, and Chen and Huang (2012) established selection consistency for SRRR when \( p \) is fixed. As for the Bayesian methods, Liquet et al. (2017) demonstrated model selection consistency under an orthogonal design, which is a bit restrictive from a practical perspective. To the best of our knowledge, the only currently existing paper to prove a consistency result in a high-dimensional Bayesian multivariate regression setting is Bai and Ghosh (2018a). However, they show an estimation consistency result for the regression coefficients, rather than a model selection consistency result. Moreover, their method is not designed to shrink coefficients to zero, so to implement variable selection they infer the insignificance of a predictor if the estimated posterior credible interval (at some a-priori specified level) of its coefficient includes zero.

The choice of the tuning parameter \( \epsilon \) used in Williams et al. (2019) is somewhat unintuitive as it is primarily driven by theoretical consistency rates, and it is dependent on the size of the true model, which is typically unknown. In our paper, we design the grouped EAS variable selection procedure in such a way that the tuning parameter can be searched over a (true sparse model agnostic) grid with respect to some pre-specified error metric. In Williams et al. (2019), \( \epsilon \) is chosen via \( k \)-fold cross-validation (CV), which is computationally expensive (especially in a multivariate setting). In our paper, we implement a computationally efficient version of the EAS algorithm that bypasses the original repeated sampling based pseudo-marginal Markov chain Monte Carlo (MCMC) algorithm, and also chooses the tuning parameter through a multivariate version of Bayesian Information Criterion (BIC), instead of choosing it through \( k \)-fold CV.

Lastly, in various simulation setups we demonstrate that our EAS procedure is either competitive with or outperforms the state-of-the-art Bayesian or frequentist approaches, based on various metrics such as prediction error, misclassification rate and average proportion of correct model selection. Moreover, our method does an excellent job in assigning a very high probability mass to the true model compared to the other Bayesian methods, consistent with its theoretical selection consistency property, in sparse/dense and low/high dimensional setting.
Standard model selection techniques for univariate linear regression via Mallow’s Cp and other types of information criterion have been extended to multivariate regression; see Sparks, Coutsourides and Troskie (1983); Bedrick and Tsai (1994); Fujikoshi and Satoh (1997), and the references therein. Since the inception of LASSO (Tibshirani, 1996), penalized methods introducing sparsity in the regression coefficients have engulfed the MLR literature. Notable contributions are the simultaneous variable selection using $L_\infty$SVS, Turlach, Venables and Wright (2005) and $L_2$SVS by Simila and Tikka (2006); the remMap procedure by Peng et al. (2010) employs an elastic net type penalty to identify master predictors. Rothman, Levina and Zhu (2010) pioneered the estimation of the regression coefficients taking into account the correlation between the responses, which was extended by Lee and Liu (2012). Provided that the groups are known, Li, Nan and Zhu (2015) proposed a multivariate sparse group LASSO strategy to impose the group structure, which was later augmented by Wilms and Croux (2018) for simultaneous covariance estimation.

Several authors approached the high-dimensional multivariate regression problem via a dimension reduction technique, termed as reduced rank regression (RRR) (Izenman, 1975; Velo and Reinsel, 2013). The key idea is to assume that the coefficient matrix admits a low-rank factorization and to enforce sparsity in the factor matrices. For instance, Yuan et al. (2007) suggested to shrink the nuclear norm of the coefficient matrix, and Chen, Chan and Stenseth (2012) suggested penalizing the left and right singular vectors. However, these methods are designed to extract the latent factors, not for the selection of significant predictors. To carry out variable selection using RRR, Chen and Huang (2012) developed a sparse RRR (SRRR) method that projects the response onto a data-driven orthonormal matrix and induces sparsity in the latent factor. Furthermore, a sparse penalized least squares (SPLS) based framework has been popular in genetic association studies, which is equipped to perform both variable selection and dimension reduction (Chun and Keleș, 2010).

From a Bayesian perspective, Brown, Vannucci and Fearn (1998, 2002) employed a stochastic search variable selection (SSVS) procedure in the multivariate regression setting. Zhu et al. (2014) developed a Bayesian version of low-rank approximation to investigate the association between the predictors and the multivariate response. Liquet et al. (2017) extended the Bayesian group LASSO using a spike-and-slab prior to perform variable selection. To mitigate the computational issues of spike-and-slab priors for the large $p$ scenario, Bai and Ghosh (2018a) introduced continuous global-local shrinkage priors to perform variable selection. Recently, Deshpande, Ročková and George (2019) formulated an expectation-maximization (EM) based maximum a posteriori (MAP) estimation procedure for fast simultaneous variable and covariance selection using continuous shrinkage priors.

So far the NP-hard problem of best subset selection has been conveniently handled by introducing sparsity in the true data generating model. However, in a high-dimensional setting, especially when there is a strong degree of collinearity amongst the predictors, there may not be a unique model that fits the data best, and so the concept of a true model is somewhat vague. Moreover, the typical $\ell_1$ and $\ell_2$ regularization methods shrink the coefficients to zero only based on their magnitude, which is again unreliable in the presence of multicollinearity. Our EAS procedure provides a fresh perspective on variable selection in the MLR setting by defining an admissibility condition for candidate models. The admissibility criterion relates to the idea that any candidate model, as defined by a set of predictors, is redundant if there exists a subset model that explains the variation in the response data as well as the candidate model. Thus, while we prove important mathematical properties of the EAS approach under a sparsity assumption, in finite sample data analyses the key functionality of our EAS approach is not to determine the model that is necessarily the true set of predictors, but to identify a parsimonious model that explains the data as well as the true model, if it exists.
This criterion is meaningful even in the absence of a sparsity assumption. We refer to the criterion as $\epsilon$-admissibility, and define it precisely in Section 2.

In addition to other factors, the $\epsilon$-admissibility of a given model takes into account the covariance structure of the multivariate response. In a multi-response setting, the noise associated with a particular component of the response may be significantly higher than the other components. Many of the variable selection procedures such as remMap, $L_2$SVS or RRR, neither consider this difference in noise levels nor the intra-dependence in the multivariate response. By rescaling the mean of the response with the square-root inverse of the covariance, the signal from each predictor can be modeled on a uniform scale, which improves the precision of our EAS algorithm to detect truly significant predictors.

Prior choice/specification in contemporary Bayesian approaches are typically not chosen because they reflect true prior knowledge/beliefs, but they are tailored to simplify computational complexities and/or achieve desirable large sample/frequentist properties. While this practice is pragmatic, it is a violation of fundamental Bayesian principles. In contrast, GFI is an equally principled framework that has an appeal to objective Bayesian perspectives, but it does not suffer from the arbitrary choice of prior specification. See Hannig et al. (2016) for a full introduction of GFI. In our paper, we introduce a GF-based inferential approach for the MLR setting under the Gaussian data generating assumption with a general covariance structure. The key characteristic of the EAS-based GF distribution is that it assigns very negligible probability to the models that fail the $\epsilon$-admissibility criterion, and in doing so significantly reduces the class of candidate models to choose from. This is the intuition for why the procedure is able to achieve strong model selection consistency, if sparsity is assumed.

An advantage of our GFI-based variable selection procedure over the frequentist counterparts is that it provides an estimate of the model probabilities, derived from the posterior-like GF distribution of the model parameters. Even many Bayesian approaches, such as Multivariate Bayesian model with Shrinkage Priors (MBSP) by Bai and Ghosh (2018a), multivariate spike-and-slab prior (mSSL) by Deshpande, Roˇcková and George (2019), and Spike-and-Slab Group Lasso (SSGL) by Bai et al. (2020) are not developed to compute relative model probabilities; rather they are designed to estimate the MAP probability model parameters. In a finite sample scenario, relative model probabilities are useful because they give a certain degree of confidence in choosing one model over another, and they reflect a useful discrimination between competing models, especially in the high-dimensional setting.

The rest of the paper is organized as follows. In Section 2 we layout the EAS methodology and highlight differences from other EAS approaches. Next, the computational algorithm to implement the method is presented in Section 3. A few essential non-asymptotic results characterizing the meaningfulness of the EAS procedure along with the main consistency result are stated in Section 4. The proof of the main result is given in the Appendix, and the proofs of all other results are relegated to the Supplementary Material. Finite sample numerical results covering both $n > p$ and $p > n$ cases are illustrated in Section 5. Computer codes to reproduce all empirical results are available at https://salilkoner.wordpress.ncsu.edu/research/.

**Notations.** Throughout the course of the paper we will use the following notations. For an vector $\mathbf{a} \in \mathbb{R}^n$, $\|\mathbf{a}\| =: \sqrt{\sum_{i=1}^n a_i^2}$ denotes vector 2-norm; for any matrix $\mathbf{A}$, $\|\mathbf{A}\|$ refers to the spectral norm (i.e., $\|\mathbf{A}\| := \sup_{\|\mathbf{x}\|=1} \|\mathbf{A}\mathbf{x}\|$); $\|\mathbf{A}\|_F$ denotes the Frobenius norm; and $\|\mathbf{A}\|_{\text{max}} := \max_{i,j} |a_{ij}|$ denotes the max norm. For any symmetric matrix $\mathbf{A}$, $\lambda_{\text{min}}(\mathbf{A})$ and $\lambda_{\text{max}}(\mathbf{A})$ denotes the minimum and maximum eigenvalues, respectively, of the matrix $\mathbf{A}$. For an $m \times r$ random matrix $\mathbf{X}$, $\mathbf{X} \sim \text{Matrix-Normal}_{m,r}(\mathbf{M}, \mathbf{U}, \mathbf{V})$ is equivalent to $\text{vec} (\mathbf{X}) \sim N_{m,r}(\text{vec}(\mathbf{M}), \mathbf{V} \otimes \mathbf{U})$ (see Gupta and Nagar, 2018a, definition 2.2.1). For a $m \times r$ random matrix $\mathbf{X}$, $\mathbf{X} \sim T_{m,r}(\nu, \mathbf{M}, \mathbf{U}, \mathbf{V})$ means $\mathbf{X}$ follows a matrix $t$-distribution with mean $\mathbf{M}$,
scale matrices \( U, V \), and degrees of freedom \( \nu \) (see Gupta and Nagar, 2018a, definition 4.2.1). For any set \( M \), \( |M| \) denotes the cardinality of \( M \). For any event \( A \), \( I(A) \) denotes the indicator function that the event happens. Lastly, for two sequences \( a_n \) and \( b_n \), \( a_n = o(b_n) \) means \( \lim_{n \to \infty} a_n/b_n = 0 \).

2. Methodology. In MLR, \( n \) pairs of examples \((X_i, Y_i)\) are observed, where \( Y_i := (Y_{i1}, \ldots, Y_{iq})^\top \) is the \( q \)-dimensional multivariate response for \( i \)-th subject, and \( X_i := (X_{i1}, \ldots, X_{ip})^\top \) contains the values of \( p \) predictor variables that are presumed to be associated with the response. The response is expressed as the linear model,

\[
Y_i = \sum_{j=1}^{p} B_j X_{ji} + A U_i,
\]

where \( B_j := (b_{1j}, \ldots, b_{qj})^\top \) is a \( q \)-dimensional regression coefficient vector where \( b_{lj} \) captures the effect of \( j \)-th predictor on \( \ell \)-th coordinate of the multivariate response, \( A \) is \( q \times q \) matrix, and \( U_i \in \mathbb{R}^{q \times 1} \) is the \( i \)-th error vector, so that \( \text{Var}(Y_i) = AA^\top \). Further denoting \( Y := [Y_1, \ldots, Y_n] \in \mathbb{R}^{q \times n} \) as the horizontal column stacked response, and \( U := [U_1, \ldots, U_n] \) as the corresponding \( q \times n \) dimensional error matrix, the multivariate regression model with a sample of size \( n \) is summarized as,

\[
Y = \left[ \sum_{j=1}^{p} B_j X_{j1}, \ldots, \sum_{j=1}^{p} B_j X_{jn} \right] + A U = B X + A U,
\]

where \( B := [B_1, \ldots, B_p] \in \mathbb{R}^{q \times p} \) is the coefficient matrix and \( X := [X_1, \ldots, X_n] \in \mathbb{R}^{p \times n} \) is the design matrix. Note that this is the traditional multivariate linear model expression, with the exception that the observations are stacked horizontally instead of vertically.

In the context of variable selection, for any index set \( M \subseteq \{1, \ldots, p\} \), let \( X_M \) denote the matrix with rows comprised of the rows of \( X \) corresponding to the indices in \( M \). In subsetting the rows of \( X \) for variable selection, the columns of \( B \) must be subset to only those corresponding to the indices in \( M \); take \( B_M \) to be the column-subsetted coefficient matrix. Accordingly, conditional on index set/model \( M \), expression (1) reduces to,

\[
Y = B_M X_M + A_M U,
\]

where the subscript \( M \) in the \( q \times q \) matrix \( A_M \) simply denotes the association with the index set \( M \). Observe that variable selection in this multivariate model is in fact a group selection problem because the active columns (i.e., the groups) of the coefficient matrix \( B \) are being selected. This fact establishes the need for the a group selection mechanism within the variable selection procedure. Nonetheless, the EAS variable selection procedure that we develop seamlessly accommodates the additional problem of selecting among known/posited groups of predictors, rather than the power set of the predictors 1, \ldots, \( p \) (i.e., the natural grouping). Our presentation will focus on EAS methodology for solving the problem of grouped variable selection for MLR under the natural grouping, but the methodology and theoretical results cover (as a sub-case) the simpler case when a class of predictor groups are known. In that case, simply restrict the class of candidate models that the algorithm is allowed to choose from.

In the case of Gaussian error, we introduce the notion of a true data generating model as the assumption that,

\[
Y \sim \text{Matrix-Normal}_{q,n} \left( B_M^0 X_M^0, V_M^0, I_n \right),
\]

for some fixed (but unknown) \( M_0 \subseteq \{1, 2, \ldots, p\} \), and some fixed (but unknown) parameter matrices \( B_M^0 \) and \( V_M^0 = A_M^0 A_M^{0\top} \), for some positive definite matrix \( A_M^{0\top} \). Note that in the
case of the covariance matrix $V_{M_o}^0$, the subscript $M_o$ simply denotes the association with the index set $M_o$ and the matrices $B_{M_o}^0 \in \mathbb{R}^{q \times |M_o|}$ and $X_{M_o}^0 \in \mathbb{R}^{|M_o| \times n}$, but it is not constructed by subsetting some more general matrix $V^0$. Analogous to Williams et al. (2019), the index ‘o’ in $M_o$ is in reference to the term ‘oracle’, and the superscript ‘0’ emphasizes that the quantities $B_{M_o}^0$, $X_{M_o}^0$, and $V_{M_o}^0$ are fixed quantities (in contrast to their GF/Bayesian-like random variable counterparts $B_{M_o}$, $X_{M_o}$, and $V_{M_o}$, to be introduced shortly). The matrix normal notation in (3) is a compact way of saying that the multivariate responses $Y_1, \ldots, Y_n$ are independent and identically distributed multivariate normal vectors with mean $B_{M_o}^0 X_{M_o}$, and $q \times q$ covariance matrix $V_{M_o}^0$.

The objective of our paper is to develop a methodology that identifies a non-redundant (i.e., $\epsilon$-admissible) set $M_o$ (the true model or possibly a related sub-model of the true model) out of the $2^p$ candidate sets in the power set of $\{1, 2, \ldots, p\}$. In the special case that the true model is sparse, the objective is to show that the method will identify the true model $M_o$, as the sample size is taken to infinity. The notion of $\epsilon$-admissibility is defined in Definition 2.1.

To build up to this definition, the following model-based perspective is required.

For any index set $M \subseteq \{1, \ldots, p\}$, we assume the conditional distribution,

$$Y | B_M, V_M \sim \text{Matrix-Normal}_{q,n}(B_M X_M, V_M, I_n),$$

where $B_M$ and $V_M = A_M A_M^\top$ are random matrices that reflect the uncertainty in not knowing the true data generating model nor true values of its parameter matrices. Under the Gaussian error assumption, the quantities $B_M$ and $V_M$ are expected to be centered, respectively, around the least squares estimator $\hat{B}_M := YY_M (X_M X_M^\top)^{-1}$ and the restricted maximum likelihood estimator $\hat{V}_M := \hat{\Sigma}_M / (n - |M|)$, with $\hat{\Sigma}_M := Y (I_n - H_M)^T Y$ and $H_M := X_M^T (X_M X_M^\top)^{-1} X_M$. Note that the matrix $H_M$ is the orthogonal projection onto the row space of $X_M$. Moreover, given the true data generating model (3), it follows that $E(\hat{Y}) = E(B_M X_M) = B_{M_o}^0 X_{M_o}^0 H_M$, and so if $M \supseteq M_o$ then $E(\hat{Y}) = B_{M_o}^0 X_{M_o}^0$. This means that any collection of predictors with linear span containing the oracle predictors, $M_o$, is as good at explaining variation in the data as the true model (in terms of residual sum of squares). However, such a large/redundant set of predictors lacks efficiency in terms of prediction accuracy. Exploiting this idea, the critical definition supporting our methodology is presented next.

**Definition 2.1.** A $q \times |M|$ regression coefficient matrix $B_M$ coupled with an index set $M \subseteq \{1, \ldots, p\}$ is said to be $\epsilon$-admissible if $h_\epsilon(B_M) = 1$, where

$$h_\epsilon(B_M) = I \left\{ \frac{1}{2} \left\| \hat{\Sigma}_M^{-1/2} (B_M X_M - B_{\min} X) \right\|^2_F \geq \epsilon \right\} I\{|M| < n - q\},$$

where $B_{\min}$ is the solution to the optimization problem,

$$\arg \min_{B \in \mathbb{R}^{q \times p}} \left\{ \left\| \hat{\Sigma}_M^{-1/2} (B_M X_M - B X) \right\|^2_F \text{ subject to } |\{j : \|B_j\| \neq 0\}| \leq |M| - 1 \right\}.$$

Definition 2.1 characterizes a notion of redundancy for any set of predictors, indexed by $M$. The quantity $\|B_M X_M - B X\|^2_F$ captures the difference in prediction of the model $M$ from all models with fewer predictors. Any model $M$ that is not $\epsilon$-admissible is redundant in the sense that there exists a subset of fewer predictors that approximately linearly spans the same subspace. This very notion of redundancy makes the EAS method different from the traditional regularization-based approaches, where redundancy is expressed as a model containing negligible or zero magnitude regression coefficients. Nonetheless, Definition 2.1 encompasses the traditional notion of redundancy because, if one column of $B_M$ is equal
to zero then $h_\epsilon(B_M)$ is 0 for all $\epsilon > 0$. Additionally, as a consequence of the rows of $X_M$ spanning a finite-dimensional vector space, $h_\epsilon(B_M)$ assigns value zero to all models $M$ with $|M| > n$, by definition. As a consequence, the EAS procedure inherently reduces the difficulty of the model selection problem from $2^p$ candidate models to $2^n$, a fact that is fundamental to the scalability of the EAS procedure for high-dimensional settings. Furthermore, if $X_M$ does not have full row rank, then $h_\epsilon(B_M)$ is again zero by its construction.

