On facets of the Newton polytope for the discriminant of the polynomial system

Irina Antipova, Ekaterina Kleshkova

Abstract

We study normal directions to facets of the Newton polytope of the discriminant of the Laurent polynomial system via the tropical approach. We use the combinatorial construction proposed by Dickenstein, Feichtner and Sturmfels for the tropicalization of algebraic varieties admitting a parametrization by a linear map followed by a monomial map.

Keywords: discriminant, Newton polytope, tropical variety, Bergman fan, matroid.

2020 Mathematical Subject Classification: 14M25, 14T15, 32S25.

1 Introduction

Consider a system of \(n\) polynomial equations of the form

\[
P_i := \sum_{\lambda \in A^{(i)}} a^{(i)}_{\lambda} y^{\lambda} = 0, \quad i = 1, \ldots, n
\]

with unknowns \(y = (y_1, \ldots, y_n) \in (\mathbb{C} \setminus 0)^n\), variable complex coefficients \(a = (a^{(i)}_{\lambda})\), where the sets \(A^{(i)} \subseteq \mathbb{Z}^n\) are fixed, finite and contain the zero element \(\overline{0}\), \(\lambda = (\lambda_1, \ldots, \lambda_n)\), \(y^{\lambda} = y_1^{\lambda_1} \cdot \cdots \cdot y_n^{\lambda_n}\). Solution \(y(a) = (y_1(a), \ldots, y_n(a))\) of (1) has a polyhomogeneity property, and thus the system usually can be written in a homogenized form by means of monomial transformations \(x = x(a)\) of coefficients (see [1]). To do this, it is necessary to distinguish a collection of \(n\) exponents \(\omega^{(i)} \in A^{(i)}\) such that the matrix \(\omega = (\omega^{(i)}_1, \ldots, \omega^{(i)}_n)\) is non-degenerated. As a result, we obtain a reduced system of the form

\[
Q_i := y^{\omega^{(i)}} + \sum_{\lambda \in A^{(i)}} x^{(i)}_{\lambda} y^{\lambda} - 1 = 0, \quad i = 1, \ldots, n,
\]

where \(\Lambda^{(i)} := A^{(i)} \setminus \{\omega^{(i)}, \overline{0}\}\) and \(x = (x^{(i)}_{\lambda})\) are variable complex coefficients. Denote by \(\Lambda\) the disjoint union of the sets \(\Lambda^{(i)}\) and by \(N\) the cardinality of this union, that is the number of variable coefficients in the system (2). The coefficients of the system vary in the vector space \(\mathbb{C}^N\) in which points \(x = (x_{\lambda})\) are indexed by elements \(\lambda \in \Lambda\).

Denote by $\nabla^o$ the set of all coefficients $x = \left( x^{(i)} \right)$ such that the polynomial mapping $Q = (Q_1, \ldots, Q_n)$ has multiple zeroes in the complex algebraic torus $(\mathbb{C} \setminus 0)^n$, that is zeroes for which the determinant of the Jacobi matrix $\frac{\partial Q}{\partial y}$ of the mapping $Q$ equals zero. The discriminant set $\nabla$ of the system (2) is defined to be the closure of the set $\nabla^o$ in the space of coefficients. If $\nabla$ is a hypersurface, then the polynomial $\Delta(x)$ that defines it is said to be the discriminant of the system (2). The set $\nabla$ is also called the reduced discriminant set of the system (1). According to the theory of $A$–discriminants developed in the book [8], the discriminant of a system of equations is appropriate to call the $(A^{(1)}, \ldots, A^{(n)})$–discriminant.

The goal of our research is to construct the tropicalization of the discriminant set $\nabla$ of the system (2) and to find normal vectors to facets of the Newton polytope of the discriminant $\Delta(x)$. Recall that the Newton polytope $N_\Delta$ of the polynomial $\Delta(x)$ is defined to be the convex hull of its support in $\mathbb{R}^n$.

The idea of computing the tropical discriminant is adopted from the paper [5], where the general combinatorial construction of the tropicalization is given for algebraic varieties that admit a parametrization in the form of the product of linear forms. We use the parametrization of the discriminant set for the system of $n$ Laurent polynomials (2) proposed and comprehensively studied in [1].

