Linear and Reed Solomon Codes Against Adversarial Insertions and Deletions

Roni Con∗ Amir Shpilka † Itzhak Tamo ‡

Abstract

In this work, we study linear error-correcting codes against adversarial insertion-deletion (insdel) errors, a topic that has recently gained a lot of attention. We focus on two different settings - codes over small alphabets and Reed-Solomon codes.

Linear codes over small fields: We construct linear codes over $\mathbb{F}_q$, for $q = \text{poly}(1/\varepsilon)$, that can efficiently decode from a $\delta$ fraction of insdel errors and have rate $(1 - 4\delta)/8 - \varepsilon$. We also show that by allowing codes over $\mathbb{F}_{q^2}$ that are linear over $\mathbb{F}_q$, we can improve the rate to $(1 - \delta)/4 - \varepsilon$ while not sacrificing efficiency. Using this latter result, we construct fully linear codes over $\mathbb{F}_2$ that can efficiently correct up to $\delta < 1/54$ fraction of deletions and have rate $R = (1 - 54 \cdot \delta)/1216$. Cheng, Guruswami, Haeupler, and Li [CGHL21] constructed codes with (extremely small) rates bounded away from zero that can correct up to a $\delta < 1/400$ fraction of insdel errors. They also posed the problem of constructing linear codes that get close to the half-Singleton bound (proved in [CGHL21]) over small fields. Thus, our results significantly improve their construction and get much closer to the bound.

Reed-Solomon codes: We prove that over fields of size $n^{O(k)}$ there are $[n, k]$ Reed-Solomon codes that can decode from $n - 2k + 1$ insdel errors and hence attain the half-Singleton bound. We also give a deterministic construction of such codes over much larger fields (of size $n^{kO(k)}$). Nevertheless, for $k = O(\log n/\log \log n)$ our construction runs in polynomial time. For the special case $k = 2$, which received a lot of attention in the literature, we construct an $[n, 2]$ Reed-Solomon code over a field of size $O(n^3)$ that can decode from $n - 3$ insdel errors. Earlier construction required an exponential field size. Lastly, we prove that any such construction requires a field of size $\Omega(n^3)$.

1 Introduction

Error-correcting codes are among the most widely used tools and objects of study in information theory and theoretical computer science. The most common model of corruption that is studied in the TCS literature is that of errors or erasures. The model in which each symbol of the transmitted word is either replaced with a different symbol from the alphabet (an error) or with a ‘?’ (an erasure). The theory of such codes began with the seminal work of Shannon, [Sha48], who studied random errors and erasures and the work of Hamming [Ham50] who studied the adversarial model for errors and erasures. These models are mostly well understood, and today we know efficiently encodable and decodable codes that are optimal for Shannon’s model of random errors. For adversarial errors, we have optimal codes over large alphabets and good codes (codes of constant relative rate and relative distance) for every constant sized alphabet.

Another important model that has been considered ever since Shannon’s work is that of synchronization errors. These are errors that affect the length of the received word. The most common model for studying synchronization errors is the insertion-deletion model (insdel for short): an insertion error is when a new symbol is inserted between two symbols of the transmitted word. A deletion is when a symbol is removed from the transmitted word. For example, over the binary alphabet, when 100110 is transmitted, we may receive the word 1101100, which is obtained from two insertions (1 at the beginning and 0 at the end) and one deletion (one of the 0’s at the beginning of the transmitted word). Observe that compared to the more common error model, if an adversary wishes to change a symbol, then the cost is that of two operations - first deleting the symbol and then inserting a new one instead.

Insdel errors appear in diverse settings such as optical recording, semiconductor devices, integrated circuits, and synchronous digital communication networks. Another important example is the trace reconstruction problem, which has applications in computational biology and DNA-based storage systems [BLC+16, YGM17, HMG19]. See the surveys [Mit09, MBT10] for a good picture of the problems and applications of error-correcting codes for the insdel model (insdel codes for short).

Unlike the (mostly) well-understood error models of Shannon and Hamming for random and worst-case errors, respectively, there are many simple questions regarding the insdel model that are widely open. In fact, even the basic question of what is the capacity of the binary deletion channel with error probability $p$ (i.e., the channel in which each symbol of the transmitted message is deleted with probability $p$) is still open. See the surveys [Mit09, MBT10] as well as [MD06, Dal11, Che18] for an overview of results regarding the capacity of the binary deletion channel. Due to the importance of the insdel model and our lack of understanding of some basic problems concerning it, the model has attracted many researchers in recent years [HS17, BGZ17, GW17, CJLW18, Hae19, CGHL21, GI21]. However, even the basic question of whether there exist good linear codes, over small alphabets\footnote{Over large alphabets this is easy to achieve, see discussion in Section 1.4} for the insdel model was unknown until the recent work of Cheng, Guruswami, Haeupler, and Li [CGHL21].