The above definition of the $h$-function is well-defined in the sense that for $M$ with $|M| < n - q$, the matrix $\hat{\Sigma}_M$ is invertible with probability 1. Lemma 4.2 in Section 4 justifies that the minimum eigenvalue of $\hat{\Sigma}_M$ diverges away from 0 for large $n$. Next, for identifiability of a sparse true model, $M_0$, the choice of $\epsilon$ must not be so large that it classifies $M_0$ as redundant. Conversely, if $\epsilon$ is chosen too small, then many redundant models might also satisfy the $\epsilon$-admissibility criterion. It will be seen throughout the remainder of the paper that this trade-off analysis is the crux of the theoretical underpinnings of the EAS approach.

The key distinction between the definition of the $h$-function defined in (5) and the one defined in Williams et al. (2019) is the introduction of the empirical error covariance matrix $\hat{\Sigma}_M$. For any fixed $M$, a common assumption is that the quantity $\|B_M X_M - B X\|_F^2$ is on the order of $n$ (for large $n$). As a result, the optimal choice of $\epsilon$ as derived in Williams et al. (2019) turned out to be a function of both $n$ and $|M_0|$. Moreover, the form of their suggested $\epsilon$ is somewhat unintuitive as it was derived purely from a theoretical result. On the other hand, since $\hat{\Sigma}_M$ is also on the order of $n$ (for large $n$), adjusting for the inverse square root of $\hat{\Sigma}_M$, as in (5), proportionately scales $\|B_M X_M - B X\|_F^2$. This enables us to choose the threshold $\epsilon$ via simple grid search based on some metric such as cross-validation (CV) technique or information criterion (IC), independently of $n$ and $|M|$. A detailed description of the computational procedure we propose is presented in Section 3.

With our $\epsilon$-admissibility notion of redundancy now defined, we are ready to build the statistical framework that will facilitate its use in a model selection. The GFI approach adopted by Williams et al. (2019) remains an advantageous pathway for constructing a posterior-like probability distribution over the class of candidate models; one that is principled in the sense of Bernstein-von Mises asymptotics, but also avoids the problem of prior choice/specification. In contrast to the univariate regression model (as in Williams et al. 2019), however, construction of the GF distribution in the MLR setting is not a simple extension and is accompanied by unique challenges, especially so for dealing with the arbitrary covariance matrix of the multivariate response vectors.

The difficulty in deriving and studying an expression for a GF distribution, for most continuous data models, is that it requires deriving a complicated function of partial derivatives with respect to the unknown model parameters. Interesting data models for which the GF density can be expressed analytically (up to a normalizing constant), such as we will show for the MLR with arbitrary coefficient and covariance matrices, are interesting in their own right for their contribution to the growing literature on GFI. The necessary assumptions and materials for deriving/computing a GF distribution are provided in Hannig et al. (2016). In the remainder of this section we provide the details relevant to our methodology.

Given an index set, $M$, the unknown parameters in model (4) are $B_M$ and $A_M$. As in the GFI setup, re-express the data generating equation (4) as,

\begin{equation}
Y = B_M X_M + A_M U =: G(U, (B_M, A_M)),
\end{equation}

where $U \sim \text{Matrix-Normal}_{q,n}(0, I_q, I_n)$. As prescribed in Theorem 1 of Hannig et al. (2016), the GF density of the parameters $(B_M, A_M)$ can be expressed as,

\[ r(B_M, A_M | Y) := \frac{f(Y, (B_M, A_M)) J(Y, (B_M, A_M))}{\int f(Y, (B_M, A_M)) J(Y, (B_M, A_M)) \, d(B_M, A_M)}, \]
where \( f \) is the matrix normal likelihood function, and the Jacobian term,

\[
J(Y, \theta) := D\left( \frac{d}{d\theta} G(U, \theta) \big|_{U = G^{-1}(Y, \theta)} \right),
\]

where \( D(C) = \sqrt{\det C^T C} \) for a matrix argument \( C \). With \( \theta = (B_M, \hat{A}_M) \), and after some routine matrix calculations the Jacobian term reduces to,

\[
J(Y, (B_M, A_M)) = \left( \det A_M A_M^T \right)^{-q/2} \left( \det X_M X_M^T \right)^{q/2} \left( \det \hat{\Sigma}_M \right)^{q/2}.
\]

Accordingly, restricting \( M \) to the class of \( \epsilon \)-admissible models yields the GF density,

\[
r_\epsilon(B_M, A_M | Y) \propto \frac{e^{-\frac{1}{2} \text{tr} [R_M V_M^{-1}]} \left( \det X_M X_M^T \right)^{q/2} \left( \det \hat{\Sigma}_M \right)^{q/2} h_\epsilon(B_M),}
\]

where \( R_M := (Y - B_M X_M) (Y - B_M X_M)^T \). Note the dependence of \( r_\epsilon(\cdot | Y) \) on the choice of \( \epsilon \). Further, \( r_\epsilon(\cdot | Y) \) should not be confused with the notation for a conditional probability density function, but should be understood to reflect the fact that the GF distribution is a function of the observed data \( Y \).

Moving along, analogous to a Bayesian model selection approach, we construct a probability distribution over all \( \epsilon \)-admissible index sets as the marginal distribution,

\[
r_\epsilon(M | Y) \propto \int_{\mathbb{R}^q \times \mathbb{R}^q} r_\epsilon(B_M, A_M | Y) \, dA_M \, dB_M
\]

\[
= \left( \det X_M X_M^T \right)^{\frac{q}{2}} \left( \det \hat{\Sigma}_M \right)^{\frac{q}{2}} \int_{\mathbb{R}^q \times \mathbb{R}^q} h_\epsilon(B_M) \frac{e^{-\frac{1}{2} \text{tr} [R_M V_M^{-1}]} \left( \det V_M \right)^{(n+q)/2}}{(\det V_M)^{(n+q)/2}} \, dA_M \, dB_M.
\]

We simplify this expression as equation \((7)\), stated next, and provide a detailed account of the intermediate steps in the Supplementary Material.

\[
(7) \quad r_\epsilon(M | Y) \propto \Gamma_q \left( \frac{n - |M|}{2} \right) \pi^{|M|/2} \left( \det \hat{\Sigma}_M \right)^{-\left( \frac{n - |M| - q}{2} \right)} \mathbb{E} \left[ h_\epsilon(B_M) \right],
\]

where the expectation is taken with respect to the density of matrix \( t \)-distribution, i.e.,

\[
(8) \quad B_M \sim T_{q, |M|} \left( n - |M| - q + 1, \hat{B}_M, \hat{\Sigma}_M, \left( X_M X_M^T \right)^{-1} \right).
\]

Note that the GF distribution of \( B_M \) is concentrated around the least squared estimator, \( \hat{B}_M \), defined previously.

Observe in \((7)\) that for models with \(|M| > n - q\), the \( h \)-function is zero by definition, and thus \( r_\epsilon(M | Y) \) is trivially zero. This probability mass function has the interpretation as the relative likelihood of the model \( M \) versus that of all other candidate models in the class of \( \epsilon \)-admissible models. It becomes clear from the expression \((7)\) that \( r_\epsilon(M | Y) \) is largely driven by the inverse of the empirical error covariance matrix, and that the \( h \)-function delivers a multiplicative effect on the probability. For a large redundant model, \( M \), we expect that the determinant of the empirical error covariance is small relative to that of \( M_o \), and so we leverage the choice of \( \epsilon \) such that \( \mathbb{E} [h_\epsilon(B_M)] \) controls the value of \( r_\epsilon(M | Y) \). This insight is formalized in Section \( 4 \).

As we illustrate in the remainder of this paper, the GF mass function \( r_\epsilon(M | Y) \) serves as a vehicle for model selection and inference. In the next section we discuss the details of the necessary computations, and provide an algorithm to generate samples from this GF distribution.
3. Model estimation and computational techniques. In order to generate samples from \( r_\varepsilon(M \mid Y) \) we must be able to compute \( \mathbb{E} [ h_\varepsilon (B_M)] \). Although the expectation is with respect to a matrix \( t \)-distribution, the complex expression for \( h_\varepsilon (B_M) \) makes the form of its expectation intractable, and so standard MCMC techniques do not apply. This issue is typical of all the previously developed EAS implementations. The MLR EAS analogue of the previous EAS approaches is to employ a pseudo-marginal MCMC algorithm by estimating \( \mathbb{E} [ h_\varepsilon (B_M)] \) with the average of a large number of random samples from the GF distribution of \( B_M \) (i.e., its matrix \( t \)-distribution). We extend these algorithms to the MLR case and discuss them briefly, here.

From Definition 2.1, evaluating \( h_\varepsilon (B_M) \) can be formulated as the mixed integer quadratic program (MIQP) with quadratic constraints,

\[
\text{vec} (B_{\text{min}}) = \arg\min_{\mathbf{b}, z_1, \ldots, z_p} \left\{ \frac{1}{2} \mathbf{b}^\top Q_M \mathbf{b} - a_M^\top \mathbf{b} \right\},
\]

subject to \( \mathbf{b} \in \mathbb{R}^{qp} \), \( z_j \in \{0, 1\} \) for \( j \in \{1, \ldots, p\} \),

\[
\mathbf{b}^\top \mathbf{C}_j \mathbf{b} \leq \mathcal{M}_U z_j^2, \quad \text{and} \quad \sum_{j=1}^p z_j \leq |M| - 1,
\]

where \( Q_M := (XX^\top) \otimes \Sigma^{-1}_M \), \( a_M := (XX^\top \otimes \Sigma^{-1}_M) \text{vec} (B_M) \), \( \mathbf{C}_j \) is a block diagonal matrix with \( p \) blocks of \( q \times q \) zero matrices, except \( \mathbf{I}_q \) in the \( j \)-th block, and \( \mathcal{M}_U > 0 \) is a properly chosen constant. In particular, the quantity \( \mathcal{M}_U \) must be chosen large enough so that \( \mathcal{M}_U > \max_j \| (B_{\text{min}})_j \|_2^2 \) (Bertsimas et al., 2016). Further, since \( B_{\text{min}} \) is not a-priori known, Bertsimas et al. (2016) provides a data-driven formula to specify \( \mathcal{M}_U \) in the MIQP, which can be solved efficiently with any MIQP solver, such as CPLEX.

| Input: | Input a model with index set \( M \), \( B_M \), the full design matrix \( \mathbf{X} \), \( \Sigma_M \), a pre-specified \( \varepsilon > 0 \) and an initial solution \( B_{\text{init}} \) with number of columns with non-zero norm less than \( |M| - 1 \) |
|---|---|
| Output: | Value of \( h_\varepsilon (B_M) \) |
| 1 | Calculate \( L = \lambda_{\max} (XX^\top) \lambda_{\min}^{-1} (\Sigma_M) \) and set \( B_{\text{cur}} = B_{\text{init}} \); |
| 2 | Calculate the objective function \( g(B_{\text{cur}}) = \frac{1}{2} \| \Sigma^{-1/2}_M (B_M \mathbf{X}_M - B_{\text{cur}} \mathbf{X}) \|_F^2 \); |
| 3 | while \( \text{diff} > \text{threshold or } g(B_{\text{cur}}) > \varepsilon \) do |
| 4 | Calculate \( \mathbf{B} = B_{\text{cur}} - \frac{1}{2} \Sigma^{-1}_M (B_{\text{cur}} XX^\top - B_M XX^\top) \); |
| 5 | Obtain indices \( i_1, i_2, \ldots, i_{|M| - 1} \) such that \( \| \mathbf{B}_{i_1} \| \geq \| \mathbf{B}_{i_2} \| \geq \cdots \geq \| \mathbf{B}_{M_{i_1}} \| \geq \cdots \geq \| \mathbf{B}_{(p)} \| \); |
| 6 | Set \( \mathbf{B}_j = 0 \) for all \( j \in \{1, 2, \ldots, p\} \setminus \{i_1, i_2, \ldots, i_{|M| - 1}\} \); |
| 7 | Calculate \( \text{diff} = |g(B_{\text{cur}}) - g(\mathbf{B})| \); |
| 8 | Update \( B_{\text{cur}} = \mathbf{B} \); |
| 9 | end |
| 10 | return \( h_\varepsilon (B_M) = I (g(B_{\text{cur}}) > \varepsilon) \)| |

Algorithm 3.1: Pseudocode for projected gradient descent to compute \( h_\varepsilon (B_M) \).

In approximating \( \mathbb{E} [ h_\varepsilon (B_M)] \) by drawing, say \( N \), random samples from the GF distribution of \( B_M \), at each step of the pseudo-marginal MCMC algorithm we need to solve the MIQP \( N \) times. Although a single MIQP is fast to solve, the complexity of the computation of \( \mathbb{E} [ h_\varepsilon (B_M)] \) grows with \( N \), and so further streamlining of the computations are needed. First, observe that a solution, \( B_{\text{min}} \), to the MIQP is not always necessary to evaluate \( h_\varepsilon (B_M) \); rather \( h_\varepsilon (B_M) = 0 \) if there exists any \( B \) (satisfying the MIQP constraints) such that
very quickly finds a solution to determine that
is Lipschitz continuous with Lipschitz constant for all

distribution of remaining task is to demonstrate the mechanism for generating samples from the GF distribution of \( B_M \) that are not \( \varepsilon \)-admissible, Algorithm 3.1 very quickly finds a solution to determine that \( h_e(B_M) \) is zero. As derived in the previous section, the GF distribution of \( B_M \) is centered around the least squared estimator, \( \hat{B}_M \), and so initializing Algorithm 3.1 at \( \hat{B}_M \) with its column having minimum norm set to zero, often yields \( h_e(B_M) = 0 \) within a few iterations.

| **Input:** | Input a model with index set \( M \) at current step, a proposal probability distribution \( q(M \mid M) \), a sufficiently large number \( N \) and a pre-specified \( \varepsilon > 0 \) |
| **Output:** | A new model with index set \( M^* \) |
| 1 | Calculate \( \tilde{M} = \begin{cases} M \cup \{ \text{a new covariate} \} & \text{w.p} \ 1/3 \\ M \setminus \{ \text{a new covariate} \} & \text{w.p} \ 1/3; \\ M \setminus \{ \text{a new covariate} \} \cup \{ \text{a new covariate} \} & \text{w.p} \ 1/3 \end{cases} \) |
| 2 | Calculate LS estimator of \( \hat{B}_M \) and \( \hat{\Sigma}_M \) for the model \( M \); |
| 3 | Calculate LS estimator of \( \hat{B}_{\tilde{M}} \) and \( \hat{\Sigma}_{\tilde{M}} \) for the proposal model with \( \tilde{M} \); |
| 4 | Generate \( B_{M}(k) \sim T_{q,M}(n - (|M| + q) + 1, \hat{B}_M, \hat{\Sigma}_M, (X_M X_M^\top)^{-1}), \) for \( k = 1, 2, \ldots, N \); |
| 5 | Generate \( B_{\tilde{M}}(k) \sim T_{q,\tilde{M}}(n - (|\tilde{M}| + q) + 1, \hat{B}_{\tilde{M}}, \hat{\Sigma}_{\tilde{M}}, (X_{\tilde{M}} X_{\tilde{M}}^\top)^{-1}), \) for \( k = 1, 2, \ldots, N \); |
| 6 | Compute \( h_e(B_{M}(k)) \) and \( h_e(B_{\tilde{M}}(k)) \) using the MIQP or Algorithm 3.1 for all \( k = 1, 2, \ldots, N \); |
| 7 | Calculate \( r_N(M) := \frac{1}{N} \sum_{k=1}^{N} r_e(M, B_M(k) \mid Y) \) and \( \tilde{r}_N(M) := \frac{1}{N} \sum_{k=1}^{N} r_e(M, B_{\tilde{M}}(k) \mid Y) \); |
| 8 | Accept \( M^* = \tilde{M} \) as the new sample with probability \( \rho(M, \tilde{M}) := \min \left\{ \frac{r_N(M) q(M \mid M)}{r_N(\tilde{M}) q(\tilde{M} \mid \tilde{M})}, 1 \right\} \); |

**Algorithm 3.2:** Pseudocode for Grouped Independence Metropolis Hastings algorithm to generate samples from \( r_e(M \mid Y) \).

Now that we have a computationally efficient algorithm for computing the \( h_e(B_M) \), the remaining task is to demonstrate the mechanism for generating samples from the GF distribution of \( M \). Observe that the GF probability mass function \( r_e(M \mid Y) \) can written as the marginal law of,

\[
(9) \quad r_e(M, B_M \mid Y) := \Gamma_q \left( \frac{n - |M|}{2} \right) \pi^{(|M|)/2} \left( \det \hat{\Sigma}_M \right)^{-\left(\frac{n-|M|-q}{2}\right)} h_e(B_M),
\]

with respect to the location-scale matrix \( t \)-distribution specified in (8). Then the Grouped Independence Metropolis Hastings (GIMH) algorithm by Andrieu et al. (2009) yields samples (asymptotically) from \( r_e(M \mid Y) \) by, for each step of the algorithm, proposing index sets \( M \) and averaging the value of \( r_e(M, B_M(k) \mid Y) \) over \( N \) generated matrices \( B_M(1), \ldots, B_M(N) \) from the matrix \( t \)-distribution in (8).
4. Theoretical Results. The main objective of this section is to establish the consistency of our model selection procedure, particularly in the high-dimensional setting (i.e., \( p \gg n \)) with the assumption that the true model is sparse. We begin by stating and describing essential conditions and necessary supporting results to show that \( r_\epsilon(M_0 \mid Y) \) converges in probability to 1 as \( n \to \infty \). Our strong model selection consistency result is stated as Theorem 4.11. Throughout this section we a-priori fix the following values. The constants \( c, C \in (0, \infty) \) that appear in our results are taken as special fixed values that depend only on the sub-Gaussian norm of a centered multivariate Gaussian vector with covariance matrix \( V^0_{M_o} \). Let \( \lambda_v \) and \( \hat{\lambda}_v \) be the minimum and maximum eigenvalues of the true covariance matrix, \( V^0_{M_o} \), respectively, and define the function \( \kappa(x) := \min \{ x, \sqrt{x} \} \). Denote by \( P_y(\cdot) \) be the probability measure associated with the sampling distribution of the response \( Y \), as in (3), and denote by \( P(\cdot) \) the probability measure associated with the GF distribution of the parameters. Similarly, denote by \( E_y(\cdot) \) be the expectation with the sampling distribution of the response \( Y \), as in (3), and denote by \( E(\cdot) \) the expectation with respect to the GF distribution of the parameters.