We write the set $\Lambda$ in the form of the block matrix $\Lambda = (\Lambda^{(1)} \mid \ldots \mid \Lambda^{(n)})$ whose columns are the vectors of exponents of monomials of the system. Introduce $(n \times N)$–matrices

$$\Psi := \omega^* \Lambda, \quad \tilde{\Psi} := \Psi - |\omega| \chi,$$

where $\omega^*$ is the adjoint matrix to the matrix $\omega$, $\chi$ is the matrix whose $i$-th row represents the characteristic function of the subset $\Lambda^{(i)} \subset \Lambda$ and $|\omega|$ is the determinant of the matrix $\omega$. In what follows, we denote the rows of the matrices $\Psi$ and $\tilde{\Psi}$ by $\psi_1, \ldots, \psi_n$ and $\tilde{\psi}_1, \ldots, \tilde{\psi}_n$ correspondingly, and we denote the rows of the identity matrix $E_N$ by $e_1, \ldots, e_N$. One of the main results of this paper is

**Theorem 1.** The vectors

$$e_1, \ldots, e_N, -\psi_1, \ldots, -\psi_n, \tilde{\psi}_1, \ldots, \tilde{\psi}_n \in \mathbb{Z}^N$$

define the normal directions of facets of the Newton polytope of the discriminant for the system (2).

The discriminant of the system of polynomials studied in the current paper is the generalization of the notion of $A$–discriminant [8]. In [9], Kapranov proved that $A$–discriminants characterize hypersurfaces with the birational logarithmic Gauss mapping, and that reduced discriminant hypersurfaces admit the parametrization by monomials depending on linear forms, which is called the Horn-Kapranov uniformization. The tropical analogue of the Horn-Kapranov uniformization was obtained in [5].

In the present research, we use the parametrization of the discriminant set that occurs to be the inverse of the logarithmic Gauss mapping in the case when the set $\nabla$ is an irreducible hypersurface that depends on all groups of the variable coefficients of the system (see [1]). However, the logarithmic Gauss mapping for the studied hypersurface $\nabla$ is not always birational, thus, in general, $(A^{(1)}, \ldots, A^{(n)})$–discriminants are not reduced to $A$–discriminants, and consequently require special research.

It is important to note that Theorem 1 does not give all normal directions to facets of the Newton polytope but only those that are represented in the parametrization of the discriminant set $\nabla$ explicitly as vectors of coefficients in linear forms. Properties of the parametrization are described in Section 2 of the paper. Further, the construction of the
tropical variety and the proof of Theorem 1 are given in Section 3. In final Section 4, we explain how the constructed tropical variety brings out the so-called «hidden» facets of the Newton polytope for the discriminant of the system.

2 Parametrization of the discriminant set \( \nabla \)

We introduce two copies of the space \( \mathbb{C}^N \): one copy \( \mathbb{C}_x^N \) with coordinates \( x = (x_\lambda) \), and another copy \( \mathbb{C}_s^N \) with coordinates \( s = (s_\lambda) \). In both cases, coordinates of points are indexed by elements \( \lambda \in \Lambda \). The space \( \mathbb{C}_x^N \) is considered as the space of homogeneous co-ordinates for \( \mathbb{CP}^N \). It is proved in [1] that the parametrization of the discriminant set \( \nabla \) of the system \( [2] \) is determined by the multivalued algebraic mapping from the projective space \( \mathbb{CP}^N \) into the space \( \mathbb{C}_x^N \) of the coefficients of the system with components

\[
x^{(i)}_\lambda = -s_\lambda \prod_{k=1}^n \left( \frac{\langle \tilde{\varphi}_k, s \rangle}{\langle \varphi_k, s \rangle} \right)^{\psi_{k\lambda}}, \quad \lambda \in \Lambda^{(i)}, \quad i = 1, \ldots, n,
\]