Linear codes are desirable for many reasons: they have a compact representation (they are determined by their generating matrix), they are efficiently encodable, in some settings, we even have linear codes with linear encoding and decoding time, and often
they are simpler to analyze. In [AGFC07], it was shown that linear codes that can correct even one deletion, have a rate at most $1/2$, which is achieved by a trivial repetition code. More generally, in [CGHL21], it was shown that codes that can decode from a $\delta$ fraction of insdel errors cannot have rate larger than $(1-\delta)/2 + o(1)$ where the $o(1)$ term goes to zero as the block length tends to infinity. This bound is called the “half-Singleton bound,” and it is in sharp contrast to the fact that nonlinear insdel codes, or even affine codes (codes that form an affine space) can achieve rate close to 1 while still being able to decode from a constant fraction of insdel errors [CGHL21]. While previous work mistakenly claimed that there could be no good binary linear insdel codes (i.e., codes of a constant rate that can handle a constant fraction of insertions and deletions over the alphabet $\{0, 1\}$), [CGHL21] proved that there are binary linear codes of rate $1/2 - \varepsilon$ that can decode from $\Omega(\varepsilon \log \varepsilon^{-1})$, which is optimal up to the $\log \varepsilon^{-1}$ factor. They also proved that over fields of size $\exp(1/\varepsilon)$ there exist linear codes of rate $(1-\delta)/4 - \varepsilon$ that can decode a $\delta$ fraction of insdel errors. In addition, [CGHL21] gave explicit constructions of linear insdel codes that can decode from $\delta < 1/400$ fraction of insdel errors, however, the rate of the codes in their construction is extremely low. This led them to pose the problem of achieving better rate-(edit-)distance trade-offs.

Another important question concerns the performance of Reed-Solomon codes in the insdel model. As Reed-Solomon codes are the most widely used family of codes in theory and practice, it is an important problem to understand whether they can also decode from insdel errors. This problem received a lot of attention recently [SNW02, WMSN04, TSN07, DLTX19, LT21, CZ21], but besides very few constructions (i.e., evaluation points for Reed-Solomon codes), not much was known before our work. We discuss this line of work in more detail in Section 1.3.

In this work, we address both questions. First, we construct an explicit family of linear codes of rate $(1-4\delta)/8 - \varepsilon$, over a field of size $q = \text{poly}(1/\varepsilon)$ that can decode from a fraction $\delta$ of adversarial insdel errors. We also construct an explicit family of codes over $\mathbb{F}_q^2$ that are linear over $\mathbb{F}_q$ of rate $(1-\delta)/4 - \varepsilon$ for decoding from a fraction $\delta$ of adversarial insdel errors. While the first construction works as long as $\delta < 1/4$, the second construction is applicable for any $\delta < 1$. Furthermore, we have efficient decoding algorithms for both constructions. Using the second result, we construct binary codes for adversarial insdel errors that can correct a fraction $\delta < 1/54$ of errors and have rate $(1 - 54 \cdot \delta)/1216$. This significantly improves upon the parameters of the construction given in [CGHL21] that could handle $\delta < 1/400$ fraction of insdel errors and have rate $< 2^{-80}$ [GK]. We note, however, that the main goal of [CGHL21] was to construct good linear codes and they did not try to optimize the parameters.

Our second set of results concerns Reed-Solomon codes. We first prove that there are Reed-Solomon codes that achieve the half-Singleton bound. In other words, there are optimal Reed-Solomon codes also against insdel errors. We also give a set of evaluation points that define a Reed-Solomon code that achieves this bound. As the field size that we get grows very fast, our construction runs in polynomial time only for very small values of $\delta$. Unfortunately, we could not develop efficient decoding algorithms for our Reed-Solomon constructions, and we leave this as an open problem for future research.

We next give some formal definitions, state our results, and give a more detailed
account of known results.

### 1.1 Basic definitions and notation

For an integer $k$, we denote $[k] = \{1, 2, \ldots, k\}$. Throughout this paper, $\log(x)$ refers to the base-2 logarithm. For a prime power $q$, we denote with $\mathbb{F}_q$ the field of size $q$.

We denote the $i$th symbol of a string $s$ (or of a vector $v$) as $s_i$ (equivalently $v_i$). Throughout this paper, we shall move freely between representations of vectors as strings and vice versa. Namely, we shall view each vector $v$ as a string and vice versa. Namely, we shall view each vector $v = (v_1, \ldots, v_n) \in \mathbb{F}_q^n$ also as a string by concatenating all the symbols of the vector into one string, i.e., $(v_1, \ldots, v_n) \leftrightarrow v_1 \circ v_2 \circ \ldots \circ v_n$. Thus, if we say that $s$ is a subsequence of some vector $v$, we mean that we view $v$ as a string and $s$ is a subsequence of that string. A run $r$ in a string $s$ is a single-symbol substring of $s$ such that the symbol before the run and the symbol after the run are different from the symbol of the run.

An error correcting code of block length $n$ over an alphabet $\Sigma$ is a subset $C \subseteq \Sigma^n$. The rate of $C$ is $\frac{\log |C|}{n \log |\Sigma|}$, which captures the amount of information encoded in every symbol of a codeword. A linear code over a field $F$ is a linear subspace $C \subseteq \mathbb{F}_q^n$. The rate of a linear code $C$ of block length $n$ is $R = \dim(C)/n$. Every linear code of dimension $k$ can be described as the image of a linear map, which, abusing notation, we also denote with $C$, i.e., $C : \mathbb{F}_q^k \rightarrow \mathbb{F}_q^n$. Equivalently, a linear code $C$ can be defined by a parity check matrix $H$ such that $x \in C$ if and only if $Hx = 0$. The minimal distance of $C$ with respect to a metric $d(\cdot, \cdot)$ is defined as $\text{dist}_C := \min_{u \neq v \in C} d(v, u)$. When $C \subseteq \mathbb{F}_q^n$ has dimension $k$ and minimal distance $d$ we say that it is an $[n, k, d]_q$ code, or simply an $[n, k]_q$ code. Naturally, we would like the rate to be as large as possible, but there is an inherent tension between the rate of the code and the minimal distance (or the number of errors that a code can decode from). In this work, we focus on codes against insertions and deletions.