Condition 4.1 requires that the true covariance matrix of the response is positive-definite and finite, which implies that none of the components of the multivariate response are degenerate and they all have finite second moments. Since the dimension of the multivariate response, \( q \), is fixed, this assumption is rather routine.

**CONDITION 4.1 (Non-singularity of true covariance).** \( \) The dimension of the multivariate response vector, \( q \), is fixed, and \( 0 < \lambda_v < \hat{\lambda}_v < \infty \).

In our methods, it is important that \( V^0_{M_o} \) is positive-definite so that there exists a positive-definite, consistent estimator of it, for example, \( \hat{\Sigma}_{M_o}/(n - |M_0|) \). This estimator plays an essential role in our definition of the \( h \) function (among other roles). In particular, Condition 4.1 makes it possible that, for large \( n \), the minimum eigenvalue of \( \hat{\Sigma}_{M}/(n - |M|) \) is bounded away from 0 with high probability, for an important class of models. This fact is established in Lemma 4.2, presented next.

**LEMMA 4.2.** Assume the data generating model (3), and that Condition 4.1 holds. Then for any fixed \( \alpha_1, \alpha_2 > 0 \) with \( 0 < \alpha_1 + \alpha_2 \leq 1 \), and for any \( M \subseteq \{1, 2, \ldots, p\} \) satisfying \( n > |M| + q \max \{ (C/\kappa(\alpha_2 \lambda_v))^2, 1 \} \),

\[
P_y \left( \lambda_{\min}(\hat{\Sigma}_{M}/(n - |M|)) \geq (1 - \alpha_1 - \alpha_2)\lambda_v \right) > 1 - V_{0,n}(M, \alpha_1, \alpha_2),
\]

where,

\[
V_{0,n}(M, \alpha_1, \alpha_2) := 2e^{-c(\kappa(\alpha_2 \lambda_v)\sqrt{n - |M| - C\sqrt{\pi}})^2} + 4\sqrt{\frac{\lambda_{\max}(\Delta_{M})}{2\pi \alpha_1 \lambda_v(n - |M|)}} \exp \left( -\frac{\alpha_1^2 \lambda_v^2(n - |M|)^2}{8 \lambda_{\max}(\Delta_{M}) \lambda_v} \right) I(\Delta_{M} \neq 0),
\]
and \( \Delta_M := B_{M_o}^0 X_{M_o} (I_n - H_M) X_{M_o}^T B_{M_o}^0 \).

Observe that the matrix \( \Delta_M \) plays an important role in approximating the probability on the right side of the inequality. In the special case that \( \Delta_M = 0 \), a tighter probability bound is established with \( V_{0,n}(M, \alpha_1, \alpha_2) := 2 \exp \left( -c \left( \kappa \alpha_2 \lambda_o \sqrt{n - |M| - C \sqrt{\lambda}} \right)^2 \right) \). In particular, this applies for the true model \( M_o \), as well as all index sets \( M \supseteq M_o \).

For the lower bound on the minimum eigenvalue in Lemma 4.2 to hold with high probability, it is required that \( V_{0,n} \to 0 \) as \( n \to \infty \). This is a fundamental necessary condition for proving that \( r_r(M | Y) \) will concentrate probability mass 1 on \( M_o \), in probability, and is ensured if and only if \( \lambda_{\max}(\Delta_M) = o(n^2) \). To better understand the behavior of \( \Delta_M \), consider two special cases presented next, which in some sense represent the ‘largest’ values of \( \Delta_M \).

**EXAMPLE 1 (Orthogonal design).** Suppose that \( X_{M_o} \) has orthogonal rows with the first row being an intercept (i.e., a vector of ones). Then \( X_{M_o} X_{M_o}^T = \text{diag}(n, d_{2,n}, \ldots, d_{|M_o|,n}) \) where \( d_{j,n} \) is the squared euclidean norm of the \( j \)-th row of \( X_{M_o} \), for \( j \in \{2, \ldots, |M_o|\} \). Next, let \( M \subset M_o \) contain only the index of the intercept row (i.e., \( X_M = 1^n \)). In this case, \( \Delta_M = \sum_{j=2}^{|M_o|} d_{j,n} B_{M_o,j}^0 B_{M_o,j}^0 \), where \( B_{M_o,j}^0 \) denotes the \( j \)-th column of \( B_{M_o}^0 \) for \( j \in \{1, \ldots, |M_o|\} \), and so,

\[
\lambda_{\max}(\Delta_M) = \sup_{|v| = 1} v^T \left( \sum_{j=2}^{|M_o|} d_{j,n} B_{M_o,j}^0 B_{M_o,j}^0 \right) v \leq \|B_{M_o}^0\| \cdot \max_j \{d_{j,n}\}.
\]

Thus, under a standard ‘restricted eigenvalues’ assumption (e.g., Bickel, Ritov and Tsybakov 2009) on \( X_{M_o} X_{M_o}^T \) (see Condition 4.4 below), if \( B_{M_o}^0 \) is sufficiently sparse (see Condition 4.3 below), then \( \lambda_{\max}(\Delta_M) = o(n^2) \).

**EXAMPLE 2 (\( M \) orthogonal to \( M_o \)).** Suppose that \( M \subseteq \{1, \ldots, p\} \) is such that \( X_{M_o} X_{M_o}^T \) is the \( |M_o| \times |M| \) zero matrix. Then, \( X_{M_o} (I_n - H_M) = X_{M_o} \), and so,

\[
\lambda_{\max}(\Delta_M) = \sup_{|v| = 1} v^T B_{M_o}^0 X_{M_o} X_{M_o}^T B_{M_o}^0 v \leq \|B_{M_o}^0\|^2 \cdot \|X_{M_o}\|^2,
\]

which requires a similar restricted eigenvalues condition and sparsity assumption as in the previous example to ensure \( \lambda_{\max}(\Delta_M) = o(n^2) \).

As motivated by these examples, the next two conditions are critical to guarantee that \( V_{0,n} \to 0 \) as \( n \to \infty \) in Lemma 4.2. Moreover, these conditions are also necessary for other supporting results needed to establish model selection consistency, presented later.

Condition 4.3 specifies a measure of sparsity in the true model, relative to the number of candidate predictors to choose from. Under a typical sparsity assumption where \( \|B_{M_o}^0\|^2 \ll n \), it follows that the number of predictors are allowed to grow at sub-exponential rate with the sample size, \( n \), ensuring that our method is suitable to perform in the high-dimensional setting. Model selection consistency with this size of \( p \) relative to \( n \) is on par with the state-of-the-art results in the literature (Bai and Ghosh, 2018a).

**CONDITION 4.3 (Sparsity and maximum number of predictors).** For some fixed \( \alpha \in (0,1) \), the true regression coefficient matrix satisfies \( \|B_{M_o}^0\|^2 \log p = o(n^{1-\alpha}) \).

In order to establish strong model selection consistency it is necessary, however, to impose a certain restriction on the sample space of \( 2^p \) candidate models. If \( |M| \) is on the order of \( n \), then the row space of \( X_M \) might span \( \mathbb{R}^n \) leading to a rank deficient empirical error.
covariance matrix, $\hat{\Sigma}_M$. Accordingly, $r_e(M \mid Y)$ from equation (7) will be undefined in this case. Since we assume that the data arise from the non-degenerate statistical model (3), we must exclude index sets $M$ with $n^\alpha < |M| < n - q$ for some fixed $\alpha \in (0, 1)$. Recall that the $h$-function assigns value 0 to $M$ with $|M| \geq n - q$, and that $q$ is small and fixed. Throughout the remainder of this section, we assume $\alpha \in (0, 1)$ to be some a-priori fixed value with $|M_0| \leq n^\alpha$, and with appeal to Condition 4.3 there certainly exists a meaningful such $\alpha$. It will be observed in the coming results that the fraction $\alpha$ can be interpreted as a tuning parameter that balances the maximum model size to be considered versus the rate of convergence of the EAS procedure.

Moving along, Condition 4.4 ensures that the design matrix for the true model has full row rank, and that its minimum and maximum squared singular values, as a proportion of the sample size, are finite and bounded away from 0. This type of restricted eigenvalues condition is routinely needed in the variable selection literature (Chen and Huang, 2012; Lahiri, 2021).

**CONDITION 4.4 (Restricted eigenvalues).** There exists constants $c_\alpha$ and $c^*$ such that,

$$0 < c_\alpha \leq \lambda_{\min} \left( X_{M_o} X_{M_o}^T / n \right) < \lambda_{\max} \left( X_{M_o} X_{M_o}^T / n \right) \leq c^* < \infty, \quad \forall n \in \mathbb{N}.$$ 

Thus, bounding the maximum eigenvalue of the idempotent matrix $I_n - H_M$ by 1, Condition 4.4 gives,

$$\lambda_{\max}(\Delta_M) \leq n \lambda_{\max}(X_{M_o} X_{M_o}^T / n) \lambda_{\max}(B_{M_o}^0 B_{M_o}^{0T}) \leq n c^* \|B_{M_o}\|^2,$$

so that, by Condition 4.3, $V_{0,n} \to 0$ as $n \to \infty$ in Lemma 4.2. This result is summarized in Corollary 4.5, stated next.

**COROLLARY 4.5.** Assume that the conditions of Lemma 4.2 are satisfied, and further assume Conditions 4.3 and 4.4. Then the $V_{0,n}(M, \alpha_1, \alpha_2)$ in Lemma 4.2 can be replaced by,

$$V_{0,n}(M, \alpha_1, \alpha_2) := 2 e^{-c \left( \frac{n^\alpha (n - |M|)}{\sqrt{n}} \right)^2} + \frac{2 \|B_{M_o}^0\| \sqrt{c^* \lambda_v \alpha_1 \lambda_v}}{\sqrt{\alpha_1 \lambda_v \alpha_2 \lambda_v}} \left( \frac{n - |M|}{\alpha_1 \lambda_v} \right) \exp \left( - \frac{\alpha_1^2 \lambda_v^2 (n - |M|)}{16 c^* \|B_{M_o}^0\|^2} \right) I(\Delta_M \neq 0).$$

Next, in order to show that $r_e(M_0 \mid Y) \to 1$ in probability, we must show that $r_e(M \mid Y) / r_e(M_0 \mid Y) \to 0$ in probability, at a rate vanishing faster than $2^{-n^\alpha}$ uniformly for every model $M \neq M_0$ with $|M| \leq n^\alpha$. Recall that the probability mass function $r_e(M \mid Y)$, in equation (7), is proportional to a polynomial of the inverse of the determinant of the empirical error covariance matrix. That being so, we must bound the ratio of determinant, as in Theorem 4.6. This ratio is analogous to the ratio of sum of squared residuals (RSS) that commonly appears in univariate model selection problems, though, the multivariate situation is much more complicated requiring delicate handling of minimum eigenvalues close to zero. That being so, this result is interesting in its own right for the (high-dimensional) MLR literature.

For for any model $M$ with $|M| \leq n^\alpha$, it is understood that the determinant of $\hat{\Sigma}_M$, as a proportion of that of $\hat{\Sigma}_M$, will behave differently depending on whether $M \subseteq M_0$ or $M \not\subseteq M_0$. In the first case, when $M \subseteq M_0$, the ratio will be strictly less than 1 since $M$ is missing at least one oracle predictor. Conversely, the extreme scenario in the other case is that $M \supset M_0$, in which case the ratio exceeds 1, but by some bound that converges to 1 as $n$ tends to infinity.
THEOREM 4.6. Assume Conditions 4.1, 4.3, and 4.4. Then for sufficiently large \( n \), the following approximations hold.

Case 1: This case pertains to the models \( M \subsetneq M_o \).

\[
\mathbb{P}_y \left( \bigcap_{M: M \subsetneq M_o} \left\{ Y : \left( \frac{\det \hat{\Sigma}_{M_o}}{\det \Sigma_M} \right)^{n-|M|-q} \leq e^{-q n^\alpha \log |M_o|} \right\} \right) \geq 1 - V_{1,n},
\]

where,

\[
V_{1,n} := |M_o| q \exp \left( -\frac{\xi_{n,|M_o|} n^\alpha \log |M_o| \lambda_v}{2 \lambda_v} - 0.09 \left( n - |M_o| \right) + |M_o| \log(|M_o|) \right)
+ 2 |M_o| \exp \left( -c \left\{ \kappa (\lambda_v/4) \sqrt{n - |M_o|} - C \sqrt{q} \right\}^2 + |M_o| \log |M_o| \right)
+ \frac{8 |M_o| |B_{M_o}| \sqrt{c^* \lambda_v}}{\sqrt{\pi} \alpha_1 \lambda_v \sqrt{n - |M_o|}} \exp \left( -\frac{(\lambda_v/16)^2 (n - |M_o|)}{c^* \|B_{M_o}^0\|^2 \lambda_v} + |M_o| \log |M_o| \right),
\]

with \( \xi_{n,|M|} := 1 - \frac{2 n^\alpha \log |M|}{n - |M| - q} \) such that \( \xi_{n,|M|} \in (0, 1) \) for large \( n \).

Case 2: This case pertains to the models \( M \not\subsetneq M_o \) such that \( |M| \leq n^\alpha \).

\[
\mathbb{P}_y \left( \bigcap_{M: M \not\subsetneq M_o, |M| \leq n^\alpha} \left\{ Y : \left( \frac{\det \hat{\Sigma}_{M_o}}{\det \Sigma_M} \right)^{n-|M|-q} \leq q (n^\alpha \log(n - |M|) + |M| \log p) \right\} \right) \geq 1 - V_{2,n},
\]

where,

\[
V_{2,n} := \frac{2 q \exp \left( -\frac{n^\alpha}{2} \log (n - |M_o|) + \frac{|M_o| + 1}{2} \log (\zeta_{n,|M|}) \right)}{n - |M| - q},
\]

and \( \zeta_{n,|M|} := 1 + \frac{2 (n^\alpha \log(n - |M|) + |M| \log p)}{n - |M| - q} \).

Observe that both quantities \( V_{1,n} \) and \( V_{2,n} \) vanish exponentially fast for large \( n \), by Condition 4.3. There are two key facts that we learn from Theorem 4.6. The first is that the ratio of the determinants, of the empirical error covariances raised to the power on the order of \( n \), will drive \( r_n(M | Y) / r_n(M_0 | Y) \) to 0 for \( M \subsetneq M_o \) (i.e., Case 1). The second fact is that the ratio of the determinants, of the empirical error covariances raised to the power on the order of \( n \), will perhaps grow at a sub-exponential rate for large \( n \), for \( M \not\subsetneq M_o \) such that \( |M| \leq n^\alpha \) (i.e., Case 2). As such, the role of the \( h \) function is necessary to control the explosive nature of these ratios for models with redundant predictors. The following two theorems establish that the \( \mathbb{E}(h_r(B_{M})) \) and \( \mathbb{E}(h_r(B_{M_0})) \) terms are adept at accomplishing this task. Necessary conditions on the choice of \( \varepsilon \) are stated in the order that they are needed.

CONDITION 4.7 (\( \varepsilon \)-admissibility). The size of the true model \( |M_o| \) is less than \( n^\alpha \). Moreover, for large \( n \), the true model \( M_o \) satisfies,

\[
\frac{1}{36 q (n - |M_o|)} \left\| (V_{M_o}^0)^{-1/2} \left( B_{M_o}^0 X_{M_o} - \tilde{B}_{\min} X \right) \right\|_F^2 > \varepsilon,
\]

where \( \tilde{B}_{\min} \) is the solution to the optimization problem,

\[
\tilde{B}_{\min} := \arg \min_{B \in \mathbb{R}^{p \times p}} \left\| (V_{M_o}^0)^{-1/2} \left( B_{M_o}^0 X_{M_o} - B X \right) \right\|_F^2,
\]

subject to \( |\{ j : \|B_j\| \neq 0 \}| \leq |M_o| - 1 \).
Condition 4.7 provides an upper bound for the choice of \( \epsilon \), necessary for the identifiability of the true model and coefficients, as in Definition 2.1 of the \( h \) function. Based on Condition 4.4 the quantity on the left side is bounded by a constant factor as \( n \to \infty \), and it re-scales for the covariance matrix \( V_{M_0}^0 \) of the response. Notice that given a specified \( \epsilon \), the smaller the norm of the regression coefficient matrix \( B_{M_0}^0 \), the more difficult it becomes to identify the true model as \( \epsilon \)-admissible. It is in this sense that \( \epsilon \)-admissibility defines redundancy both in the sense of correlated predictors and in the sense of predictors with weak signal (after scaling for the response covariance). This is related to the ‘beta-min’ condition commonly discussed in the variable selection literature for LASSO (Section 7.4 of Bühlmann and Van De Geer, 2011).

Recall that Condition 4.3 is a sparsity condition imposed on the size of \( \| B_{M_0}^0 \| \), rather than directly on the size of \( |M_0| \). As such, Condition 4.3 allows for increasing \( |M_0| \) so long as the components of \( B_{M_0}^0 \) are diminishing in magnitude, but not necessarily zero. However, Condition 4.7 rules out the identifiability of \( B_{M_0}^0 \) in that case. Thus, the combined implications of Conditions 4.7 and 4.3 for identifiability of the true model, is a dense coefficient matrix allowed for increasing \( |M_0| \), and an upper bound on the size of \( |M_0| \).

With the addition of Condition 4.7, Theorem 4.8 ensures that the oracle model is \( \epsilon \)-admissible. In our proof strategy, this theorem provides a necessary, non-asymptotic probabilistic guarantee that \( \mathbb{E}(h_{\epsilon}(B_{M_0})) \) in the denominator of \( r_{\epsilon}(M \mid Y)/r_{\epsilon}(M_0 \mid Y) \) is bounded away from zero, so long as \( \epsilon \) is not too large.