where \( \varphi_k \) and \( \tilde{\varphi}_k \) are rows of matrices \( \Phi := \omega^{-1} \Lambda \) and \( \tilde{\Phi} := \Phi - \chi \) correspondingly, \( \varphi_{k\lambda} \) is a coordinate of the row \( \varphi_k \) indexed by \( \lambda \in \Lambda^{(i)} \subset \Lambda \), the angle brackets denote the inner product. The number of branches in \( [4] \) equals to the absolute value of the determinant \( |\omega| \) but some branches may coincide. If the discriminant set \( \nabla \) of the system \( [2] \) is an irreducible hypersurface that depends on all groups of variables, then the mapping \( [4] \) parametrizes it with the multiplicity that is equal to the index \( |\mathbb{Z}^n : H| \) of the sublattice \( H \subset \mathbb{Z}^n \) generated by columns of the matrix \( (\omega|\Lambda) \), i.e., by all exponents of the monomials from the system \( [2] \). The image of the mapping \( [4] \) is a hypersurface if all coordinates of vectors \( \varphi_k, \tilde{\varphi}_k \) are non-zero, \( k = 1, \ldots, n \).

We consider the rational mapping \( \mathbb{CP}^N \rightarrow \mathbb{C}_w^N \) that is obtained from the mapping \( [4] \) as a result of raising of all its coordinates to the power \( |\omega| \). It has components

\[
w^{(i)}_\lambda = \left( -\frac{|\omega| s_\lambda}{\langle \varphi_1, s \rangle} \right)^{|\omega|} \prod_{k=1}^n \left( \frac{\langle \psi_k, s \rangle}{\langle \tilde{\psi}_k, s \rangle} \right)^{\psi_{k\lambda}},
\]

where \( \psi_{k\lambda} \) is a coordinate of the row \( \psi_k \) indexed by \( \lambda \in \Lambda^{(i)} \subset \Lambda \). The mapping \( [5] \) defines the hypersurface \( \nabla \subset \mathbb{C}_w^N \) whose amoeba has the same asymptotic directions as the amoeba of the discriminant hypersurface \( \nabla \). Recall that the amoeba \( A_\nabla \) of the algebraic hypersurface

\[
\nabla = \{ x \in (\mathbb{C} \setminus 0)^N : \Delta(x) = 0 \}
\]

is the image of \( \nabla \) by the mapping \( \text{Log} : (\mathbb{C} \setminus 0)^N \rightarrow \mathbb{R}^N \) defined by means of the formula

\[
\text{Log} : (x_1, \ldots, x_N) \rightarrow (\log |x_1|, \ldots, \log |x_N|).
\]

Each component of the mapping \( [5] \) is a monomial with integer exponents composed with linear functions. It is convenient to associate the mapping \( [5] \) with the pair of two block matrices

\[
U = \left( -|\omega| E_N |\Psi^T| \tilde{\Psi}^T \right)^T, \quad V = \left( |\omega| E_N |\Psi^T| \tilde{\Psi}^T \right),
\]

where \( E_N \) is the identity matrix. The rows of the matrix \( U \) determine linear functions, and the rows of \( V \) determine exponents of monomials in the parametrization \( [5] \).
3 Tropicalization of the rational variety

Further, we pay attention to the algebraic variety ˜∇ ⊂ C^N. Let us study its tropicalization τ(˜∇). According to need, we recall notions and facts from the tropical geometry. Elements of this theory and numerous references to fundamental research can be found in the book [10]. Since the variety ˜∇ admits the parametrization (5) in the form of the product of linear forms, we implement the general combinatorial construction proposed in [5] in order to compute the tropical variety τ(˜∇).

A tropical variety has the structure of a polyhedral fan. In particular, the tropicalization of a linear subspace X ⊂ C^k is the Bergman fan of the matroid M(X) associated with this subspace (see [2], [7]). The construction of the Bergman fan of a variety X is related to the notion of the logarithmic limit-set of the variety X introduced in [3]. The Bergman fan of an irreducible subvariety X ⊂ C^k is the finite union of convex polyhedral cones with the vertex at the origin of the dimension that coincides with the dimension of the variety [4].

Let us dwell in more detail on the concept of a matroid, which covers the general combinatorial essence of the concepts of independence in linear algebra, graph theory, etc. There exist several different equivalent systems of axioms that define matroid (see, for instance, [2], [10], [12]). Let us determine matroid in terms of independent sets.

Definition 1. The matroid M is defined to be a pair (E, I) that consists of a finite set E and a collection I of subsets of E such that

(I-1) ∅ ∈ I.

(I-2) If J ∈ I and I ⊆ J, then I ∈ I.

(I-3) If I, J ∈ I and |I| < |J|, then there exists j ∈ J − I such that I ∪ j ∈ I.