**Definition 1.1.** Let $s$ be a string over the alphabet $\Sigma$. The operation in which we remove a symbol from $s$ is called a deletion and the operation in which we place a new symbol from $\Sigma$ between two consecutive symbols in $s$, in the beginning, or at the end of $s$, is called an insertion.

A substring of $s$ is a string obtained by taking consecutive symbols from $s$. A subsequence of $s$ is a string obtained by removing some (possibly none) of the symbols in $s$.

The relevant metric for such codes is the edit-distance that we define next.

**Definition 1.2.** Let $s, s'$ be strings over the alphabet $\Sigma$. A longest common subsequence between $s$ and $s'$, is a subsequence $s_{\text{sub}}$ of both $s$ and $s'$, of maximal length. We denote by $\text{LCS}(s, s')$ the length of a longest common subsequence.

The edit distance between $s$ and $s'$, denoted by $\text{ED}(s, s')$, is the minimal number of insertions and deletions needed in order to turn $s$ into $s'$. One can verify that this measure indeed defines a metric (distance function).

**Lemma 1.3** (See e.g. Lemma 12.1 in [CR03]). It holds that $\text{ED}(s, s') = |s| + |s'| - 2\text{LCS}(s, s')$.

---

\(^3\)Note that a longest common subsequence may not be unique as there can be a number of subsequences of maximal length. For example in the strings $s = (1, 0)$ and $s' = (0, 1)$.  

We next define Reed-Solomon codes (RS-codes from now on).

**Definition 1.4** (Reed-Solomon codes). Let $\alpha_1, \alpha_2, \ldots, \alpha_n \in \mathbb{F}_q$ be distinct points in a finite field $\mathbb{F}_q$ of order $q \geq n$. For $k \leq n$ the $[n,k]_q$ RS-code defined by the evaluation set $\{\alpha_1, \ldots, \alpha_n\}$ is the set of codewords

$$\{c_f = (f(\alpha_1), \ldots, f(\alpha_n)) \mid f \in \mathbb{F}_q[x], \deg f < k\}.$$ 

In words, a codeword of an $[n,k]_q$ RS-code is the evaluation vector of some polynomial of degree less than $k$ at $n$ predetermined distinct points. It is well known (and easy to see) that the rate of $[n,k]_q$ RS-code is $k/n$ and the minimal distance, with respect to the Hamming metric, is $n - k + 1$.

### 1.2 Our results

In this paper, we improve the results presented in [CGHL21] and in [DLTX19, LT21, CZ21]. Our first set of results gives explicit constructions of codes over small fields that are efficient (namely, have polynomial-time encoding and decoding algorithms) and almost attain the half-singleton bound. Specifically,

**Theorem 1.5.** For every small enough constant $\varepsilon > 0$, $\delta \in (0, 1/4)$ and $q = \text{poly}(1/\varepsilon)$, there is an explicit construction of a linear code over $\mathbb{F}_q$ of rate $R > (1 - 4\delta)/8 - \varepsilon$ that can correct from a $\delta$ fraction of adversarial insdel errors. Furthermore, the running time of the decoding algorithm is $O(n^3)$.

By relaxing the linearity requirement, we construct “half-linear” codes. We say that a code is half-linear when it is defined over the field $\mathbb{F}_{q^2}$ and is linear over $\mathbb{F}_q$. The half-linear codes that we construct can decode from any $\delta$ fraction of insdel errors, and their rate is close to $(1 - \delta)/4$.

**Theorem 1.6.** For every small enough constant $\varepsilon > 0$, $\delta \in (0, 1)$, and $q = \text{poly}(1/\varepsilon)$ there is an explicit construction of a code over $\mathbb{F}_{q^2}$, which is linear over the subfield $\mathbb{F}_q$, that has rate $R > (1 - \delta)/4 - \varepsilon$ and can correct from $\delta$ fraction of insdel errors. Furthermore, the running time of the decoding algorithm is $O(n^3)$.

Using this construction, we obtain linear binary codes against insdel errors.

**Theorem 1.7.** There exists an explicit linear binary code that can correct from $\delta < 1/54$ fraction of worst-case deletions in $O(n^3)$ time and has the rate $R = (1 - 54 \cdot \delta)/1216$.

While the algorithm in Theorem 1.7 is only guaranteed to decode from deletions, we note that, information-theoretically, the code can also decode from $1/54$ fraction of worst-case insdel errors, as the claim implies a lower bound on the edit distance between any two codewords.

Theorems 1.5 and 1.7 improve upon the (explicit) constructions of linear codes given in [CGHL21], which can handle a fraction $\delta < 1/400$ of insdel errors and whose rate is $< 2^{-80}$. We note, however, that Theorem 1.7 only gives an efficient decoder against deletions, whereas the algorithm in [CGHL21] decodes from both insertions and deletions.

Our second set of results concerns RS-codes. First, we prove that there are RS-codes that achieve the half-Singleton bound. Namely, they are optimal linear codes for insdel errors.
Theorem 1.8. Let \( k \) and \( n \) be positive integers such that \( 2k - 1 \leq n \). For \( q = O(n^{4k^2 - 2}) \) there exists an \([n, k]_q\) RS-code defined by \( n \) distinct evaluation points \( \alpha_1, \ldots, \alpha_n \in \mathbb{F}_q \), that can recover from \( n - 2k + 1 \) adversarial insdel errors.