**Theorem 4.8.** Assume Conditions 4.1, 4.4. Then, for every \( \epsilon > 0 \) satisfying Condition 4.7,

\[
\mathbb{P}_y \left[ \mathbb{E}(h_{\epsilon}(B_{M_0})) \geq 1 - \exp \left( -\frac{\epsilon(n - |M_0|)}{36} + \frac{q |M_0|}{2} \right) - 2 \exp \left( -\frac{1}{8} \left\{ \sqrt{n - |M_0|} - 2\sqrt{q} \right\}^2 \right) \right] 
\geq 1 - V_{3,n},
\]

where

\[
V_{3,n} := \exp \left( -\frac{\epsilon(n - |M_0|)}{4} + \frac{q |M_0|}{2} \right) + 2 \exp \left\{ -\epsilon \left( \frac{\kappa(\lambda_0/4)}{\sqrt{n - |M_0|} - C\sqrt{q}} \right)^2 \right\} + \exp \left( -0.15q(n - |M_0|) \right).
\]

Lastly, to justify that \( r_{\epsilon}(M \mid Y)/r_{\epsilon}(M_0 \mid Y) \to 0 \) for all redundant models, it remains to establish that \( \mathbb{E}(h_{\epsilon}(B_M)) \) vanishes rapidly for all models \( M \not\subseteq M_0 \) with \( |M| \leq n^\alpha \) (recall the cases in Theorem 4.6). This brings us to the final major supporting result, Theorem 4.10, for establishing strong model selection consistency. However, in contrast to the the upper bound condition on \( \epsilon \) in Condition 4.7, a lower bound condition on \( \epsilon \) is necessary to ensure that \( h_{\epsilon}(B_M) \) assigns negligible probability mass to redundant models via \( r_{\epsilon}(M \mid Y) \).

**Condition 4.9 (Redundancy).** For any model \( M \) with \( M \not\subseteq M_0 \) with \( |M| \leq n^\alpha \), for large \( n \),

\[
\frac{9}{\lambda_0(n - |M|)} \left\| B_{M_0}^0 X_{M_0} (H_M - H_{M(-1)}) \right\|_F^2 < \epsilon,
\]

where \( H_{M(-1)} := H_{M \setminus \{j^*\}} \) is the projection matrix for the size that is constructed after omitting the predictor \( j^* \) from the model \( M \) that minimizes

\[
j^* = \arg\min_{j \in M} \left\| B_{M_0}^0 X_{M_0} (H_M - H_{M \setminus \{j\}}) \right\|_F^2.
\]
Condition 4.9 is necessary for showing that \( \mathbb{E}(h_\epsilon(B_M)) \to 0 \) in probability for all redundant models, and further characterizes the non-\( \epsilon \)-admissible notion of redundancy. The quantity on the left side of the condition is the mean difference in the prediction between models \( M \) and \( M \setminus \{j^*\} \). Condition 4.9 implies that models \( M \) with \( M \not\subseteq M_o \) are redundant in the sense that they contain at least one predictor whose omission will not change the mean predicted response by more than \( \epsilon \), as measured by the properly scaled squared Frobenius norm.

Condition 4.7 coupled with Condition 4.9 provides the crucial interval for the choice of \( \epsilon \) within which the oracle model is identifiable and the EAS procedure achieves strong model selection consistency. Notably, due to the appropriate scaling of quantities in the \( h \) function, this interval neither depends on the sample size \( n \) nor the size of the model \( M \).

**Theorem 4.10.** Assume Conditions 4.1, 4.3, and 4.4. Then, for sufficiently large \( n \), and for every \( \epsilon > 0 \) satisfying Condition 4.9,

\[
P_{y} \left[ \bigcap_{M \not\subseteq M_o \atop |M| \leq n^\alpha} \left\{ Y : \mathbb{E}(h_\epsilon(B_M)) \leq \exp \left( -\frac{\epsilon(n - |M|)}{36} + \frac{q|M|}{2} \right) + 2\exp \left( -\frac{1}{8} \left\{ \sqrt{n - |M|} - 2\sqrt{q} \right\}^2 \right) \right\} \right] \\
\geq 1 - V_{4,n},
\]

where,

\[
V_{4,n} := n^\alpha \left\{ \exp \left( -\frac{\epsilon(n - n^\alpha)\lambda_v}{36} + \frac{qn^\alpha}{2} + n^\alpha \log p \right) + 4\exp \left( -c \left\{ \kappa(\lambda_v/4)\sqrt{n - n^\alpha} - C\sqrt{q} \right\}^2 + n^\alpha \log p \right) \right\} \\
+ \frac{16n^\alpha \|B^0_{M_o}\| \sqrt{c^\ast \lambda_v}}{\sqrt{n}\lambda_v \sqrt{n - n^\alpha}} \exp \left( -\frac{(\lambda_v/16)^2(n - n^\alpha)}{c^\ast \|B^0_{M_o}\|^2 \lambda_v} + n^\alpha \log p \right).
\]

Theorem 4.10 is a non-asymptotic concentration bound for \( \mathbb{E}(h_\epsilon(B_M)) \) that applies uniformly over all model \( M \not\subseteq M_o \). This is the critical theoretical aspect of the \( h \) function that addresses the explosive nature of the ratios of the determinants, of the empirical error covariances raised to the power on the order of \( n \), uniformly over all models \( M \not\subseteq M_o \) such that \( |M| \leq n^\alpha \), as exhibited in Case 2 of Theorem 4.6.

To this point in the article, sufficient analysis has been constructed to argue the *pairwise* model selection consistency result that \( r_\epsilon(M \mid Y)/r_\epsilon(M_o \mid Y) \to 0 \) in probability for any \( M \neq |M_o| \) with \( |M| \leq n^\alpha \). For the case when \( p \) is fixed, this also implies *strong* model selection consistency. In the case when \( p \to \infty \) and particularly for \( p \gg n \), however, further justification is required because the number of candidate models to consider is \( 2^{n^\alpha} \). Theorems 4.8 and 4.10 are able to manage this exponential-sized class of candidate model with the essential attribute that they provide concentration inequalities of tails that are uniform and vanish exponentially fast in \( n \). This fact is stated as our main result, Theorem 4.11.

**Theorem 4.11.** Assume the data generating model (3), and suppose that Conditions 4.1, 4.3 and 4.4 are satisfied. Then for every \( \epsilon > 0 \) satisfying Conditions 4.7 and 4.9,

\[
\frac{r_\epsilon(M_o \mid Y)}{\sum_{M : |M| \leq n^\alpha} r_\epsilon(M \mid Y)} \xrightarrow{p} 1,
\]

as \( n \to \infty \) or \( n, p \to \infty \).
The proof of Theorem 4.11 is presented in the Appendix, and the proofs of all other results are organized in the Supplementary Material. Note that Theorem 4.11 is the only non-asymptotic result in our theoretical developments, and so as long as the conditions are satisfied, it is expected that it is reasonably illustrative of the performance of our constructed EAS procedure on observed data. We provide evidence substantiate this claim in finite sample numerical studies presented next in Section 5.

5. Numerical Results. In this section we demonstrate the performance of our EAS method in comparison to the state-of-the-art variable selection procedures for MLR. Very recently Bai and Ghosh (2018a) developed the MBSP method that is equipped to perform variable selection for MLR. They demonstrate a distinctly superior performance of MBSP over all the existing methods, especially in a high-dimensional setting. To make standard the comparison between the MBSP and EAS approaches, we mimic the exact same synthetic data simulation study design constructed in Bai and Ghosh (2018a).

The simulation design can be broadly categorized into three parts, low dimensional (LD) ($n > p$), high dimensional (HD) ($p > n$) and ultra high dimensional (UHD) ($p \gg n$). Two sub-categories are considered within each of these categories, to analyze performance for varying sizes of the true model, $|M_0|$, versus the total number of predictors, $p$. Within each category the dimension of the multivariate response, $q$, is also varied to study the effect of $q$ on the model selection performance. In total, there are six experiments, summarized in Table 1.

| Dimension | Sparsity | $n$  | $p$  | $q$  | $|M_0|$ |
|-----------|----------|-----|-----|-----|------|
| LD ($n > p$) | Sparse | 60  | 30  | 3   | 5    |
|           | Dense   | 80  | 60  | 6   | 40   |
| HD ($p > n$) | Sparse | 50  | 200 | 5   | 20   |
|           | Dense   | 60  | 100 | 6   | 40   |
| UHD ($p \gg n$) | Ultra-sparse | 100 | 500 | 3   | 10   |
|           | Sparse  | 150 | 1000| 4   | 50   |

For each of the six simulation designs, we generate synthetic data by the following mechanism: The $n$ columns of the design matrix $X$ are sampled from a multivariate normal distribution with mean zero and covariance matrix $\Gamma$, that has an AR(1) structure with correlation coefficient 0.5 (i.e., $\Gamma_{ij} = 0.5^{|i-j|}$, for $i, j \in \{1, \ldots, p\}$). The true model $M_0$ is constructed by randomly selecting $|M_0|$ elements from $\{1, \ldots, p\}$. Once the true model $M_0$ is constructed, each component of the $q \times |M_0|$ true regression coefficient matrix $B_{M_0}$ is set as a value generated from the random variable $U + 1(U > -0.5)$, with $U \sim \text{Uniform}(-5, 4)$, so that the values always lie within $[-5, -0.5] \cup [0.5, 5]$. The multivariate response vectors $Y_1, \ldots, Y_n$ are independently generated from a multivariate normal distribution with mean $B_{M_0}X_{M_0}$ and covariance $V_{M_0}^0$, where the covariance matrix $V_{M_0}^0$ also has an AR(1) structure with $V_{M_0,ij}^0 = \sigma^2 0.5^{|i-j|}$ for $i, j \in \{1, \ldots, q\}$ and $\sigma^2 = 2$.

</table>
The EAS procedure is implemented by computing Algorithm 3.2 described in Section 3 to draw MCMC samples from the space of all \(2^p\) candidate models. Observe that Algorithm 3.2 is developed to work for a fixed \(\epsilon\). We propose two methods for selecting the tuning parameter \(\epsilon\): (i) 10-fold CV and (ii) via BIC by searching over a pre-specified grid of \(\epsilon\) values. For both the CV and BIC routines, we take a uniform grid of 24 possible values for \(\epsilon\), from 0.05 to 10 in all six experiments. In the CV procedure, for each of the 10 folds we implement our EAS method on the training set by running the MCMC 500 steps, discarding the first 200 steps, and evaluating the performance on the validation set, as follows. The initial estimates from the multivariate LASSO (MLasso) (Friedman, Hastie and Tibshirani, 2010) serves as the weights for proposing/removing predictors in the MCMC algorithm. The expectation of \(h_{BM}^{\epsilon}(B_M)\) for any model \(M\) is approximated by evaluating the \(h\) at the least square estimator \(\hat{B}_M\), which makes the computation very fast compared to the previous version of EAS procedures. The MAP estimated model from the MCMC sample is taken as a point estimator to compute the mean squared prediction error (MSPE) on the validation set. The optimal \(\epsilon\) is chosen as the one that minimizes the average of the MSPE over the 10 folds. Finally, we re-run Algorithm 3.2 on the entire dataset using the optimal selected \(\epsilon\) for 10,000 MCMC steps and discard the first 5,000.

For the BIC procedure, the computational cost is much less. In this case, for every \(\epsilon\) in the grid, we run Algorithm 3.2 for 5,000 steps, discard the initial 2,000 in obtaining the MAP estimated model, and compute the BIC for the MAP model. The \(\epsilon\) corresponding to the minimum BIC value is selected as optimal. The advantage of using BIC is that we do not need to run the algorithm again for the optimally chosen \(\epsilon\), we can simply use the MCMC chain from the initial runs as our estimated sample for the chosen \(\epsilon\).

We compare the performance of our method with (1) the MBSP approach as implemented in the R package MBSP (Bai and Ghosh, 2018b); (2) the MBGL-SS method as implemented in the R package MBGS (Liquet and Sutton, 2017) with the natural grouping (i.e., each predictor represents one group); (3) the SRRR method as implemented in the R package rrpack (Chen, 2019), with pre-specified rank \(q\) and adaptive group LASSO penalty; (4) the SPLS approach as implemented in the R package spls (Chung, Chun and Keles, 2019), with the thresholding parameter \(\eta\) selected by cross-validation, and the number of hidden components is set as \(q\); (5) the MSGlasso method as implemented via R package MSGlasso (Li, Nan and Zhu, 2016) with each predictor representing its own group; (6) the MLasso method as implemented via the glmnet package (Friedman, Hastie and Tibshirani, 2010) that penalizes the norm of each of the columns of the coefficient matrix. The objective function for MLasso is specified in Section 4 of Liquet et al., 2017. We also wanted to compare with the MRCE method that was originally implemented in the R package MRCE (Rothman, 2017), but the package is now removed from CRAN. Lastly, we could not implement the mSSL (Deshpande, Ročková and George, 2019) method because it is not yet available in CRAN and the github version requires a specific older version of Rcpp that is no longer supported.

For the frequentist procedures, the estimated model is defined to be the non-zero columns of the estimated coefficient matrix. For MBGL-SS the median thresholding estimator is used, and for MBSP the coefficients selected in the estimated model are those for which the 95% credible interval does not contain 0. For our EAS method we take the least square estimator of the MAP model as the point estimator for \(B^0_{M_o}\).

The metrics we use to evaluate the performance of the various methods, over 1,000 synthetic data sets for each of the 6 experiments, are the following. We report median MSPE on an out-of-sample test set, say \(Y_{\text{new}}\), that is of the same size as \(Y\). We also report the average false discovery rate (FDR), the average false negative rate (FNR), average mis-classification probability (MP), and average proportion of correct model selection (PCM). The results are displayed in Table 2. The results are a bit less noisy than those reported in the simulation.
study in Bai and Ghosh (2018a) because they only generated 100 synthetic datasets, and they did not report the out-of-sample prediction performance.

The explicit formulas for computing the metrics are, $\text{MSE} := \|Y - \hat{Y}\|^2/nq$, $\text{MSPE} := \|Y_{\text{new}} - \hat{Y}_{\text{new}}\|^2/nq$, $\text{FDR} := \text{FP} / \text{TP} + \text{FP}$, $\text{FNR} := \text{FN} / \text{FN} + \text{TN}$, and $\text{MP} := (\text{FP} + \text{FN}) / pq$, where TP, FP, TN, and FN are, respectively, the number of true positives, false positives, true negatives, and false negatives. Moreover, we also present the average estimated posterior probability of the true model, denoted $\mathbb{P}(M_0 | Y)$, for the Bayesian procedure and average fiducial probability, $r_r(Y_0 | Y)$, for the EAS procedure. Note that neither $r_r(Y_0 | Y)$ nor $\mathbb{P}(M_0 | Y)$ can be calculated for the frequentist methods, or the MAP or credible region based Bayesian methods, like MBSP.

In the generic $n > p$ case for both sparsity levels of the true model, irrespective of whether $\epsilon$ is chosen based on BIC or CV, our method performs on par with all other methods in terms of predictive performance, except SPLS which tends to exhibit inferior level of accuracy. In terms of variable selection performance, our method chooses the correct model with a high probability and very low FDR and FNR, similar to the Bayesian methods MBGLSS, MBSP and frequentist method SRRR. Other frequentist procedures tend to exhibit a lot of false positives. Our method does an excellent job in assigning a very high (GF) probability to the true model. Moreover, it is an advantage of our method, and MBGLSS, that they provide a probabilistic assessment of the competing models $M$ so that inference can be made on how much better, say the MAP estimated model is from the second best model and so on. For instance, if there are many models that are assigned similar probabilities, then the practitioner is warned not to over-interpret inference based on a single model.

In the $p > n$ and $p \gg n$ scenarios, our EAS method does fulfill the expectations consistent with the strong model selection consistency property. This is demonstrated by the fact that the EAS procedure, either using the BIC or CV tuning selection procedures, outperforms MBSP in terms of both the prediction performance and the average proportion of correct model selections. It also assigns a very high GF probability to the true model, which, again is consistent with our strong model selection consistency theoretical result. The selection performance of the frequentist procedures seem to degrade rapidly when one moves from small to large $p$. They tend to select a lot of false signals in the estimated model. An interesting remark in support of MBGLSS is that it seems to perform on par with the EAS procedure and outperform MBSP in some of the high-dimensional designs considered, arguably when either $p$ is not so much larger than $n$ or when the true model is ultra-sparse. This contradicts the numerical results presented in Bai and Ghosh (2018a) where MBGLSS is shown to perform poorly in all of the high-dimensional scenarios. In the $p \gg n$ and the ultra-sparse, when the optimal $\epsilon$ is chosen by CV, it seems to commit a lot of false discoveries. This might be attributed to the lack of identifiability of the true model in some of the folds, thus choosing an $\epsilon$ that it is relatively smaller than the optimal one. However, choosing the $\epsilon$ through BIC seems to mitigate these computational bottlenecks observed with the CV procedure.

6. Concluding remarks. The theoretical results presented in this article assume that the dimension $q$ of response is fixed. However, we kept careful account of all instances of $q$ in all of the non-asymptotic results presented, leaving an indication for the reader to understand the influence of $q$ in the consistency rates. An obvious extension of our work is to allow $q$ to grow, and in that case a careful account of the role of $q$ in the theory is critical to determine the circumstances in which the EAS method remains a consistent model selection procedure. A field where this extended theory could be applied is functional data analysis (FDA), where the response is measured very densely for each subject and naturally the dimension of the response grows. Although smoothness in the mean and the covariance function is fundamental to the analysis of FDA, many FDA procedures simply rely on techniques that are developed
for multivariate response data. Thus, we view this article as a promising first step on the pathway to a novel functional variable selection procedure.