Elements of I are called independent sets.

It is supposed that all one-element subsets of E are independent. Maximal independent sets are called bases of a matroid. From the axiom (I-3), it follows that all bases of a matroid M have the same cardinality r = r(M) that is called the rank of the matroid. If A is a subset of the set E, then the cardinality of maximal independent set in A is called the rank of A, and it is denoted by r(A). The minimal by inclusion dependent set C ⊂ E is said to be the cycle of the matroid M. A subset F ⊆ E is said to be the flat if r(F ∪ e) > r(F) for all e /∈ F. We say F is proper if its rank equals neither 0 nor r. Every flat F of the matroid M is represented by the incidence vector

\[ e_F := \sum_{i \in F} e_i. \]

The vector e_F is considered as an element of the tropical projective space \( \mathbb{R}^{|E|}/\mathbb{R}1 \), where 1 = (1, 1, …, 1). The partially ordered set of all flats forms the lattice of flats of the matroid.

The Bergman fan is one of geometric models of matroids. We use the first statement of Theorem 2 as the definition of the Bergman fan of the matroid M.

Theorem 2 (Ardila–Klivans [2]).

(1) The Bergman fan \( \mathcal{B}_M \) of a matroid M on E is the polyhedral complex in \( \mathbb{R}^{|E|}/\mathbb{R}1 \) that consists of the cones

\[ \sigma_F = \text{cone}\{e_F : F \in \mathcal{F}\} \]

for each flag \( \mathcal{F} = \{F_1 \subset \ldots \subset F_l\} \) of proper flats of M. Here, \( e_F := e_{f_1} + \ldots + e_{f_k} \) for \( F = \{f_1, \ldots, f_k\} \).
(2) The tropicalization of a linear subspace $X$ is the Bergman fan $\mathfrak{B}_{M(X)}$ of the matroid $M(X)$ related to the subspace $X$.

Proof of Theorem 1. We first find the tropicalization $\tau(\tilde{\nabla})$ of the hypersurface $\tilde{\nabla}$. Note that the tropicalization of an irreducible hypersurface is the union of all cones of codimension 1 of the normal fan for the Newton polytope of the polynomial defining the hypersurface. Moreover, the collection of one-dimensional generators of the normal fan for the Newton polytope of the polynomial defining $\tilde{\nabla}$ coincides with the same collection for the polynomial defining the discriminant hypersurface $\nabla$.

Let $X$ be a linear subspace in $\mathbb{C}^{N+2n}$, and let it be the image of the linear mapping $s \to Us$ defined by the matrix $U$, where $s \in \mathbb{C}P^{N-1}$. Let us consider the matroid $M(X)$ on the set of rows of the matrix $U$ (on the set $E = \{1, 2, \ldots, N + 2n\}$). By Theorem 2, the Bergman fan $\mathfrak{B}_{M(X)}$ of the matroid $M(X)$ is the tropicalization of the subspace $X$. The following lemma holds.

Lemma 1. The tropical variety $\tau(\tilde{\nabla})$ is the image of the Bergman fan $\mathfrak{B}_{M(X)}$ under the mapping $\mathbb{R}^{N+2n} \to \mathbb{R}^N$ given by the matrix $V$.

Proof of Lemma 1. Coordinates of the parametrization of the variety $\tilde{\nabla}$ given by (5) are monomials composed with linear forms. The linear forms are defined by the rows of the matrix $U$ that is associated with the matroid $M(X)$ of the rank $N$ on the set $E$. Exponents of the monomials in parametrization are rows of the matrix $V$. According to [5, Theorem 3.1], the tropicalization of the variety $\tilde{\nabla}$ can be defined in terms of the matrices $U$ and $V$. More precisely, the tropicalization is the image of the Bergman fan $\mathfrak{B}_{M(X)}$ under the linear mapping $V$. 

It follows from Lemma 1 that one-dimensional cones (rays) of the tropical variety $\tau(\tilde{\nabla})$ are generated by the columns of the matrix $V$. They do determine the normal directions for the facets of the Newton polytope for the discriminant of the system. Thus Theorem 1 is proved.