Observe that the constructed code achieves the half Singleton bound: its rate is \( R = k/n = (1 - \delta)/2 + o(1) \) and \( \delta = (n - 2k + 1)/n \).

Theorem 1.8 is an existential result and does not give an explicit construction. Using ideas from number theory and algebra, we construct RS-codes that can decode from \( n - 2k + 1 \) adversarial insdel errors, in particular, they achieve the half-Singleton bound. Specifically,

Theorem 1.9. Let \( k \) and \( n \) be positive integers, where \( 2k - 1 \leq n \). There is a deterministic construction of an \([n, k]_q\) RS-code that can correct from \( n - 2k + 1 \) insdel errors where \( q = O(n^{k^2 - ((2k)^2)/2}) \). The construction runs in polynomial time for \( k = O(\log(n)/\log(\log(n))) \).

We note that for \( k = \omega(\log(n)/\log(\log(n))) \) the field size is \( \exp(n^{o(1)}) \) and in particular, there is no efficient way to represent arbitrary elements of \( \mathbb{F}_q \) in this case.

Special attention was given in the literature to the case \( k = 2 \), see e.g., [WMSN04, LT21, DLTX19, CZ21] and references within. [DLTX19, CZ21] obtained an optimal construction, i.e., an \([n, 2]_q\) RS-codes that can decode from \( n - 3 \) adversarial insdel errors, over fields of size \( q = \exp(\Omega(n)) \). These constructions are discussed in more detail in Section 1.3.

Using Sidon spaces constructed in [RRT17], we explicitly construct a family of \([n, 2]_q\) RS-codes that can decode from \( n - 3 \) insdel errors for \( q = O(n^4) \). Besides improving on all previous constructions in terms of field size, our construction also requires a smaller field size than the one guaranteed by the randomized argument in Theorem 1.8. Such phenomena, where a deterministic algebraic construction outperforms the parameters obtained by a randomized construction, are scarce in coding theory and combinatorics. Well-known examples are AG codes that outperform the GV-bound [TVZ82] and constructions of extremal graphs with “many” edges that do not contain cycles of length 4, 6 or 10 (see [Con21]).

Theorem 1.10. For any \( n \geq 4 \), there exists an explicit \([n, 2]_q\) RS-code that can correct from \( n - 3 \) insdel errors, where \( q = O(n^4) \).

We also prove a (very) weak lower bound on the field size.

Proposition 1.11. Any \([n, k]_q\) RS-code that can correct from \( n - 2k + 1 \) worst case insdel errors must satisfy

\[
q \geq \frac{1}{2} \left( \frac{n}{(2k - 1)(k - 1)} \right)^{\frac{4k^2 - 1}{2k - 1}}
\]

While for large values of \( k \), this bound is meaningless, it implies that when \( k = 2 \), the field size must be \( \Omega(n^3) \). Thus, the construction given in Theorem 1.10 is nearly optimal. The gap between the field size in our construction and the one implied by the lower bound raises an interesting question: what is the minimal field size \( q \) for which an optimal \([n, 2]_q\) RS-code exists?
1.3 Previous results

Codes against synchronization errors were studied since the 1950s. We refer the reader [Mit09, MBT10] for a detailed account of early work.

The field received a serious boost with the breakthrough result of Haeupler and Shahrasbi [HS17]. They introduced the notion of synchronization strings (Definition 1.14) and used it to give optimal constructions of (non-linear) insdel codes over fixed alphabets. Specifically, for every $\varepsilon > 0$ and $\delta \in (0, 1)$ they constructed a code of rate $1 - \delta - \varepsilon$ that can efficiently correct a $\delta$ fraction of insdel errors, over an alphabet of size $|\Sigma| = O(1)$ (Theorem 1.16).

Linear codes against insdel errors: Linear codes against worst-case insdel errors were recently studied by Cheng, Guruswami, Haeupler, and Li [CGHL21]. Correcting an error in a preceding work, they proved that there are good linear codes against insdel errors.

**Theorem 1.12** (Theorem 4.2 in [CGHL21]). For any $\delta > 0$ and prime power $q$, there exists a family of linear codes over $F_q$ that can correct up to $\delta n$ insertions and deletions, with rate $(1 - \delta)/2 - h(\delta)/\log_2(q)$.

The proof of Theorem 1.12 uses the probabilistic method, showing that, with high probability, a random linear map generates such code. Complementing their result, they proved that their construction is almost tight. Specifically, they provided the following upper bound, which they call “half-Singleton bound,” that holds over any field.

**Theorem 1.13** (Half-Singleton bound: Corollary 5.1 in [CGHL21]). Every linear insdel code which is capable of correcting a $\delta$ fraction of deletions has rate at most $(1 - \delta)/2 + o(1)$.

In a recent work, Guruswami, He, and Li [GHL21] strengthened this result for binary codes and showed that there exists an absolute constant $\delta$ such that any binary code $C \subseteq \{0, 1\}^n$ (not only linear) that can decode from $(1/2 - \delta)$ fraction of deletions must satisfy $|C| \leq 2^{\text{poly} \log n}$. In particular, we cannot hope to decode a fraction of insdel errors arbitrarily close to 1/2 with codes of positive rate.