APPENDIX: PROOFS

PROOF OF THEOREM 4.11. The statement of the theorem is equivalent to showing that,

\[ \sum_{\substack{M : |M| \leq n\alpha \\ M \neq M_0}} \frac{r_e(M|Y)}{r_e(M_0|Y)} \xrightarrow{P_y} 0, \]

as \( n \to \infty \) or \( n,p \to \infty \). To show this, observe that the ratio in sum has the form,

\[ \frac{r_e(M|Y)}{r_e(M_0|Y)} \]

The multivariate gamma function is defined as the product of univariate gamma functions, and so, using the gamma function inequalities in Jameson (2013a), the ratio of the multivariate gamma functions is bounded by,

\[ \frac{\Gamma_q \left( \frac{n-|M|}{2} \right)}{\Gamma_q \left( \frac{n-|M_0|}{2} \right)} \]

Moreover, for the true model \( M_0 \), because \( \hat{\Sigma}_{M_0} \sim \text{Wishart}_q \left( n - |M_0|, V^0_{M_0} \right) \),

\[ \frac{\det \hat{\Sigma}_{M_0}}{\det V^0_{M_0}} \sim \prod_{j=1}^q \chi^2_{n - |M_0| - j + 1}, \]

(Muirhead, 2009a, Theorem 3.2.15). Applying the Chernoff bound for the chi-square distribution and using the sub-additivity property of the probability measure,

\[ \Pr \left( \det \hat{\Sigma}_{M_0} > \prod_{j=1}^q 3\lambda_0 \left( n - |M_0| - j + 1 \right) \right) \leq q \exp \left( - \frac{n - |M_0| - q + 1}{4} \right) := V_{5,n}. \]

Expanding the quantity in (10),

\[ \sum_{\substack{M : |M| \leq n\alpha \\ M \neq M_0}} \frac{r_e(M|Y)}{r_e(M_0|Y)} = \sum_{M : M \subseteq M_0} \frac{r_e(M|Y)}{r_e(M_0|Y)} + \sum_{M : |M| \leq n\alpha} \frac{r_e(M|Y)}{r_e(M_0|Y)} \]

\[ = \sum_{j=1}^{|M_0|} \sum_{\substack{M : |M| = j \\ M \subseteq M_0}} \frac{r_e(M|Y)}{r_e(M_0|Y)} + \sum_{j=1}^{|M_0|} \sum_{\substack{M : |M| = j \\ M \nsubseteq M_0}} \frac{r_e(M|Y)}{r_e(M_0|Y)}. \]
Denote the two terms on the right side as $S_1$ and $S_2$, respectively. First consider $S_1$. By Theorem 4.8, with probability exceeding $1 - V_{3,n}$, $\mathbb{E}(h_e(B_{M_0}))$ is bounded from below by $1 - g_n(M_0, \epsilon)$ with,

$$g_n(M_0, \epsilon) := \exp \left( -\frac{\epsilon (n - |M_0|)}{36} + \frac{q |M_0|}{2} \right) + 2 \exp \left( -\frac{1}{8} \left( \sqrt{n - |M_0|} - 2\sqrt{q} \right)^2 \right).$$

Since the quantity $g_n(M_0, \epsilon)$ vanishes as $n \to \infty$, for sufficiently large $n$, $g_n(M_0, \epsilon) < K$ for some $K \in (0, 1)$. Bounding the ratio of the determinants of the residual matrices by Case 1 of Lemma 4.6, choosing $n$ large enough so that $\mathbb{E}(h_e(B_{M_0})) > 1 - K$, and bounding the $\mathbb{E}(h_e(B_{M}))$ for any model $M \not\subseteq M_0$ by 1,

$$r_e(M | Y) \leq \frac{e^{-\alpha n \log |M_0|}}{1 - K} \prod_{j=1}^{q} \frac{n - |M_0| - j + 1}{6\pi \lambda_0 (n - |M_0| - j + 1)} \left( \frac{|M_0| - |M|}{2} \right)^{\frac{|M_0| - |M|}{2}} \left( n - |M_0| - j + 1 \right)^{\frac{|M_0| - |M|}{2}} \left( n - |M| - j + 1 \right)^{\frac{|M_0| - |M|}{2}} \left( 1 - K \right) \left( e^{-\alpha n \log |M_0|} - q \log(\bar{x}_0)(|M_0| - |M|)/2 \right),$$

where the last inequality holds for $n > \frac{|M_0| + q}{1 - 1/6\pi}$. This implies that with probability exceeding $1 - V_{1,n} - V_{3,n} - V_{5,n}$,

$$S_1 = \sum_{j=1}^{\left\lfloor \frac{|M_0|}{M_0} \right\rfloor} \sum_{M \subset M_0} \frac{r_e(M | Y)}{r_e(M_0 | Y)} \leq \sum_{j=1}^{\left\lfloor \frac{|M_0|}{M_0} \right\rfloor} \sum_{M \subset M_0 \not\subseteq M_0} \left( |M_0| \right)^j \max_{M \subseteq M_0 | M = j} \frac{r_e(M | Y)}{r_e(M_0 | Y)}$$

$$\leq \sum_{j=1}^{\left\lfloor \frac{|M_0|}{M_0} \right\rfloor} (1 - K)^{-1} \exp \left( -\alpha n \log |M_0| - q \log(\bar{x}_0)(|M_0| - j)/2 + j \log |M_0| \right)$$

$$\leq (1 - K)^{-1} |M_0| \exp \left( -\alpha n \log |M_0| + |M_0| \log |M_0| - q \log(\bar{x}_0) < 1 \log(\bar{x}_0)(|M_0| - |M|)/2 \right).$$

By Condition 4.3, $1 - V_{1,n} - V_{3,n} - V_{5,n} \to 1$ as $n \to \infty$ or $n, p \to \infty$, and so $S_1 \to 0$ in probability as $n \to \infty$ or $n, p \to \infty$.

Next, consider $S_2$. Note that for models $M$ such that $M \not\subseteq M_0$ and $|M| \leq n^6$, By Theorem 4.10, for large $n$, with probability exceeding $1 - V_{4,n}$, $\mathbb{E}(h_e(B_{M})) \leq \tilde{g}_n(\epsilon, M)$ where,

$$\tilde{g}_n(\epsilon, M) := \exp \left( -\frac{\epsilon (n - |M|)}{36} + \frac{q |M|}{2} \right) + 2 \exp \left( -\frac{1}{8} \left( \sqrt{n - |M|} - 2\sqrt{q} \right)^2 \right).$$

Bounding the ratio of the determinants of the residual matrices as in Case 2 of Theorem 4.6, and choosing $n$ large enough so that $\mathbb{E}(h(B_{M})) > 1 - K$ with high probability, for all $M \subseteq M_0$ with $|M| \leq n^a$,

$$r_e(M | Y) \leq \left\{ \begin{array}{ll} \frac{n}{6\pi \lambda_0 (n - |M_0| - q)} \left( \frac{|M_0| - |M|}{2} \right)^{\frac{|M_0| - |M|}{2}} \tilde{g}_n(\epsilon, M) \exp \left( q \left( \sqrt{n - |M|} - 2\sqrt{q} \right)^2 \right) & \text{if } |M| \leq |M_0| \\
\frac{n}{6\pi \lambda_0 (n - |M_0| - q)} \left( \frac{|M_0| - |M|}{2} \right)^{\frac{|M_0| - |M|}{2}} \tilde{g}_n(\epsilon, M) \exp \left( q \left( \sqrt{n - |M_0|} - 2\sqrt{q} \right)^2 \right) & \text{if } |M_0| + 1 \leq |M| \leq n^a \end{array} \right.$$

$$\frac{n}{6\pi \lambda_0 (n - |M_0| - q)} \left( \frac{|M_0| - |M|}{2} \right)^{\frac{|M_0| - |M|}{2}} \tilde{g}_n(\epsilon, M) \exp \left( q \left( \sqrt{n - |M_0|} - 2\sqrt{q} \right)^2 \right) & \text{if } |M_0| + 1 \leq |M| \leq n^a$$
Then,
\[
S_2 = \sum_{j=1}^{[M_o]} \left( \sum_{M:|M|=j, M \not\subseteq M_o} \frac{r_e(M \mid Y)}{r_e(M_o \mid Y)} \right) + \sum_{j=[M_o]+1}^{n^\alpha} \left( \sum_{M:|M|=j, M \not\subseteq M_o} \frac{r_e(M \mid Y)}{r_e(M_o \mid Y)} \right) =: S_{21} + S_{22}.
\]

Consider \(S_{21}\) and \(S_{22}\) separately. For sufficiently large \(n\), using \(g_n(\epsilon, M)\) to bound \(\mathbb{E}(h_n(B_M))\), with probability exceeding \(1 - V_{2,n} - V_{3,n} - V_{4,n} - V_{5,n}\),
\[
S_{21} \leq \sum_{j=1}^{[M_o]} \left( \frac{p}{j} \right) \max_{M \not\subseteq M_o: |M|=j} \frac{r_e(M \mid Y)}{r_e(M_o \mid Y)} \leq \frac{2}{1 - K} \sum_{j=1}^{[M_o]} \exp \left( -\frac{n - j}{8} - q j \log(\tilde{\lambda}_v)(|M_o| - j)/2 + q n^\alpha \log(n - |M_o|) + (q + 1)j \log p \right)
\]
\[
+ \frac{1}{1 - K} \sum_{j=1}^{[M_o]} \exp \left( -\frac{\epsilon(n - j)}{8} - \frac{q j}{2} - q \log(\tilde{\lambda}_v)(|M_o| - j)/2 + q n^\alpha \log(n - |M_o|) + (q + 1)j \log p \right)
\]
\[
\leq \frac{2 [M_o]}{1 - K} \exp \left( -\frac{n - [M_o]}{8} - \frac{q [M_o]}{2} \log(\tilde{\lambda}_v < 1) \log(\tilde{\lambda}_v) + q n^\alpha \log(n - |M_o|) + (q + 1) |M_o| \log p \right)
\]
\[
+ \frac{1}{1 - K} \sum_{j=1}^{[M_o]} \exp \left( -\frac{\epsilon(n - [M_o])}{8} + q n^\alpha \log(n - |M_o|) + (q + 1) |M_o| \log p + \frac{q [M_o]}{2} \{1 - I(\tilde{\lambda}_v < 1) \log(\tilde{\lambda}_v)\} \right).
\]

For \(S_{22}\), because \((n - |M_o|)/(n - |M| - q - 1)\) converges to 1 for all \(M\) with \(|M| \leq n^\alpha\), we can choose \(n\) large enough so that \((n - |M_o|)/(n - |M| - q - 1) < 2\). Then, again using the bound \(g_n(\epsilon, M)\), we obtain that for all \(M \not\subseteq M_o\) such that \(|M_o| \leq |M| \leq n^\alpha\), with probability exceeding \(1 - V_{2,n} - V_{3,n} - V_{4,n} - V_{5,n}\),
\[
S_{22} := \sum_{j=[M_o]+1}^{n^\alpha} \left( \sum_{M:|M|=j, M \not\subseteq M_o} \frac{r_e(M \mid Y)}{r_e(M_o \mid Y)} \right)
\]
\[
\leq \sum_{j=[M_o]+1}^{n^\alpha} \left( \max_{M \not\subseteq M_o: |M|=j} \frac{r_e(M \mid Y)}{r_e(M_o \mid Y)} \right)
\]
\[
\leq \frac{2}{1 - K} \sum_{j=1}^{n^\alpha} \exp \left( -\frac{n - j}{8} + \frac{q j}{2} \log(12\pi \tilde{\lambda}_v) + q n^\alpha \log(n - |M_o|) + (q + 1)j \log p \right)
\]
\[
+ \frac{1}{1 - K} \sum_{j=1}^{n^\alpha} \exp \left( -\frac{\epsilon(n - j)}{36} + \frac{q j}{2} (1 + \log(12\pi \tilde{\lambda}_v)) + q n^\alpha \log(n - |M_o|) + (q + 1)j \log p \right)
\]
\[
\leq \frac{2 n^\alpha}{1 - K} \exp \left( -\frac{n - n^\alpha}{8} + \frac{q}{2} \log(12\pi \tilde{\lambda}_v) \{n^\alpha \tilde{\lambda}_v > \frac{1}{12\pi}\} + 1\} + n^\alpha \{q \log(n - |M_o|) + (q + 1) \log p\} \right)
\]
\[
+ \frac{1}{1 - K} \sum_{j=1}^{n^\alpha} \exp \left( -\frac{\epsilon(n - n^\alpha)}{36} + q n^\alpha \log(n - |M_o|) + (q + 1) n^\alpha \log p
\]
\[
+ \frac{q}{2} (1 + \log(12\pi \tilde{\lambda}_v)) \{n^\alpha \tilde{\lambda}_v > \frac{1}{12\pi} + 1\}\right).
\]

Lastly, by Condition 4.3 since \(1 - V_{2,n} - V_{3,n} - V_{4,n} - V_{5,n} \rightarrow 1\) as \(n \rightarrow \infty\) or \(n, p \rightarrow \infty\), \(S_2 = S_{21} + S_{22} \rightarrow 0\) in probability as \(n \rightarrow \infty\) or \(n, p \rightarrow \infty\). This completes the proof of Theorem 4.11.
REFERENCES

Recall that \( H_M \) is the symmetric projection matrix onto row space of \( X_M \), and let \( r := \text{rank}(H_M) \). Since \( I_n - H_M \) is symmetric and idempotent with rank \( r \), it can be decomposed as \( I_n - H_M = P_{\perp H_M} \). Therefore, the derivative of the matrix logarithm of \( H_M \) is given by

\[
\log(\text{det}(H_M)) = \text{tr} \left( \log(H_M) \right) = \text{tr} \left( \log(\text{det}(H_M)) \right)
\]

where the last identity follows from the fact that the logarithm of a determinant is the sum of the logarithms of the eigenvalues of the matrix. This fact is a consequence of the spectral theorem for symmetric matrices, which states that any symmetric matrix can be diagonalized by an orthogonal matrix. The proof of this fact is detailed in Appendix A of [16], and it is used to establish the relationship between the matrix logarithm and the logarithm of the determinant.

### Supplementary Material

#### Supplement to “The EAS approach to variable selection for multivariate response data in high-dimensional settings”

This supplement contains the proof of the lemmas and theorems in the paper, derivation of the generalized fiducial probability distribution for the subset models.
We consider two sub-cases. First, suppose $a^\top L_M a = a^\top \left( YG_M - B^0_{M, n} X_M G_M \right) \left( G_M Y^\top - G_M X_M B^0_{M, n} \right) a$

$$= a^\top \left\{ YG_M G_M Y^\top - YG_M G_M X_M B^0_{M, n} - B^0_{M, n} X_M G_M G_M Y^\top + B^0_{M, n} X_M G_M G_M X_M B^0_{M, n} \right\} a$$

$$= a^\top \left\{ \hat{\Sigma}_M - Y (I - H_M) X_M B^0_{M, n} - B^0_{M, n} X_M (I - H_M) Y^\top + \Delta_M \right\} a$$

$$= a^\top \hat{\Sigma}_M a - 2a^\top Y (I - H_M) X_M B^0_{M, n} a + a^\top \Delta_M a$$

$$= a^\top \hat{\Sigma}_M a - 2a^\top \left( B^0_{M, n} X_M + A^0_{M, n} U \right) (I - H_M) X_M B^0_{M, n} a + a^\top \Delta_M a$$

$$= a^\top \hat{\Sigma}_M a - 2a^\top A^0_{M, n} U (I - H_M) X_M B^0_{M, n} a - a^\top \Delta_M a.$$

Since we have to obtain a lower bound for $\lambda_{\text{min}}(\hat{\Sigma}_M)$, we pick a particular $a^*$ with $\|a^*\| = 1$ such that $a^*^\top \hat{\Sigma}_M a^* = \lambda_{\text{min}}(\hat{\Sigma}_M)$. Applying the triangle inequality on the absolute value of the terms with that $a^*$, we get,

$$|a^*^\top \hat{\Sigma}_M a^* - (n - r) a^*^\top V^0_{M, a^*} - a^*^\top \Delta_M a^*| \leq |a^*^\top L_M L_M a^* - (n - r) a^*^\top V^0_{M, a^*}|$$

$$+ 2|a^*^\top A^0_{M, n} U (I - H_M) X_M B^0_{M, n} a^*|$$

(12)

From the above inequality, one aspect for obtaining a lower bound for the minimum eigenvalue of $\hat{\Sigma}_M$ requires that $a^*^\top L_M L_M a^*/(n - r)$ concentrates around $a^*^\top V^0_{M, a^*}$. This fact follows since $n - r > q$, $L_M^\top L_M \sim \text{Wishart}_q(n - r, V^0_{M, n})$, and $L_M^\top L_M$ is positive definite with probability 1. With this observation in mind, we will deal with the two terms on the right hand side of equation (12) separately.

For the second term, by Condition 4.1, $a^*^\top V^0_{M, a^*} \geq \lambda_{\text{in}}$. Since $\Delta_M$ is a positive semidefinite matrix, $a^*^\top \Delta_M a^* \geq 0$. Defining $\tilde{a} := A^0_{M, n} a^*$ and $\bar{a} := (I - H_M) X_M B^0_{M, n} a^*$, $\|\tilde{a}\|^2 = a^*^\top V^0_{M, a^*}$ and $\|\bar{a}\|^2 = a^*^\top \Delta_M a^*$, and,

$$a^*^\top A^0_{M, n} U (I - H_M) X_M B^0_{M, n} \bar{a}^* = \tilde{a}^\top U \tilde{a} = \sum_{i=1}^{q} \sum_{j=1}^{n} U_{ij} \tilde{a}_i \tilde{a}_j \sim N \left( 0, \|\tilde{a}\|^2 \|\tilde{a}\|^2 \right).$$

We consider two sub-cases. First, suppose $a^*^\top \Delta_M a^* = 0$. Then the variance of $a^*^\top A^0_{M, n} U (I - H_M) X_M B^0_{M, n} \bar{a}^*$ is 0 and the random variable is degenerate at 0. Therefore, $a^*^\top L_M L_M a^* = a^*^\top \hat{\Sigma}_M a^* = \lambda_{\text{min}}(\hat{\Sigma}_M)$. On the other hand if $a^*^\top \Delta_M a^* > 0$, using the tail bound for a standard Gaussian random variable, that for $x > 0$, $\Phi(-x) \leq \frac{1}{x^2 + 2x} e^{-\frac{x^2}{2}}$, for any $\alpha_1 \in (0, 1)$,

$$\mathbb{P}_y \left( \left| a^*^\top A^0_{M, n} U (I - H_M) X_M B^0_{M, n} \bar{a}^* \right| > \frac{\alpha_1 \lambda_{\text{in}}}{2} (n - r) \right)$$

$$= \mathbb{P}_y \left( \sum_{i=1}^{q} \sum_{j=1}^{n} U_{ij} \tilde{a}_i \tilde{a}_j > \frac{\alpha_1 \lambda_{\text{in}}}{2} (n - r) \right)$$

$$= 2\Phi \left( -\frac{\alpha_1 \lambda_{\text{in}} (n - r)}{2 \|\tilde{a}\| \|\tilde{a}\|} \right)$$
The proof is completed by observing that
\[
\|W\| = \sup_{a, \|a\| = 1} |a^T W a|, \text{ so putting } a = a^* \text{ and } t = \kappa(\alpha_2 \lambda_v) \sqrt{n - r} - C \sqrt{q} > 0 \text{ for some } \alpha_2 \in (0, 1) \text{ in equation (14) we obtain}
\]
\[
P_y \left( \left| a^T L_M^* L_M - V_M^0 \right| \leq \delta_n \right) \geq 1 - 2 \exp \left( -c \left( \kappa(\alpha_2 \lambda_v) \sqrt{n - r} - C \sqrt{q} \right)^2 \right).
\]
Note that the requirement that \( t > 0 \) and \( n - r > q \) is the origin of the condition that \( n > |M| + q \max \left\{ (C/\kappa(\alpha_2 \lambda_v))^2, 1 \right\} \), in the statement of Lemma.