It is important to note that the acquired information about the structure of the normal fan of the Newton polytope for the discriminant, as well as the parametrization (4), can be used for the study of truncations of the discriminant $\Delta(x)$ of the system (2). The truncation of the polynomial $\Delta(x)$ with respect to a face $h$ of the Newton polytope $N_\Delta$ is defined to be the sum of all monomials of $\Delta(x)$ whose exponents lie in the face $h$. The geometric proof of factorization identities for truncations of the classical discriminant with respect to hyperfacets of its Newton polytope was given in the recent paper [11]. The proof is based on the blow-up property of the logarithmic Gauss map for the zero set of the discriminant. These identities were proved earlier in the book [8, Chapter 10] using the complicated machinery of the theory of $A$–determinants.

4 «Hidden» normal directions

Consider the system of two equations with two unknowns $y_1, y_2$ and three variable coefficients $x_1, x_2, x_3$:

$$
\begin{align*}
y_1^2 + x_1 y_1 y_2 + x_2 y_1 y_2^2 - 1 &= 0, \\
y_2^2 + x_3 y_1^2 y_2 - 1 &= 0.
\end{align*}
$$

(7)

The matrix of exponents of the system (7) has the form

$$
(\omega|\Lambda) = \begin{pmatrix} 2 & 0 & 1 & 1 & 2 \\
0 & 2 & 1 & 2 & 1 \end{pmatrix}.
$$
The index of the sublattice in $\mathbb{Z}^2$ generated by its columns equals 1. It is the greatest common divisor of all second order minors of the matrix. Moreover, the matrices

$$\Phi = \begin{pmatrix} 1/2 & 1/2 & 1 \\ 1/2 & 1 & 1/2 \end{pmatrix}, \quad \tilde{\Phi} = \begin{pmatrix} -1/2 & -1/2 & 1 \\ 1 & 1/2 & -1/2 \end{pmatrix}$$

do not contain zero elements, so the discriminant set $\nabla$ of the system (7) is the hypersurface, which can be parametrized with the multiplicity 1 by the mapping $\mathbb{C}P^2_s \to \mathbb{C}^3_x$ of the form

$$x_1 = -\frac{2s_1}{-s_1 - s_2 + 2s_3} \left( \frac{-s_1 - s_2 + 2s_3}{s_1 + s_2 + 2s_3} \right)^{\frac{1}{2}} \left( \frac{s_1 + 2s_2 - s_3}{s_1 + 2s_2 + s_3} \right)^{\frac{1}{2}},$$

$$x_2 = -\frac{2s_2}{-s_1 - s_2 + 2s_3} \left( \frac{-s_1 - s_2 + 2s_3}{s_1 + s_2 + 2s_3} \right)^{\frac{1}{2}} \left( \frac{s_1 + 2s_2 - s_3}{s_1 + 2s_2 + s_3} \right)^{\frac{1}{2}},$$

$$x_3 = -\frac{2s_3}{s_1 + 2s_2 - s_3} \left( \frac{-s_1 - s_2 + 2s_3}{s_1 + s_2 + 2s_3} \right)^{\frac{1}{2}} \left( \frac{s_1 + 2s_2 - s_3}{s_1 + 2s_2 + s_3} \right)^{\frac{1}{2}}.$$  \hspace{1cm} (8)

Here $s = (s_1, s_2, s_3) \in \mathbb{C}^3$ are the homogeneous coordinates in $\mathbb{C}P^2_s$.

Let us study the tropicalization $\tau(\nabla)$ of the rational variety $\nabla \subset \mathbb{C}P^2_w$ given as follows

$$w_1 = (-4s_1)^4(2s_1 + 2s_2 + 4s_3)^{-2}(2s_1 + 4s_2 + 2s_3)^{-2}(-2s_1 - 2s_2 + 4s_3)^{-2}(2s_1 + 4s_2 - 2s_3)^2,$$

$$w_2 = (-4s_2)^4(2s_1 + 2s_2 + 4s_3)^{-2}(2s_1 + 4s_2 + 2s_3)^{-4}(-2s_1 - 2s_2 + 4s_3)^{-2}(2s_1 + 4s_2 - 2s_3)^4,$$

$$w_3 = (-4s_3)^4(2s_1 + 2s_2 + 4s_3)^{-4}(2s_1 + 4s_2 + 2s_3)^{-2}(-2s_1 - 2s_2 + 4s_3)^{-2}(2s_1 + 4s_2 - 2s_3)^{-2}. \hspace{1cm} (9)$$