As we already mentioned, [CGHL21] constructed explicit linear codes for insdel errors. Their codes have rate $R < 2^{-80}$ [GK], a linear time encoding algorithm and an $O(n^4)$ time algorithm for decoding a $\delta < 1/400$ fraction of insdel errors [CGHL21, Theorem 1.4, Corollary 7.1]. They left the question of constructing efficient codes with better rates open.

Reed Solomon codes: RS-codes are one of the most important families of linear codes. Indeed, they have found many applications both in theory and in practice (their applications include QR codes [Soo08], secret sharing schemes [MSS1], space transmission [WB99], encoding data on CDs [WB99] and more. The ubiquity of these codes can be attributed to their simplicity as well as to their efficient encoding and decoding algorithms.

The performance of RS-codes against insdel errors was studied much earlier than the recent work of Cheng et al. [CGHL21]. To the best of our knowledge, Safavi-Naini and Wang [SNW02] were the first to study the performance of RS-codes against insdel errors. They gave an algebraic condition that is necessary and sufficient for an RS-code
to correct from insdel errors, yet they did not provide any construction. In fact, in our work, we consider an almost identical algebraic condition, and by simply using the Schwartz-Zippel-Demillo-Lipton lemma, we prove that there are RS-codes that meet this condition and, in addition, achieve the half-Singleton bound. In particular, RS-codes are optimal for insdel errors (see discussion in Section 4). Wang, McAven, and Safavi-Naini [WMSN04] constructed a $[5, 2]$ RS-code capable of correcting a single deletion. Then, in [TSN07], Tonien and Safavi-Naini constructed an $[n, k]$ generalized-RS-codes capable of correcting from $\log_{k+1} n - 1$ insdel errors. Similar to our results, they did not provide an efficient decoding algorithm.

In another line of work, Liu and Tjuawinata [LT21] and Duc, Liu, Tjuawinata, and Xing [DLTX19] constructed 2-dimensional RS-codes. Specifically, in [DLTX19 Theorem 2] the authors show, non explicitly, that there exist $[n, 2]$ RS-codes that can correct from $n - 3$ insdel errors, for $q = \exp(n^2)$. In [DLTX19, LT21], the authors presented constructions of $[n, 2]$ RS-codes that for every $\varepsilon > 0$ can correct from $(1 - \varepsilon) \cdot n$ insdel errors, for codes of length $n = \text{poly}(1/\varepsilon)$ over fields of size $\Omega(\exp((\log n)^{1/\varepsilon}))$ and $\Omega(\exp(n^{1/\varepsilon}))$, respectively. Lastly, in [CZ21], the authors present construction of two-dimensional RS-codes where the field size is exponential in $n$ that can correct from $n - 3$ insdel errors. Observe that the codes that we construct in Theorem 1.10 are explicit, can decode from $n - 3$ errors, and are defined over a field of size $O(n^4)$. In a very recent work by Chen [Che21] gave some new Singleton-type upper bounds on the insdel distance of linear codes and applied them to certain families of Reed-Muller and algebraic geometry codes. Chen also speculated that RS-codes have “moderate good insertion-deletion error-correcting capabilities” and conjectures that some RS-codes attain the half-Singleton bound. Theorem 1.8 proves this conjecture and Theorem 1.9 gives a construction of RS-codes that are optimal linear codes against insdel errors.

### 1.4 Proof idea

**Linear codes over small alphabets:** We first observe that it is easy to construct codes against deletions from any code that can correct erasures: simply add indices to the coordinates of each codeword. Specifically, if $C$ is a code that can correct from $\varepsilon$ erasures, then we can consider the following code

$$C' = \{(1, c_1), \ldots, (n, c_n) \mid c \in C\}.$$

It is easy to see that this code can decode from $\varepsilon$ adversarial deletions - the missing indices indicate the location of the deletions, and therefore we can treat them as erasures. With a slightly more advanced algorithm, this code can also decode from adversarial insertions (for this to work, we need a code that can decode from errors as well). This construction has two problems. The first is that it is not linear. The second is that it requires an alphabet of size $\Omega(n)$.

The problem of linearity can be solved as follows. Assume $C \subseteq \mathbb{F}_q^n$ is linear. To add indices while preserving linearity we replace $(i, c_i)$ with $(c_i, i \cdot c_i)$. Observe that the resulting code is linear over $\mathbb{F}_q$, but symbols of the codeword are in $\mathbb{F}_q^2$. We shall call such codes half-linear codes. To make the code fully linear, we replace each symbol $(c_i, i \cdot c_i)$ with two symbols, $c_i$ and $i \cdot c_i$. The problem is that now, after adversarial deletions, it is unclear which indices “survived” and which were deleted or corrupted. To overcome this
difficulty, we add small “buffers” of zeros between the different indices. That is, the new codeword is \((c_1, 1 \cdot c_1, 0, 0, c_2, 2 \cdot c_2, 0, 0, c_3, \ldots)\). Note that we still need a large alphabet to have \(n\) different field elements that can serve as indices.

To reduce the alphabet size, we use synchronization strings instead of field elements for the indices. Synchronization strings were defined in the breakthrough work of Haeupler and Shahrasbi [HS17].