Combining equations (12), (13) and (15), we derive that for any \( \alpha_1, \alpha_2 > 0 \) such that \( 0 < \alpha_1 + \alpha_2 \leq 1 \), with probability exceeding \( 1 - 2 \exp \left( -c \left( \kappa(\alpha_2 \lambda_v) \sqrt{n - r} - C \sqrt{q} \right)^2 \right) - \frac{4 \sqrt{\lambda_{\text{max}}(\Delta_M) \lambda_v}}{\sqrt{2 \pi \alpha_1 \lambda_v (n - r)}} \exp \left( -\frac{\alpha_1^2 \lambda_v^2 (n - r)^2}{8 \lambda_{\text{max}}(\Delta_M) \lambda_v} \right) |\Delta_M \neq 0|),
\]
\[
\left| a^* \tilde{\Sigma} M a^* - (n - r) a^* V_M^0 a^* - a^* \Delta_M a^* \right| \leq \alpha_1 \lambda_v (n - r) + \alpha_2 \lambda_v (n - r).
\]
The proof is completed by observing that \( a^* \tilde{\Sigma} M a^* = \lambda_{\text{min}}(\tilde{\Sigma}_M), \ a^* \Delta_M a^* \geq 0, \ a^* V_M^0 a^* \geq \lambda_v > 0, \text{ and } n - r \geq n - |M| \).

**Proof of Theorem 4.6. Case 1.** First we consider models \( M \subseteq M_0 \). Let \( r_{n,M} = 1 - (1 + \xi_{n,|M|} \lambda_v / \lambda_u) / 2 \). Then for sufficiently large \( n, (1 - r_{n,M}) = (1 + \xi_{n,|M|} \lambda_v / \lambda_u) / 2 \in (1/2, 1) \). We take \( \alpha_1 = \alpha_2 = (1 - r_{n,M}) / 2 \in (1/4, 1/2) \) in Corollary 4.5 to get,
\[
P_y \left( \lambda_{\text{min}}(\tilde{\Sigma}_M) < r_{n,M} \lambda_v (n - |M|) \right) \leq \tilde{V}_{0,n}(M, r_{n,M}, r_{n,M}),
\]
Then,
\[
P_y \left( \frac{\det M_0}{\det \tilde{\Sigma}_M} > \xi_{n,|M|} \right)
\]
\[
\leq P_y \left( \frac{\det M_0}{\det \tilde{\Sigma}_M} \geq \xi_{n,|M|} \left( \lambda_{\text{min}}(\tilde{\Sigma}_M) \right)^q \right)
\]
\[
\leq P_y \left( \frac{\det M_0}{\det \tilde{\Sigma}_M} \geq \xi_{n,|M|} \left( r_{n,M} \lambda_v (n - |M|) \right)^q \right) + \mathbb{P} \left( \lambda_{\text{min}}(\tilde{\Sigma}_M) < r_{n,M} \lambda_v (n - |M|) \right)
\]
\[
\leq P_y \left( \frac{\det M_0}{\det \tilde{\Sigma}_M} \geq \xi_{n,|M|} \left( \lambda_v \right)^q \left( r_{n,M} (n - |M|) \right)^q \right) + \tilde{V}_{0,n}(M, r_{n,M}, r_{n,M}),
\]
and by Theorem 3.3.22 of Gupta and Nagar (2018b) with $\xi_{n,M}^* = \xi_{n,M} \lambda_v / \bar{\lambda}_v \in (0, 1)$,

\[
P_y \left( \frac{\det \hat{\Sigma}_{M_o}}{\det \Sigma_M} > \xi_{n,M}^q \right)
\leq \sum_{i=1}^q P_y \left( \chi_{n,-|M_o|-i+1}^2 \geq r_{n,M} \xi_{n,M}^*(n - |M|) \right) + \tilde{V}_{0,n}(M, r_{n,M}, r_{n,M})
\leq q \exp \left( -s r_{n,M} \xi_{n,M}^*(n - |M|) - \left( \frac{n - |M| - i + 1}{2} \right) \log(1 - 2s) \right) + \tilde{V}_{0,n}(M, r_{n,M}, r_{n,M})
\leq q \exp \left( -(n - |M|) \left( s r_{n,M} \xi_{n,M}^* + \frac{1}{4} \log(1 - 2s) \right) \right) + \tilde{V}_{0,n}(M, r_{n,M}, r_{n,M}),
\]

where the second to last inequality holds for any $s < 1/2$ by Chernoff’s bound, and the last inequality holds for any $n > 2|M_o| + 2q - |M| \geq 2q + 1$. Taking $s = \frac{1}{2} \left( 1 - \frac{1}{2r_{n,M} \xi_{n,M}^*} \right) < 0$,

\[
s r_{n,M} \xi_{n,M}^* + \frac{1}{4} \log(1 - 2s)
= \frac{1}{4} \left( \xi_{n,M}^*(1 - \xi_{n,M}^*) - 1 - \log \left( \xi_{n,M}^*(1 - \xi_{n,M}^*) \right) \right)
\geq \frac{1}{4} \left( \xi_{n,M}^*(1 - \xi_{n,M}^*) - 1 + \log 4 \right) \geq \frac{\xi_{n,M}^* \lambda_v n^\alpha \log |M_o|}{2\lambda_v (n - |M|)} + 0.09 > 0,
\]

which implies that,

\[
P_y \left( \frac{\det \hat{\Sigma}_{M_o}}{\det \Sigma_M} > \xi_{n,M}^q \right) \leq q \exp \left( -\frac{\xi_{n,M}^* n^\alpha \log |M_o| \lambda_v}{2\lambda_v} - 0.09 (n - |M|) \right) + \tilde{V}_{0,n}(M, r_{n,M}, r_{n,M}).
\]

Therefore,

\[
P_y \left( \bigcup_{M \subseteq M_o} \left\{ Y : \left( \frac{\det \hat{\Sigma}_{M_o}}{\det \Sigma_M} \right)^{\frac{n - |M| - q}{2}} > \xi_{n,M}^q \right\} \right)
\leq \sum_{j=1}^{M_o} \left( \left\lfloor \frac{|M_o|}{j} \right\rfloor \max_{M \subseteq M_o : |M| = j} P_y \left( \left\{ Y : \left( \frac{\det \hat{\Sigma}_{M_o}}{\det \Sigma_M} \right)^{\frac{n - |M| - q}{2}} > \xi_{n,j}^q \right\} \right) \right)
\leq \sum_{j=1}^{M_o} q^j \log(|M_o|) \max_{M \subseteq M_o : |M| = j} \left\{ q e^{-\frac{\xi_{n,j}^* n^\alpha \log |M_o| \lambda_v}{2\lambda_v} - 0.09 (n - j) - |M_o| \log |M_o|} \right\}
\leq |M_o| q \exp \left( -\frac{\xi_{n,M_o}^* n^\alpha \log |M_o| \lambda_v}{2\lambda_v} - 0.09 (n - |M_o|) + |M_o| \log |M_o| \right)
+ 2 |M_o| \exp \left( -c \left\{ \kappa (\lambda_v / 4) \sqrt{n - |M_o|} - C \sqrt{q} \right\}^2 + |M_o| \log |M_o| \right)
+ 8 |M_o| \left\| B_{M_o}^0 \right\| \sqrt{\pi \alpha_1 \lambda_v} \sqrt{n - |M_o|} \exp \left( \frac{(\lambda_v / 16)^2 (n - |M_o|)}{c^* \left\| B_{M_o}^0 \right\|^2 \lambda_v} + |M_o| \log |M_o| \right),
\]
where the last inequality follows because $\alpha_1 = \alpha_2 > 1/4$ implies,
\[
\overline{V}_{0,n}(M, r_n, M, r_n, M) \leq 2 \exp \left( -c \left\{ \kappa(\lambda_v/4) \sqrt{n - |M|} - C \sqrt{q} \right\}^2 \right) \\
+ \frac{8 \|B^0_M\|}{\sqrt{n} \lambda_v} \sqrt{c^* \lambda_v} \exp \left( -\frac{(\lambda_v/16)^2(n - |M|)}{c^* \|B^0_M\|^2 \lambda_v} \right) I(\Delta_M \neq 0).
\]

The proof for Case 1 completes by noting that,
\[
\det \hat{\Sigma}_M \leq \xi_{n, |M|^2} \leq \left( 1 - \frac{2n^\alpha \log |M_o|}{n - |M| - q} \right) q(n - |M| - q)/2 \leq e^{-qa \log |M_o|}.
\]

Case 2. Fix an arbitrary model $M$ such that $M \not\subseteq M_o$ and $|M| \leq n^\alpha$, and construct a new model $M' := M \cup M_o$ where $|M'| = |M| + \ell$ for some $\ell \in \{1, \ldots, |M_o|\}$. Further, $M' \supset M_o$ implies $(H_{M'} - H_{M_o})(I - H_{M'}) = 0$, which means $\tilde{\Sigma}_{M'} = \tilde{\Sigma}_{M}$ is independent of $\hat{\Sigma}_M$. For sufficiently large $n$, $\tilde{\Sigma}_M \sim \text{Wishart}_q \left(n - r - \ell, V^0_{M_o}\right)$ and $\hat{\Sigma}_M - \tilde{\Sigma}_M \sim \text{Wishart}_q \left(r + \ell - |M_o|, V^0_{M_o}\right)$, where $r := \text{rank}(X_M) \leq |M|$. Without loss of generality for the bounds we derive it suffices to work with $r = |M|$. By Theorem 10.5.3 of Muirhead (2009b),
\[
\frac{\det \hat{\Sigma}_M}{\det \hat{\Sigma}_M'} \sim \left\{ \begin{array}{ll}
\prod_{i=1}^{q} V_i^{(1)} & \text{if } |M| + \ell - |M_o| \geq q \\
\prod_{i=1}^{[|M|+\ell-|M_o|]} V_i^{(2)} & \text{if } |M| + \ell - |M_o| < q
\end{array} \right.
\]
\[
\text{where } V_i^{(1)} \text{ are independently distributed Beta} \left(\frac{1}{2} (n - |M| - \ell - i + 1), \frac{1}{2} (|M| + \ell - |M_o|)\right) \text{ and } V_i^{(2)} \text{ are independently distributed Beta} \left(\frac{1}{2} (n - |M_o| - q - i + 1), \frac{q}{2}\right).
\]

We will handle the two cases separately.

Case 2a: Suppose $|M| + \ell - |M_o| \geq q$. Because, $M' \supset M$, $\hat{\Sigma}_M - \tilde{\Sigma}_M$ is a positive definite matrix and that implies $\hat{\Sigma}_M \geq \det \hat{\Sigma}_M$. Hence,
\[
\mathbb{P}_y \left( \frac{\det \hat{\Sigma}_M}{\det \hat{\Sigma}_M} > \zeta_{n, |M|^2} \right) \leq \mathbb{P}_y \left( \frac{\det \hat{\Sigma}_M}{\det \hat{\Sigma}_M'} > \zeta_{n, |M|}^{q} \right) \leq \sum_{i=1}^{q} \mathbb{P}_y \left( V_i^{(1)} < \zeta_{n, |M|^2}^{-1} \right).
\]
The probabilities in the sum on the right side are bounded by approximating the CDF of the Beta density, and approximating of the beta function by Theorem 2 of Jameson (2013b) as,
\[
\mathbb{P}_y \left( V_i^{(1)} < \zeta_{n, |M|^2}^{-1} \right)
\]
\[
= \frac{1}{B\left(\frac{n - |M| - \ell - i + 1}{2}, \frac{|M| + \ell - |M_o|}{2}\right)} \int_0^{\zeta_{n, |M|^2}^{-1}} y^{\frac{1}{2}(n - |M| - \ell - i + 1) - 1}(1 - y)^{\frac{1}{2}(|M| + \ell - |M_o|) - 1} dy
\]
\[
\leq \frac{n - |M| - i + 1}{2} \Gamma\left(\frac{|M| + \ell - |M_o|}{2}\right) \zeta_{n, |M|^2}^{-\left(\frac{2 - |M| - \ell - i + 1}{2}\right)} \left[ 1 - \left(\frac{\zeta_{n, |M|} - 1}{\zeta_{n, |M|^2}}\right)^{\frac{|M| + \ell - |M_o|}{2}} \right]
\]
\[
\leq \frac{n - |M_o|}{2} \zeta_{n, |M|^2}^{-\left(\frac{n - |M| - q}{2}\right)} + |M_o| + 1 \cdot 1.
\]
**Case 2b:** Suppose $|M| + \ell - |M_o| < q$. Then similar to the previous case,

$$
P_y \left( \det \hat{\Sigma}_M > \zeta_{\mathbb{R}^n,|M|}^q \right) \leq P_y \left( \det \hat{\Sigma}_{M^*} > \zeta_{\mathbb{R}^n,|M^*|}^{|M^*|+\ell-|M_o|} \right) \leq \sum_{i=1}^{\mathbb{R}^n,|M|} P_y \left( V_i^{(2)} < \zeta_{\mathbb{R}^n,|M|}^{-1} \right),
$$

and,

$$
P_y \left( V_i^{(2)} < \zeta_{\mathbb{R}^n,|M|}^{-1} \right)
= \frac{1}{B \left( \frac{n-|M_o|-q+i+1}{2}, \frac{n}{2} \right)} \int_0^{\zeta_{\mathbb{R}^n,|M|}^{-1}} y^{\frac{1}{2} \left(n-|M_o|-q-i+1\right)} \left(1 - y\right)^{\frac{n}{2} - 1} dy
\leq \frac{\left(n-|M_o|-q+i+1\right)^{\frac{1}{2}}}{\Gamma \left( \frac{n}{2} \right)} \zeta_{\mathbb{R}^n,|M|}^{-1} \left[1 - \left(\frac{\zeta_{\mathbb{R}^n,|M|}}{n}\right)^{\frac{1}{2}}\right]
\leq \left(n - |M_o|\right)^{\frac{1}{2}} \zeta_{\mathbb{R}^n,|M|}^{-1}.
$$

Thus, in any case, for sufficiently large $n$,

$$
P_y \left( \det \hat{\Sigma}_M > \zeta_{\mathbb{R}^n,|M|}^q \right) \leq 2q e^{-n^\alpha \log(n-|M_o|)-|M| \log p + \max \left\{ \frac{|M|}{2}, \frac{q}{2} \right\} \log \left(\frac{n-|M_o|}{2} + \frac{|M_o|+1}{2} \log (\zeta_{\mathbb{R}^n,|M|}) \right)}.
$$

Therefore,

$$
P_y \left( \bigcup_{M \not\subseteq M_o: |M| \leq n^\alpha} \left\{ Y : \left( \frac{\det \hat{\Sigma}_M}{\det \Sigma_M} \right)^{\frac{n-|M|-q}{2}} > \zeta_{\mathbb{R}^n,|M|}^{q(n-|M|-q)} \right\} \right)
\leq \sum_{j=1}^{n^\alpha} \left( \frac{p}{j} \right) \max_{M \not\subseteq M_o: |M| = j} P_y \left( \left( \frac{\det \hat{\Sigma}_M}{\det \Sigma_M} \right)^{\frac{n-j-q}{2}} > \zeta_{\mathbb{R}^n,|M|}^{q(n-j-q)} \right)
\leq \sum_{j=1}^{n^\alpha} \max_{M \not\subseteq M_o: |M| = j} \left\{ 2q \exp \left( -n^\alpha \log(n-|M_o|) + \max \left\{ \frac{j}{2}, \frac{q}{2} \right\} \log (n-|M_o|) + \frac{|M_o|+1}{2} \log (\zeta_{\mathbb{R}^n,|M|}) \right) \right\}
\leq 2q \exp \left( \frac{-n^\alpha}{2} \log(n-|M_o|) + \frac{|M_o|+1}{2} \log (\zeta_{\mathbb{R}^n,|M|}) \right).
$$

The proof is completed by noting that $\zeta_{\mathbb{R}^n,|M|}^{q(n-|M|-q)} \leq e^{q(n^\alpha \log(n-|M_o|)+|M| \log p)}$.

**Proof of Theorem 4.8.** To prove Theorem 4.8 and Theorem 4.10 we need two additional results, which are stated below. The proofs of Lemma A.1 and Lemma A.2 are provided after the proof of the Theorem 4.10. Since these two lemmas are only necessary to bound the $E(h_\alpha(B_M))$ from above for the large models, without loss of generality assume that $X_M$ is of full row rank, as in the statement of both the lemmas. If $X_M$ is not of full rank, $h_\alpha(B_M)$ is automatically zero.