As we noted above, the mapping (9) is associated with the matrices

$$U = \begin{pmatrix} -4 & 0 & 0 \\ 0 & -4 & 0 \\ 2 & 2 & -4 \end{pmatrix} \quad \text{and} \quad V = \begin{pmatrix} 4 & 0 & 0 & -2 & -2 & 2 \\ 0 & 4 & 0 & -2 & -4 & -2 \\ 2 & 4 & 2 & -4 & -2 & 0 \end{pmatrix},$$

that play a crucial role in constructing of the tropical variety $\tau(\nabla) \subset \mathbb{R}^3$. Consider the matroid $M$ on the set $\mathcal{E} = \{1, 2, 3, 4, 5, 6, 7\}$ of rows of the matrix $U$. The tropical linear space that is associated with the matroid $M$ is the Bergman fan $\mathfrak{B}_M$. It is a two-dimensional fan in $\mathbb{R}^7/\mathbb{R}^1$ or a graph depicted in Fig. 1.

![Figure 1: The Bergman complex $\mathfrak{B}_M$](image)

The graph has nine vertices: seven of them correspond to one-element flats 1, 2, 3, 4, 5, 6, 7, and two vertices correspond to the cycles 346 and 357 of the matroid $M$.  

6
The image of the fan $\mathcal{B}_M$ under the mapping $V$ is the two-dimensional fan in $\mathbb{R}^3$ (see Fig. 2). It consists of sixteen cones: fifteen of them are generated by the pairs $12, 13, 14, 15, 16, 17, 23, 24, 25, 26, 27, 45, 47, 56, 67$ of the columns of the matrix $V$, and one cone is generated by the triple $346$.

The tropical variety $\tau(\nabla)$ constructed in this way allows to find the normal fan for the Newton polytope $\mathcal{N}_\Delta$ of the discriminant of the system (7). Seven rays of the fan $\tau(\nabla)$ generated by the columns of the matrix $V$ define normal directions of facets of the Newton polytope $\mathcal{N}_\Delta$. They are denoted by numbers $1, 2, 3, 4, 5, 6, 7$ in Fig. 2. These are exactly the normal directions obtained in Theorem 1. Besides these normals, there are three more rays arising as a result of the intersection of cones of the fan $\tau(\nabla)$. Namely, the cones $346$ and $25$ intersect at the ray $\mathbb{R}_{\geq 0}(-1, -1, -1)^T$ (number 8 in Fig. 2), the cones $67$ and $23$ intersect at the ray $\mathbb{R}_{\geq 0}(0, 1, 1)^T$ (number 9 in Fig. 2), while the cones $67$ and $12$ intersect at the ray $\mathbb{R}_{\geq 0}(1, 3, 0)^T$ (number 10 in Fig. 2). Therefore, ten inward normals of the facets of the Newton polytope $\mathcal{N}_\Delta$ are found:

$$n_1 = (4, 0, 0), \quad n_6 = (-2, -2, 4),$$
$$n_2 = (0, 4, 0), \quad n_7 = (2, 4, -2),$$
$$n_3 = (0, 0, 4), \quad n_8 = (-1, -1, -1),$$
$$n_4 = (-2, -2, -4), \quad n_9 = (0, 1, 1),$$
$$n_5 = (-2, -4, -2), \quad n_{10} = (1, 3, 0).$$

The discriminant of the system (7) is computed using the computer algebra system

---

Figure 2: The tropical variety $\tau(\nabla)$
for polynomial computations SINGULAR [6]. It has the following form

\[
\Delta(x) = 432x_1^3 - 1296x_1^2x_2x_3^3 - 64x_1^2x_3^5 + 1296x_1x_2^2x_3^3 + 192x_1^2x_2x_3^5 - 432x_1^3x_2x_3^3 - 192x_1^3x_3^5

Figure 3: The Newton polytope \( \mathcal{N}_\Delta \)

Its Newton polytope \( \mathcal{N}_\Delta \) is depicted in Fig. 3 from two angles. It has ten two-dimensional faces. They are numbered in accordance with the sequence of rays of the polyhedral fan in Fig. 2. Therefore, all facets of the Newton polytope are detected.