**Definition 1.14.** A string \(S \in \Sigma^n\) is called an \(\varepsilon\)-synchronization string if for every \(1 \leq i < j < k \leq n + 1\) it holds that \(ED(S[i, j], S[j, k]) > (1 - \varepsilon) \cdot (k - i)\), where \(S[i, j]\) denotes the string \(S_i \circ S_{i+1} \circ \cdots \circ S_{j-1}\) and \(S_i\) is the \(i\)th coordinate of \(S\).

Haeupler and Shahrasbi proved the existence of such strings and gave a polynomial-time randomized algorithm for constructing them. An explicit construction, with improved alphabet size, was given in [CHL+19].

**Theorem 1.15** (Theorem 1.2 in [CHL+19]). For every \(n \in \mathbb{N}\) and for every \(\varepsilon \in (0, 1)\), there is a polynomial time (in \(n\)) deterministic construction of an \(\varepsilon\)-synchronization string, of length \(n\), over an alphabet of size \(O(\varepsilon^{-2})\).

In [HS17] Haeupler and Shahrasbi showed that synchronization strings could be used instead of indices. Specifically, they proved that if \(C\) can decode from \(d\) hamming errors and \(e\) erasures, for \(2d + e < \delta\), and \(S = (S_1 S_2 \ldots S_n)\) is an \(\varepsilon\)-synchronization string, then the code

\[
C_{\text{ID}} := \{(S_1, c_1), \ldots, (S_n, c_n) \mid c \in C\}
\]

(1)
can decode from \((\delta - O(\sqrt{\varepsilon}))n\) indel errors.

**Theorem 1.16** ([HS21]). Let \(\delta, \varepsilon \in (0, 1)\) and let \(S\) be an \(\varepsilon\)-synchronization string. Let \(C\) be a code that can decode, in time \(T(n)\), from \(d\) hamming errors and \(e\) erasures, where \(2d + e < \delta n\). Then, the code \(C_{\text{ID}} := \{(S_1, c_1), \ldots, (S_n, c_n) \mid c \in C\}\) can decode from \((\delta - 12\sqrt{\varepsilon})n\) indel errors in time \(O(n^2/\sqrt{\varepsilon}) + T(n)\).

We note that this code is not linear, even when \(C\) is a linear code, as the synchronization string \(S\) is fixed. However, as outlined above, we can tweak this construction to make the code linear while still maintaining its decoding property. We combine this idea with an algebraic geometry code (AG-code) as the base code \(C\) to obtain our results. We choose these codes as our base codes as they have the best-known rate-distance tradeoff, and in addition, they come with efficient decoding algorithms. Thus, codewords of our code have the form

\[
C' = \{(c_1, S_1 \cdot c_1, 0, 0, \ldots, 0, 0, c_n, S_n \cdot c_n) \mid c \in C\}.
\]

To further reduce the alphabet to binary, we perform two additional steps. First, we concatenate our code from Theorem 1.6 with a carefully chosen binary code of fixed length. Then we add buffers of zeroes between any two concatenated words. A short buffer between the encodings of \(c_i\) and \(S_i \cdot c_i\) and a long buffer between the encodings of \(S_i \cdot c_i\) and \(c_{i+1}\). The buffers allow our decoding algorithm to correctly identify the encoding of many pairs \((c_i, S_i \cdot c_i)\). Then, by using the synchronization string, \(S\), and the decoder of \(C\), we obtain a decoding algorithm.
Reed-Solomon codes: To show that RS-codes can be used against insdel errors, we first prove an algebraic condition that is necessary and sufficient for \( n \) evaluation points to define an RS-code that can decode from insdel errors. This condition requires that a certain set of (exponentially many) matrices, determined by the evaluation points, must all have full rank. Then, a simple application of the Schwartz-Zippel-DeMilo-Lipton lemma [Sch80, Zip79, DL78] implies the existence of good evaluation points over fields of exponential size. To obtain a deterministic construction, we show that by going to much larger field size, one can find evaluation points satisfying the full-rank condition. While the field size needs to be of size roughly \( \Omega(n^k) \), we note that, for not too large values of \( k \), it is of exponential size, and in this case, our construction runs in polynomial time.

For the case of \( k = 2 \), we use a different idea that gives a better field size than the one implied by the probabilistic argument above. We do so by noting that in this case the full-rank condition can be expressed as the requirement that no two different triples of evaluation points \((x_1, x_2, x_3)\) and \((y_1, y_2, y_3)\) satisfy

\[
\frac{y_1 - y_2}{x_1 - x_2} = \frac{y_2 - y_3}{x_2 - x_3}.
\]

This condition is reminiscent of the condition behind the construction of Sidon spaces of [RRT17], and indeed, we build on their construction of Sidon spaces to define good evaluation points in a field of size \( O(n^4) \).

1.5 Organization of the paper

The paper is organized as follows. In Section 2 we construct linear (and half-linear) codes, over small alphabets, that can handle insdel errors, and prove Theorem 1.6 and Theorem 1.5. In Section 3, we give the construction of linear binary codes that can decode from deletions, thus proving Theorem 1.7. In Section 4, we prove our results concerning RS-codes. Specifically, we prove Theorems 1.8, 1.9 and 1.10.

2 Linear Insdel Codes over Finite Alphabet via Synchronization Strings

In this section, we prove Theorems 1.5 and 1.6. We follow the strategy outlined in Section 1.4.