**Lemma A.1.** For model $M$ with $|M| < n - 4q$,

$$
B_M \sim T_{q,M} \left(n - |M| - q + 1, \hat{B}_M, \hat{\Sigma}_M, \left(X_M X_M^T\right)^{-1}\right),
$$

(17)
where \( \hat{B}_M = YX_M^\top (X_MX_M^\top)^{-1} \), and for any \( \epsilon > 0 \),
\[
P\left( \frac{1}{2} \left\| \Sigma_M^{-1/2} \left( B_MX_M - \hat{B}_M X_M \right) \right\|_F^2 \leq \frac{\epsilon}{9} \right) \geq 1 - V_{5,n,M},
\]
with,
\[
V_{5,n,M} := \exp \left( -\frac{\epsilon(n-|M|)}{36} + \frac{q|M|}{2} \right) + 2 \exp \left( -\frac{\left( \sqrt{n-|M|} - 2\sqrt{q} \right)^2}{8} \right).
\]

**Lemma A.2.** For any model \( M \) such that \(|M| < n - C^2q/\kappa^2(\lambda_v/4)\), assume that \( Y|B_M, A_M \sim \text{Matrix-Normal}_{q,n}(B_MX_M, V_M, I_n) \), then the least-squared estimator;
\[
\hat{B}_M \sim \text{Matrix-Normal}_{q,|M|}\left( \mathbb{E}_y(\hat{B}_M), \Sigma_{M_0}^{0} (X_MX_M^\top)^{-1} \right),
\]
and,
\[
P_g\left( \frac{1}{2} \left\| \Sigma_M^{-1/2} \left( \hat{B}_M - \mathbb{E}_y(\hat{B}_M) \right) X_M \right\|_F^2 \leq \frac{\epsilon}{9} \right) \geq 1 - V_{6,n,M},
\]
where,
\[
V_{6,n,M} := \exp \left( -\frac{\epsilon(n-|M|)}{36\lambda_v} + \frac{q|M|}{\lambda_v} \right) + 2 \exp \left( -c\left\{ \kappa(\lambda_v/4) \sqrt{n-|M|} - C\sqrt{q} \right\}^2 \right) + \frac{8 \left\| B_M^0 \right\| \sqrt{c^2\lambda_v}}{\sqrt{\pi} \lambda_v \sqrt{n-|M|}} \exp \left( -\frac{(\lambda_v/16)n-|M|}{c^2 \left\| B_M^0 \right\|^2 \lambda_v} \right) \Pi(A_M \neq 0).
\]

Let \( \hat{B}_{\min} \) minimize the objective function \( \frac{1}{2} \left\| A_{M_0}^{-1} (B_{M_0}X_{M_0} - BX) \right\|_F^2 \) subject to \(|\{j : \left\| B_j \right\| \neq 0\}| \leq |M_0| - 1 \). Also, suppose \( B_{\min} \) minimize the objective function \( \frac{1}{2} \left\| \Sigma_{M_0}^{-1/2} (B_MX_M - BX) \right\|_F^2 \) subject to \(|\{j : \left\| B_j \right\| \neq 0\}| \leq |M_0| - 1 \). Then,
\[
\left\| A_{M_0}^{-1} (B_{M_0}X_{M_0} - \hat{B}_{\min} X) \right\|_F \leq \left\| A_{M_0}^{-1} (B_{M_0}X_{M_0} - B_{\min} X) \right\|_F \leq \left\| A_{M_0}^{-1} \Sigma_{M_0}^{1/2} \right\|_F \left\| \Sigma_{M_0}^{-1/2} (B_{M_0}X_{M_0} - B_{\min} X) \right\|_F.
\]
Now, \( \left\| A_{M_0}^{-1} \Sigma_{M_0}^{1/2} \right\|_F^2 = \text{tr} \left( A_{M_0}^{-1} \Sigma_{M_0} A_{M_0}^{-1} \right) \). Now, \( \hat{\Sigma}_{M_0} \sim \text{Wishart}_{q,|M_0|} \) implies \( A_{M_0}^{-1} \Sigma_{M_0} A_{M_0}^{-1} \sim \text{Wishart}_q(n-|M_0|, I_q) \). This means, \( \left\| \hat{\Sigma}_{M_0}^{-1/2} \right\|_F^2 \sim \chi^2 \) distribution with \( q(n-|M_0|) \) degrees of freedom. Using triangle inequality,
\[
\left\| \hat{\Sigma}_{M_0}^{-1/2} (B_{M_0}X_{M_0} - B_{\min} X) \right\|_F \leq \left\| \hat{\Sigma}_{M_0}^{-1/2} (B_{M_0}X_{M_0} - B_M X_M) \right\|_F + \left\| \hat{\Sigma}_{M_0}^{-1/2} (B_M X_M - B_{\min} X) \right\|_F \leq \left\| \hat{\Sigma}_{M_0}^{-1/2} [B_{M_0} - \hat{B}_{M_0}] X_M \right\|_F + \left\| \hat{\Sigma}_{M_0}^{-1/2} (B_M X_M - B_{\min} X) \right\|_F.
\]
Then,

$$I \left( \left\| A_{M_0} M_0^{-1} (B_{B_{M_0}} X_{M_0} - \hat{B}_{\text{min}} X) \right\|_F^2 > 36q \, (n - |M_0|) \epsilon \right)$$

$$\leq I \left( \left\| A_{M_0} M_0^{-1} \Sigma_{M_0}^{1/2} \left( B_{B_{M_0}} X_{M_0} - B_{\text{min}} X \right) \right\|_F^2 > 36q \, (n - |M_0|) \epsilon \right)$$

$$\leq I \left( \frac{1}{2} \left\| \hat{\Sigma}_{M_0}^{1/2} \left( B_{B_{M_0}} X_{M_0} - \hat{B}_{\text{min}} X \right) \right\|_F^2 > 9 \epsilon \right) + I \left( \left\| A_{M_0} M_0^{-1} \Sigma_{M_0}^{1/2} \right\|_F^2 > 2q(n - |M_0|) \right)$$

$$\leq I \left( \frac{1}{2} \left\| \hat{\Sigma}_{M_0}^{1/2} \left( B_{M_0} - \hat{B}_{M_0} \right) X_{M_0} \right\|_F^2 > \epsilon \right) + I \left( \frac{1}{2} \left\| \hat{\Sigma}_{M_0}^{1/2} \left( \hat{B}_{M_0} - B_{0_{M_0}} \right) X_{M_0} \right\|_F^2 > \epsilon \right)$$

$$+ I \left( \frac{1}{2} \left\| \hat{A}_{M_0} \left( B_{M_0} X_{M_0} - B_{\text{min}} X \right) \right\|_F^2 > \epsilon \right) + I \left( \left\| A_{M_0} M_0^{-1} \hat{\Sigma}_{M_0}^{1/2} \right\|_F^2 > 2q(n - |M_0|) \right) .$$

Taking expectation with respect to Fiducial distribution of $B_{M_0}$ given the data $Y$ we get,

$$I \left( \left\| A_{M_0} M_0^{-1} \left( B_{0_{M_0}} X_{M_0} - \hat{B}_{\text{min}} X \right) \right\|_F^2 > 36q \, (n - |M_0|) \epsilon \right)$$

$$\leq P \left( \frac{1}{2} \left\| \hat{\Sigma}_{M_0}^{1/2} \left( B_{M_0} - \hat{B}_{M_0} \right) X_{M_0} \right\|_F^2 > \epsilon \right) + I \left( \frac{1}{2} \left\| \hat{\Sigma}_{M_0}^{1/2} \left( \hat{B}_{M_0} - B_{0_{M_0}} \right) X_{M_0} \right\|_F^2 > \epsilon \right)$$

$$+ E \left( h_{\epsilon}(B_{M_0}) \right) + I \left( \left\| A_{M_0} M_0^{-1} \hat{\Sigma}_{M_0}^{1/2} \right\|_F^2 > 2q(n - |M_0|) \right) .$$

(18)

Next,

$$P_y \left( \left\{ I \left( \frac{1}{2} \left\| \hat{\Sigma}_{M_0}^{1/2} \left( B_{M_0} - B_{0_{M_0}} \right) X_{M_0} \right\|_F^2 > \epsilon \right) = 0 \right\} \cap \left\{ I \left( \left\| A_{M_0} M_0^{-1} \hat{\Sigma}_{M_0}^{1/2} \right\|_F^2 > 2q(n - |M_0|) \right) = 0 \right\} \right)$$

$$\geq P_y \left( \frac{1}{2} \left\| \hat{\Sigma}_{M_0}^{1/2} \left( B_{M_0} - B_{0_{M_0}} \right) X_{M_0} \right\|_F^2 \leq \epsilon \right) + P_y \left( \left\| A_{M_0} M_0^{-1} \hat{\Sigma}_{M_0}^{1/2} \right\|_F^2 \leq 2q(n - |M_0|) \right) - 1$$

$$\geq 1 - \exp \left( - \frac{\epsilon(n - |M_0|) \lambda_v}{4 \lambda_v} + \frac{q|M_0|}{2} \right) - 2 \exp \left( -c \left( \frac{\lambda_v}{2} \sqrt{n - |M_0|} - C \sqrt{q} \right)^2 \right)$$

$$- \exp (-0.15q(n - |M_0|)) ,$$

where the first probability is obtained by an application of Lemma A.2 and noticing that $\Delta_{M_0} = 0$ and the second probability is computed by the Chernoff bound for the $\chi^2$ distribution with $q(n - |M_0|)$ degrees of freedom evaluated at $1/4$. The proof is complete by applying Lemma A.1 to the first term in (18).}

**Proof of Theorem 4.10.** Let $j^* := \arg \min_j \| \hat{B}_{M,j} \|_2$, where $\hat{B}_{M,j}$ is the $j$th column of the least square coefficient matrix $\hat{B}_M$ for model $M$. Construct the model $M(-1) := M \setminus \{j^*\}$ with $|M| - 1$ covariates from model $M$. Suppose $\hat{B}_{M(-1)}$ be the least-squared estimator corresponding to the model $M(-1)$. Because $B_{\text{min}}$ minimizes the objective function corresponding to the $h$ function,

$$\frac{1}{2} \left\| \hat{\Sigma}_M^{1/2} \left( B_{M} X_{M} - B_{\text{min}} X \right) \right\|_F^2 \leq \frac{1}{2} \left\| \hat{\Sigma}_M^{1/2} \left( B_{M} X_{M} - E_y \left( \hat{B}_{M(-1)} \right) X_{M(-1)} \right) \right\|_F^2 .$$
By triangle inequality for the Frobenius norm,
\[
\mathbb{E}(h_\epsilon(B_M)) = \mathbb{P}\left( \frac{1}{2} \left\| \hat{\Sigma}_M^{-1/2} (B_M X_M - B_{\min} X) \right\|_F^2 \geq \epsilon \right)
\]
\[
\leq \mathbb{P}\left( \frac{1}{2} \left\| \hat{\Sigma}_M^{-1/2} (B_M X_M - \mathbb{E}_y (\hat{B}_M M(-1)) X_{M(-1)}) \right\|_F^2 \geq \epsilon \right)
\]
\[
\leq \mathbb{P}\left( \frac{1}{2} \left\| \hat{\Sigma}_M^{-1/2} (B_M X_M - \hat{B}_M X M) \right\|_F^2 \geq \frac{\epsilon}{9} \right) + \mathbb{P}\left( \frac{1}{2} \left\| \hat{\Sigma}_M^{-1/2} (\mathbb{E}_y [\hat{B}_M] X_M - \mathbb{E}_y (\hat{B}_M M(-1)) X_{M(-1)}) \right\|_F^2 \geq \frac{\epsilon}{9} \right)
\]
\[
+ \mathbb{P}\left( \frac{1}{2} \left\| \hat{\Sigma}_M^{-1/2} (\mathbb{E}_y [\hat{B}_M] X_M - \mathbb{E}_y \hat{B}_M X_M) \right\|_F^2 \geq \frac{\epsilon}{9} \right)
\]
\[
\leq \exp \left( -\frac{\epsilon (n - |M|)}{36} + q |M| \right) + 2 \exp \left( -\frac{\left( \sqrt{n - |M|} - 2\sqrt{q} \right)^2}{8} \right)
\]
\[
+ \mathbb{P}\left( \frac{1}{2} \left\| \hat{\Sigma}_M^{-1/2} (\mathbb{E}_y [\hat{B}_M] X_M - \mathbb{E}_y \hat{B}_M X_M) \right\|_F^2 \geq \frac{\epsilon}{9} \right)
\]
(19)
\[
+ \mathbb{P}\left( \frac{1}{2} \left\| \hat{\Sigma}_M^{-1/2} B_0^0 M, X_M (H_M - H_{M(-1)}) \right\|_F^2 \geq \frac{\epsilon}{9} \right)
\]
where the first probability is computed by Lemma A.1. Next,
\[
\mathbb{P}_y \left( \left\{ \left\| \hat{\Sigma}_M^{-1/2} (\mathbb{E}_y [\hat{B}_M] X_M) \right\|_F^2 < \frac{2\epsilon}{9} \right\} \cap \left\{ \left\| \hat{\Sigma}_M^{-1/2} B_0^0 M, X_M (H_M - H_{M(-1)}) \right\|_F^2 < \frac{2\epsilon}{9} \right\} \right)
\]
(20)
\[
\geq 1 - \mathbb{P}_y \left( \frac{1}{2} \left\| \hat{\Sigma}_M^{-1/2} (\mathbb{E}_y [\hat{B}_M] X_M) \right\|_F^2 \geq \frac{\epsilon}{9} \right) - \mathbb{P}_y \left( \frac{1}{2} \left\| \hat{\Sigma}_M^{-1/2} B_0^0 M, X_M (H_M - H_{M(-1)}) \right\|_F^2 \geq \frac{\epsilon}{9} \right).
\]
By Condition 4.9 and Corollary 4.5,
\[
\mathbb{P}_y \left( \frac{1}{2} \left\| \hat{\Sigma}_M^{-1/2} B_0^0 M, X_M (H_M - H_{M(-1)}) \right\|_F^2 \geq \frac{\epsilon}{9} \right)
\]
\[
\leq \mathbb{P}_y \left( \lambda_{\min} (\hat{\Sigma}_M) \leq \frac{9}{2\epsilon} \left\| B_0^0 M, X_M (H_M - H_{M(-1)}) \right\|_F^2 \right) \leq \mathbb{P}_y \left( \lambda_{\min} (\hat{\Sigma}_M) \leq \frac{\lambda_\nu (n - |M|)}{2} \right)
\]
(21)
\[
\leq 2e^{-c \left( \kappa (\lambda_\nu / 4) \sqrt{n - |M|} - C\sqrt{q} \right)^2} + \frac{8 \left\| B_0^0 M \right\| \sqrt{c^* \lambda_\nu}}{\sqrt{\pi \lambda_\nu} \sqrt{n - |M|}} \exp \left( -\frac{(\lambda_\nu / 16)^2 (n - |M|)}{c^* \left\| B_0^0 M \right\|^2 \lambda_\nu} \right) I(\Delta_M \neq 0).
\]
Bounding the first probability in equation (20) by Lemma A.2 and combining equation (19),(20), and (21),
\[
\mathbb{P}_y \left[ \mathbb{E}(h_\epsilon (B_M)) \geq \exp \left( -\frac{\epsilon (n - |M|)}{36} + q |M| \right) + 2 \exp \left( -\frac{1}{8} \left( \sqrt{n - |M|} - 2\sqrt{q} \right)^2 \right) \right] \leq V_{7,n,M}
\]
where
\[
V_{7,n,M} := \exp \left( -\frac{\epsilon (n - |M|) \lambda_\nu}{36 \lambda_\nu} + q |M| \right) + 4 \exp \left( -c \left( \kappa (\lambda_\nu / 4) \sqrt{n - |M|} - C\sqrt{q} \right)^2 \right).
\]
Finally,

\[ P_y \left( \bigcup_{M \notin \mathcal{M}_o} \left\{ Y : \mathbb{E}(h_x(B_M)) \geq \exp \left( -\frac{\epsilon (n - |M|)}{36} + \frac{q |M|}{2} \right) + 2 \exp \left( -\frac{1}{8} \left( \sqrt{n - |M|} - 2\sqrt{q} \right)^2 \right) \right\} \right) \]

\leq n^\alpha \sum_{j=1}^{n^\alpha} \exp \left( -\frac{\epsilon (n - j) \lambda_v}{36 \lambda_v} + \frac{q j}{2} + j \log p \right) + 4 \exp \left( -c \left( \frac{\lambda_v}{4} \sqrt{n - j} - C \sqrt{q} \right)^2 + j \log p \right)

\leq n^\alpha \left\{ \exp \left( -\frac{\epsilon (n - n^\alpha) \lambda_v}{36 \lambda_v} + \frac{q n^\alpha}{2} - n^\alpha \log p \right) + 4 \exp \left( -c \left( \frac{\lambda_v}{4} \sqrt{n - n^\alpha} - C \sqrt{q} \right)^2 + n^\alpha \log p \right) \right\}

\leq n^\alpha \left\{ \exp \left( -\frac{\epsilon (n - n^\alpha) \lambda_v}{36 \lambda_v} + \frac{q n^\alpha}{2} - n^\alpha \log p \right) + 4 \exp \left( -c \left( \frac{\lambda_v}{4} \sqrt{n - n^\alpha} - C \sqrt{q} \right)^2 + n^\alpha \log p \right) \right\}

\leq n^\alpha \left\{ \exp \left( -\frac{\epsilon (n - n^\alpha) \lambda_v}{36 \lambda_v} + \frac{q n^\alpha}{2} + n^\alpha \log p \right) + 4 \exp \left( -c \left( \frac{\lambda_v}{4} \sqrt{n - n^\alpha} - C \sqrt{q} \right)^2 + n^\alpha \log p \right) \right\}

This concludes the proof of the theorem. \( \square \)

**Proof of Lemma A.1.** Defining \( \hat{B}_M = \hat{\Sigma}_M^{-1/2} \left( B_M - \hat{B}_M \right) \) and \( \Omega_M = X_M X_M^T \), observe that,

\[
\left\| \hat{\Sigma}_M^{-1/2} \left( B_M X_M - \hat{B}_M X_M \right) \right\|^2_F = \left\| \hat{\Sigma}_M^{-1/2} \left( B_M - \hat{B}_M \right) X_M \right\|^2_F
\]

\[
= \text{tr} \left( \hat{B}_M X_M X_M^T \hat{B}_M^T \right) = \text{tr} \left( \hat{B}_M \Omega_M \hat{B}_M^T \right)
\]

\[
= \text{tr} \left( \hat{B}_M \Omega_M^{1/2} \Omega_M^{1/2} \hat{B}_M^T \right) = \left\| \hat{\Sigma}_M^{-1/2} \left( B_M - \hat{B}_M \right) \Omega_M^{1/2} \right\|^2_F.
\]