As our base code \( \mathcal{C} \), we shall use an AG-code. The well-known construction of [TVZ82] beats the Gilbert-Varshamov bound\(^4\) over \( \mathbb{F}_q \), for \( q \geq 49 \). Moreover, this code has an efficient decoder that can correct both errors and erasures, almost up to its correction capability [SV90, Kot96]. The interested reader is referred to [Sti09] for further information on AG-codes and their decoding.

**Theorem 2.1** ([TVZ82] \[SV90, Kot96\]). Let \( q = p^{2m} \) be a square where \( p \) is a prime and \( m \) is a positive integer. For every \( 0 < \delta \leq 1 - \frac{1}{\sqrt{q - 1}} \) there exists an explicit linear code \( \mathcal{C} \) over \( \mathbb{F}_q \), of minimal distance \( \delta \) and rate

\[
R \geq 1 - \frac{1}{\sqrt{q - 1}} - \delta.
\]

\(^4\)The Gilbert-Varshamov bound shows what parameters random (linear) codes achieve.
Algorithm 1: Decode $C'$

**input**: A corrupted codeword $y = (e_1, \ldots, e_t)$.

**output**: A message $x \in \mathbb{F}_q^k$.

1. Set $L$ to be an empty list.
2. For $i = 1, \ldots, t$
   - Let $e_i = (a, b)$
     - If $b = 0$ then
       - Go to the next $i$
     - End
   - Add to $L$ the tuple $(b/a, a)$
   - End
3. If $L$ is empty, return the zero codeword $c = 0$; else decode $L$ using the decoding algorithm of $C^\text{ID}$ given in Theorem 1.16.
4. Let $c^\text{ID} = ((S_1, c_1), \ldots, (S_n, c_n))$ be the decoded codeword. Return the codeword $c = ((c_1, S_1c_1), \ldots, (c_n, S_nc_n))$.

Moreover, there is a decoding algorithm that runs in time $O(n^3)$ and can correct from $d$ hamming errors and $e$ erasures, for $2d + e < \left(\delta - \frac{1}{\sqrt{p-1}}\right)n$.

We first prove Theorem 1.6 as the proof of its decoding algorithm is easier and then prove Theorem 1.3.

### 2.1 Half-linear insdel codes

**Construction 2.2.** Let $\delta \in (0, 1)$ and $\epsilon$ a small constant. Let $p$ be a prime such that $p = \Theta(\epsilon^{-2})$ and set $q = p^2 = \Theta(\epsilon^{-4})$. Let $\delta_C = (1 + \delta + 13\epsilon)/2$ and let $C$ be the code from Theorem 2.1, defined over the finite field $\mathbb{F}_q$, with rate $R_C > 1 - \delta_C - \epsilon$. Let $S = (S_1, S_2, \ldots, S_n)$ be an $\epsilon^2$-sync string, where $S_i \in \mathbb{F}_q \setminus \{0\}$ for all $i \in [n]$. Let $\text{Enc}_C: \mathbb{F}_q^k \rightarrow \mathbb{F}_q^n$ be the encoding map of $C$. We define the code $C'$ via the encoding map $\text{Enc}_{C'}$: For $a \in \mathbb{F}_q^k$, let $\text{Enc}_{C'}(a) = c = (c_1, \ldots, c_n)$. Then,

$$\text{Enc}_{C'}(a) = ((c_1, S_1c_1), (c_2, S_2c_2), \ldots, (c_n, S_nc_n)) \quad (2)$$

Namely, $C'$ is the image of $\mathbb{F}_q^k$ under $\text{Enc}_{C'}$. One can easily observe that the rate $C'$ is $R_{C'} = R_C/2 > (1 - \delta)/4 - 4\epsilon$, and that the code is linear over $\mathbb{F}_q$.

**Proposition 2.3.** Algorithm 1 runs in time $O(n^3)$ and can decode $C'$ (given in Construction 2.2), from $\delta n$ worst case insdel errors.

**Proof.** For $c = ((c_1, S_1c_1), \ldots, (c_n, S_nc_n)) \in C'$ let $c^\text{ID} = ((S_1, c_1), \ldots, (S_n, c_n)) \in C^\text{ID}$. Observe that $C^\text{ID}$ is as in Equation (1). To prove the claim we shall interpret insdel errors in $C'$ as insdel errors in $C^\text{ID}$ and then apply Theorem 1.16.

Assume first that the corrupted codeword is the zero vector. Then, since the hamming-weight of each nonzero codeword of $C'$ is at least $\delta_C n > \delta n$, the only codeword that would produce this corrupted codeword from $\delta n$ insdel errors is the zero codeword, hence, in
Step 3 successfully decodes the zero codeword. Next, we assume that the corrupted codeword is *not* the zero vector.

The map \((a, b) \rightarrow (b/a, a)\) maps each nonzero coordinate of \(c \in C'\) to the corresponding coordinate of \(c^{\text{ID}} \in C^{\text{ID}}\) and therefore, by applying it coordinate-wise, we can interpret any insdel error to \(c\) as an insdel error to \(c^{\text{ID}}\).

Observe that in addition to the errors introduced by the adversary, in Step 2 of Algorithm 1, we treat any zero coordinate as a deletion. Since the minimal distance of \(C\) is \(\delta_C\), a nonzero codeword \(c \in C'\) has at most \(n(1 - \delta_C)\) zero coordinates. Therefore, Step 2 can cause \((1 - \delta_C)n\) additional insdel errors. In conclusion,

\[
ED(c^{\text{ID}}, L) \leq (1 - \delta_C) + \delta)n = (\delta_C - 13\varepsilon)n,
\]

where the equality follows from the choice of \(\delta_C\) in Construction 2.2. As \(C\) can correct from \(d\) hamming errors and \(e\) erasures, for \(2d + e \leq (\delta_C - \varepsilon)n\), Theorem 2.16 implies that Step 3 succeeds, and the decoder outputs \(c^{\text{ID}}\). Step 4 clearly returns the codeword \(c\).