By the property of Matrix-t distribution, (see Theorem 4.3.5, page 137 of Gupta and Nagar (2018b)),

\[
\hat{\Sigma}_M^{-1/2} \left( B_M - \hat{B}_M \right) \Omega_M^{1/2} \sim T_{q,M} (n - |M| - q + 1, 0, I_q, I_{|M|}).
\]
Additionally, by Theorem 4.2.1 (page 134) of Gupta and Nagar (2018b),
\[
\tilde{\Sigma}_M^{-1/2} \left( B_M - \hat{B}_M \right) \Omega_M^{1/2} d = \left( W^{-1/2} \right) ^\top Z,
\]
where \( W \) follows \( \text{Wishart}(n - |M|, I_q) \) and \( Z \) follows Matrix-Normal \( (0, I_q, I_{|M|}) \). Then,
\[
\left\| \tilde{\Sigma}_M^{-1/2} \left( B_M X_M - \hat{B}_M X_M \right) \right\|_F^2 = \text{tr} \left( Z^\top W^{-1/2} W^{-1/2}^\top Z \right)
\leq \lambda_{\text{max}}(W) \text{tr}(Z Z^\top)
\leq \frac{1}{\lambda_{\text{min}}(W)} \text{tr}(Z Z^\top),
\]
Since, \( \text{tr}(Z Z^\top) \sim \chi^2_{q+|M|} \),
\[
\mathbb{P} \left( \frac{1}{2} \left\| \tilde{\Sigma}_M^{-1/2} \left( B_M X_M - \hat{B}_M X_M \right) \right\|_F^2 \geq \frac{\epsilon}{9} \right)
\leq \mathbb{P} \left( \frac{\text{tr}(Z Z^\top)}{\lambda_{\text{min}}(W)} \geq \frac{2\epsilon}{9} \right)
\leq \mathbb{P} \left( \frac{\text{tr}(Z Z^\top)}{\lambda_{\text{min}}(W)} \geq \frac{2\epsilon}{9}, \lambda_{\text{min}}(W) \geq \frac{(n - |M|)}{4} \right) + \mathbb{P} \left( \frac{\text{tr}(Z Z^\top)}{\lambda_{\text{min}}(W)} \geq \frac{2\epsilon}{9}, \lambda_{\text{min}}(W) < \frac{(n - |M|)}{4} \right)
\leq \mathbb{P} \left( \text{tr}(Z Z^\top) \geq \frac{\epsilon (n - |M|)}{18} \right) + \mathbb{P} \left( \lambda_{\text{min}}(W) < \frac{1}{4} (n - |M|) \right)
\leq \mathbb{P} \left( \chi^2_{q+|M|} \geq \frac{\epsilon (n - |M|)}{18} \right) + \mathbb{P} \left( \lambda_{\text{min}}(W) < \frac{1}{4} (n - |M|) \right)
\leq \exp \left( - \frac{\epsilon (n - |M|)}{72} + q |M| \right) + 2 \exp \left( - \frac{(\sqrt{n - |M|} - 2\sqrt{q})^2}{8} \right),
\]
where the first probability in the second to last line is obtained by using the Chernoff’s bound for \( \chi^2 \) distribution and and the second probability by substituting \( t = (1/2)\sqrt{n - |M| - \sqrt{q}} > 0 \) (by the condition on \( |M| \) in the statement of the lemma) in the corollary 5.35 (page 21) of Vershynin (2010) and noting that any central \( \text{Wishart}_q(n - |M|, I_q) \) matrix is identically distributed as \( \tilde{Z}^\top \tilde{Z} \) where \( \tilde{Z} \sim \text{Matrix-Normal}_{n-|M|, q} (0, I_{n-|M|}, I_q) \), provided \( n - |M| > q \) which is again true by the specified condition in the lemma. This completes the proof.

Proof of Lemma A.2. Defining, \( \Omega_M = X_M X_M^\top \), the quadratic form can be alternatively written as
\[
\left\| \tilde{\Sigma}_M^{-1/2} \left( \hat{B}_M X_M - \mathbb{E}_y \hat{B}_M \right) X_M \right\|_F^2
= \text{tr} \left[ \tilde{\Sigma}_M^{-1} \left( \hat{B}_M - \mathbb{E}_y \hat{B}_M \right) \Omega_M \left( \hat{B}_M - \mathbb{E}_y \hat{B}_M \right)^\top \right].
\]
\[ \leq \lambda_{\max}(\Sigma_M^{-1}) \text{tr} \left[ \left( \hat{B}_M - \mathbb{E}_y (\hat{B}_M) \right) \Omega_M^{1/2} \Omega_M^{1/2T} \left( \hat{B}_M - \mathbb{E}_y (\hat{B}_M) \right)^T \right] \]
\[ = \lambda_{\min}^{-1}(\Sigma_M) \left\| \left( \hat{B}_M - \mathbb{E}_y (\hat{B}_M) \right) \Omega_M^{1/2} \right\|_F^2 \]
\[ \leq \lambda_{\min}^{-1}(\Sigma_M) \lambda_v \left\| A_{M_0}^{-1} \left( \hat{B}_M - \mathbb{E}_y (\hat{B}_M) \right) \Omega_M^{1/2} \right\|_F^2. \]

By the sampling distribution of least-squared estimator \( \hat{B}_M \),
\[
(22) \quad A_{M_0}^{-1} \left( \hat{B}_M - \mathbb{E}_y (\hat{B}_M) \right) \Omega_M^{1/2} \sim \text{Matrix-Normal}_{\lambda_v | M} \left( 0, I_\lambda, I_{|M|} \right).
\]

This implies, \( \left\| A_{M_0}^{-1} \left( \hat{B}_M - \mathbb{E}_y (\hat{B}_M) \right) \Omega_M^{1/2} \right\|_F^2 \sim \lambda_v^2 \). Choosing \( \alpha_1 = \alpha_2 = 1/4 \) in Corollary 4.5,
\[
P_y \left( \lambda_{\min}(\Sigma_M) < \lambda_v (n - |M|)/2 \right) \leq 2 e^{-c \left( \kappa(\lambda_v/4) \sqrt{n - |M|} - C \sqrt{\lambda_v} \right)^2}
+ 8 \left\| B_{M_0}^0 \right\| \sqrt{c^* \lambda_v} \exp \left( - (\lambda_v/16)^2 (n - |M|) \right)
+ \sqrt{\pi \lambda_v} \sqrt{n - |M|} c^* \left\| B_{M_0}^0 \right\|^2 \lambda_v \right).
\]

Finally,
\[
P_y \left( \frac{1}{2} \left\| A_{M_0}^{-1} \left[ \hat{B}_M - \mathbb{E}(\hat{B}_M) \right] X_M \right\|_F^2 \geq \frac{\epsilon}{9} \right)
\leq P_y \left( \lambda_{\min}(\Sigma_M) > \frac{2 \epsilon}{9} \right)
\leq P_y \left( \frac{\lambda_v \lambda_{\min}(\Sigma_M)}{\lambda_{\min}(\Sigma_M)} \geq \frac{2 \epsilon}{9} \right)
\leq P_y \left( \frac{\lambda_v \lambda_{\min}(\Sigma_M)}{\lambda_{\min}(\Sigma_M)} \geq \frac{2 \epsilon}{9}, \lambda_{\min}(\Sigma_M) > \frac{\lambda_v (n - |M|)}{2} \right)
+ P_y \left( \lambda_{\min}(\Sigma_M) \leq \frac{\lambda_v (n - |M|)}{2} \right)
\leq P_y \left( \lambda_{\min}(\Sigma_M) \leq \frac{\epsilon (n - |M|)}{9 \lambda_v} \right)
+ P_y \left( \lambda_{\min}(\Sigma_M) \leq \frac{\lambda_v (n - |M|)}{2} \right)
\leq \exp \left( - \frac{\epsilon (n - |M|)}{36 \lambda_v} + \frac{q |M|}{2} \right)
+ 2 \exp \left( - c \left( \kappa(\lambda_v/4) \sqrt{n - |M|} - C \sqrt{\lambda_v} \right)^2 \right)
+ \frac{8 \left\| B_{M_0}^0 \right\| \sqrt{c^* \lambda_v}}{\sqrt{\pi \lambda_v} \sqrt{n - |M|}} \exp \left( - \frac{(\lambda_v/16)^2 (n - |M|)}{c^* \left\| B_{M_0}^0 \right\|^2 \lambda_v} \right),
\]

where the first quantity in the last line is obtained by Chernoff’s bound for chi-square distribution. This completes the proof of Lemma A.2.

**Generalized fiducial distribution for multivariate linear regression.** The data generating equation corresponding to \( i \)-th data, \( Y_i \) is,
\[ G_i := G(\boldsymbol{B}_M, A_M, U_i) = \boldsymbol{B}_M X_{M,i} + A_M U_i \quad i = 1, 2, \ldots, n, \]
where, $X_{M,i}$ is the $i$th column of the matrix $X_M$. Then,

$$\frac{\partial G_i}{\partial B_M} = \left[ \frac{\partial (B_M X_{M,i})}{\partial b_1}, \ldots, \frac{\partial (B_M X_{M,i})}{\partial b_q} \right]$$

$$= \left[ J^{11} X_{M,i} \cdots J^{1|M|} X_{M,i} \cdots J^{q|M|} X_{M,i} \right] = I_q \otimes X_{M,i}^T \in \mathbb{R}^{q \times |M|},$$

where $J^{kl} \in \mathbb{R}^{|M| \times |M|}$ is a sparse matrix of which $(k, l)$th element is 1 and all others are zero. Similarly, $\frac{\partial G_i}{\partial A_M} = I_q \otimes U_i^T \in \mathbb{R}^{q \times q^2}$. So the matrix of derivatives corresponding to the $i$-th data generating equation is,

$$D_{M,i} = \left[ \frac{\partial G_i}{\partial B_M}, \frac{\partial G_i}{\partial A_M} \right] = \left[ I_q \otimes X_{M,i}^T, I_q \otimes U_i^T \right] \in \mathbb{R}^{q \times q^2}.$$

The entire matrix of derivatives corresponding to all observations is,

$$D_M = \begin{bmatrix} I_q \otimes X_{M,1}^T & I_q \otimes U_1^T & \vdots & \vdots & \vdots \\
I_q \otimes X_{M,n}^T & I_q \otimes U_n^T \end{bmatrix}$$

which is almost surely of full column rank if $n > |M| + q$. Now, define, $P_M := [I_q \otimes X_M^T, I_q \otimes U^T]$, and evaluate the derivatives at $U = A_M^{-1} (Y - B_M X_M) = A_M^{-1} \tilde{U}$ with $\tilde{U} = Y - B_M X_M \in \mathbb{R}^{q \times n}$. Because $P_M$ is obtained rearranging rows of $D_M$, we can write,

$$D_M^T D_M = P_M^T P_M$$

$$= \begin{bmatrix} I_q \otimes X_M^T, I_q \otimes U^T \end{bmatrix} [I_q \otimes X_{M,1}^T & I_q \otimes U_1^T & \vdots & \vdots & \vdots \\
I_q \otimes X_{M,n}^T & I_q \otimes U_n^T \end{bmatrix}$$

$$= \begin{bmatrix} I_q \otimes X_M X_M^T & I_q \otimes X_M U^T \\
I_q \otimes U X_M & I_q \otimes U U^T \end{bmatrix}$$

$$= \begin{bmatrix} I_q \otimes \left( X_M \tilde{U}^T A_M^{-1} \right) \\
I_q \otimes \left( A_M^{-1} \tilde{U} X_M^T \right) \end{bmatrix}$$

$$= \begin{bmatrix} I_q \otimes I_{|M|} & 0 \\
0 & I_q \otimes A_M^{-1} \end{bmatrix} \begin{bmatrix} I_q \otimes X_M X_M^T & I_q \otimes X_M U^T \\
I_q \otimes \tilde{U} X_M & I_q \otimes \tilde{U} U^T \end{bmatrix} \begin{bmatrix} I_q \otimes I_{|M|} & 0 \\
0 & I_q \otimes A_M^{-1} \end{bmatrix}.$$

Then,

$$\det D_M^T D_M = \left( \det A_M A_M^T \right)^{-q} \det \begin{bmatrix} I_q \otimes X_M X_M^T & I_q \otimes X_M U^T \\
I_q \otimes \tilde{U} X_M & I_q \otimes \tilde{U} U^T \end{bmatrix}.$$

After row and column operations,

$$\det \begin{bmatrix} I_q \otimes X_M X_M^T & I_q \otimes X_M U^T \\
I_q \otimes \tilde{U} X_M & I_q \otimes \tilde{U} U^T \end{bmatrix} = \det \left\{ I_q \otimes \begin{bmatrix} X_M X_M^T & X_M \tilde{U} U^T \end{bmatrix} \right\} = \left( \det \begin{bmatrix} X_M X_M^T & X_M \tilde{U} U^T \end{bmatrix} \right)^q.$$
Further, by property of determinant of block matrices,
\[
\det \begin{bmatrix}
X_M X_M^T & X_M \bar{U}^T \\
\bar{U} X_M^T & \bar{U} \bar{U}^T
\end{bmatrix} = \left( \det X_M X_M^T \right) \det \left[ \bar{U} \bar{U}^T - \bar{U} X_M \left( X_M X_M^T \right)^{-1} X_M \bar{U}^T \right].
\]

Analogous to univariate linear regression,
\[
Y - \hat{B}_M X_M = Y - Y X_M^T \left( X_M X_M^T \right)^{-1} X_M = Y - Y H_M = Y (I - H_M),
\]
and,
\[
\bar{U} \bar{U}^T - \bar{U} X_M \left( X_M X_M^T \right)^{-1} X_M \bar{U}^T \\
= \bar{U} [I - H_M] \bar{U}^T \\
= \left( Y - \hat{B}_M X_M + \hat{B}_M X_M - B_M X_M \right) [I - H_M] \left( Y - \hat{B}_M X_M + \hat{B}_M X_M - B_M X_M \right)^T \\
= \left( Y - \hat{B}_M X_M \right) [I - H_M] \left( Y - \hat{B}_M X_M \right)^T \\
= Y (I - H_M) [I - H_M]^T Y^T \\
= \left( Y - \hat{B}_M X_M \right) \left( Y - \hat{B}_M X_M \right)^T \\
= \hat{\Sigma}_M.
\]

The Jacobian is obtained as
\[
J(Y, (B_M, A_M)) := \sqrt{\det \Omega_M} = (\det \Omega_M)^{1/2} \left( \det \hat{\Sigma}_M \right)^{1/2} = C_M \left( \det \Omega_M \right)^{1/2}
\]
where \(C_M := (\det \Omega_M)^{1/2} \left( \det \hat{\Sigma}_M \right)^{1/2}\). The likelihood function of \(Y|B_M, \Omega_M\) is,
\[
f(Y, (B_M, A_M)) \propto (\det \Omega_M)^{-p/2} \exp \left[ -\frac{1}{2} \text{tr} \left( R_M \Omega_M^{-1} \right) \right],
\]
where,
\[
R_M = \left( Y - B_M X_M \right) \left( Y - B_M X_M \right)^T \\
= \left( Y - \hat{B}_M X_M + \hat{B}_M X_M - B_M X_M \right) \left( Y - \hat{B}_M X_M + \hat{B}_M X_M - B_M X_M \right)^T \\
= \left( Y - \hat{B}_M X_M \right) \left( Y - \hat{B}_M X_M \right)^T + \left( B_M X_M - \hat{B}_M X_M \right) \left( B_M X_M - \hat{B}_M X_M \right)^T \\
[\text{because } \left( Y - \hat{B}_M X_M \right) X_M^T \Omega_M^{-1} = 0] \\
= \hat{\Sigma}_M + \left( B_M - \hat{B}_M \right) X_M X_M^T \left( B_M - \hat{B}_M \right)^T.
\]

Under the matrix change of variables \(V_M = A_M A_M^T\), we use Theorem 1.4.10 of Gupta and Nagar, 2018b, to derive the marginal GF distribution of model \(M\) as,
\[
r_\ast(M|Y) \propto \int_{B_M \in \mathbb{R}^{p \times q}} \int_{A_M \in \mathbb{R}^{q \times q}} f(Y, (B_M, A_M)) J(Y, (B_M, A_M)) h_\ast(B_M) d(A_M, B_M)
\]
\[ \propto C_M \int_{B_M \in \mathbb{R}^{q \times |M|}} \int_{A_M \in \mathbb{R}^{q \times q}} (\det V_M)^{-\frac{a+n}{2}} \exp \left[ -\frac{1}{2} \text{tr} \left( R_M V_M^{-1} \right) \right] h_\epsilon(B_M) dA_M dB_M \]

\[ \propto C_M \int_{\mathbb{R}^{q \times |M|}} \int_{V_M > 0} (\det V_M)^{-\frac{a+n+1}{2}} \exp \left[ -\frac{1}{2} \text{tr} \left( R_M V_M^{-1} \right) \right] h_\epsilon(B_M) dV_M dB_M \]

\[ \propto C_M \int_{\mathbb{R}^{q \times |M|}} [\det R_M]^{-\frac{n}{2}} h_\epsilon(B_M) dB_M \quad \text{(w.r.t inverse-wishart kernel)} \]

\[ = C_M \int_{\mathbb{R}^{q \times |M|}} \left( \det \left[ \hat{\Sigma}_M + (B_M - \hat{B}_M) \Omega_M (B_M - \hat{B}_M)^\top \right] \right)^{-\frac{n}{2}} h_\epsilon(B_M) dB_M \]

\[ = C_M \int_{\mathbb{R}^{q \times |M|}} \left( \det \left[ \Omega_M^{-1} + (B_M - \hat{B}_M)^\top \hat{\Sigma}_M^{-1} (B_M - \hat{B}_M) \right] \det \left[ \Omega_M \hat{\Sigma}_M \right] \right)^{-\frac{n}{2}} h_\epsilon(B_M) dB_M \]

\[ = C_M \int_{\mathbb{R}^{q \times |M|}} \left( \det \left[ I_M + \Omega_M (B_M - \hat{B}_M)^\top \hat{\Sigma}_M^{-1} (B_M - \hat{B}_M) \right] \right)^{-\frac{n}{2}} \det \left[ \hat{\Sigma}_M \right]^{-\frac{n}{2}} h_\epsilon(B_M) dB_M \]

\[ \propto C_M \int_{\mathbb{R}^{q \times |M|}} \left( \det \left[ I_M + \Omega_M (B_M - \hat{B}_M)^\top \hat{\Sigma}_M^{-1} (B_M - \hat{B}_M) \right] \right)^{-\frac{n}{2}} \det \left[ \hat{\Sigma}_M \right]^{-\frac{n}{2}} h_\epsilon(B_M) dB_M \]

\[ \propto \Gamma_q \left( \frac{n - |M|}{2} \right) \pi^{-\frac{|M|}{2}} (\det \hat{\Sigma}_M)^{-\left( \frac{n - |M| - q}{2} \right)} \mathbb{E} (h_\epsilon(B_M)) \quad \text{(w.r.t matrix-t kernel)} \]