To prove the claim regarding the running time we note that Steps 1 and 2 take linear time and that by Theorem 2.14, the decoding algorithm of Theorem 1.16 runs in time \(O(n^2/\varepsilon) + O(n^3) = O(n^3)\).

**Remark 2.4.** As the proof shows, Step 3 of Algorithm 1 ignores the symbol \((0,0)\). In other words, it treats this symbol as a deletion. Thus, from the point of view of the adversary, there is no need to corrupt the zero symbol.

**Proof of Theorem 1.16.** The proof follows immediately from Construction 2.2 and Proposition 2.3. Indeed, the code described in Construction 2.2 maps \(k\) symbols of \(\mathbb{F}_q\) to \(n\) symbols of \(\mathbb{F}_q^n\) and hence its rate is \(k/(2n)\). As \(k\) was chosen so that \(|R_C| = k/n > 1 - \delta_C - \varepsilon = (1 - \delta - 15\varepsilon)/2\), we get that \(|R_{C'}| = R_C/2 > (1 - \delta)/4 - 4\varepsilon\). By construction the code is linear over \(\mathbb{F}_q\).

### 2.2 Full linear insdel codes

We next prove Theorem 1.5. As described in Section 1.4, to get full linear insdel codes we use a similar construction albeit with two significant modifications: First, we “flatten” the code, i.e., we expand each symbol \((c_i, S_i \cdot c_i) \in \mathbb{F}_q^2\) to two symbols \(c_i, S_i \cdot c_i \in \mathbb{F}_q\). Secondly, to protect our codeword from insdel errors, we additionally insert two zeros between every two adjacent pairs. Thus, the corresponding word to \(((c_1, S_1 \cdot c_1), (c_2, S_2 \cdot c_2), \ldots, (c_n, S_n \cdot c_n))\) is \((c_1, S_1 \cdot c_1, 0, 0, c_2, S_2 \cdot c_2, 0, 0, \ldots, c_n, S_n \cdot c_n)\).

It is clear that in this way we get a linear code. Formally:

**Construction 2.5.** Let \(\delta \in (0, 1/4)\) and \(\varepsilon\) a small enough constant. Set \(\delta_C = (1 + 4\delta + 13\varepsilon)/2 < 1\). Let \(p\) be a prime such that \(p = \Theta(\varepsilon^{-2})\) and set \(q = p^2\). Let \(C\) be the code from Theorem 2.14 defined over the finite field \(\mathbb{F}_q\), with minimal distance \(\delta_C\), and rate \(R_C = 1 - \delta_C - \varepsilon\). Let \(S = (S_1S_2 \ldots S_n)\) be an \(\varepsilon^2\)-sync string, where \(S_i \in \mathbb{F}_q \setminus \{0\}\) for all \(i \in [n]\) Let \(\text{Enc}_C : \mathbb{F}_q^k \rightarrow \mathbb{F}_q^n\) be the encoding map of \(C\). We define the code \(C''\) via the encoding map \(\text{Enc}_{C''}\): For \(a \in \mathbb{F}_q^k\), let \(\text{Enc}_{C''}(a) = c = (c_1, \ldots, c_n)\). Then,

\[
\text{Enc}_{C''}(a) = (c_1, S_1 \cdot c_1, 0, 0, c_2, S_2 \cdot c_2, 0, 0, \ldots, c_n, S_n \cdot c_n) .
\]  

Namely, \(C''\) is the image of \(\mathbb{F}_q^k\) under \(\text{Enc}_{C''}\). Clearly, \(C'' \subset \mathbb{F}_q^{4n-2}\) is an \(\mathbb{F}_q\) linear space.
Algorithm 2: Decode $C''$

**input**: A corrupted codeword $y = (e_1, \ldots, e_t)$.

**output**: A message $x \in \mathbb{F}_q^k$.

[1] Set $L$ to be an empty list

Write $y$ as

$$y = s_1 \circ 0 \circ s_2 \circ 0 \circ \cdots \circ 0 \circ s_m,$$

where $0 \leq m \leq t$, the $s_i$'s are strings of symbols that do not contain any 0's, and the notation $\bar{0}$ corresponds to a string of consecutive zeros of any length.

[2] for $i = 1, \ldots, m$
do
  if $|s_i| \neq 2$
  then
    Continue
  end

Let $a, b$ be the first and second elements in $s_i$. Add to $L$ the tuple $(b/a, a)$

[3] If $L$ is empty, return the zero codeword, $c = 0$; else decode $L$ using the algorithm of $C^{ID}$ given in Theorem 1.16.

[4] Let $c^{ID} = ((S_1, c_1), \ldots, (S_n, c_n))$ be the decoded codeword. Return the codeword $c = (c_1, S_1c_1, 0, 0, \ldots, 0, 0, c_n, S_nc_n)$.

Proposition 2.6. Algorithm 2 runs in time $O(n^3)$ and can decode $C''$, given in Construction 2.5, from $\delta n$ worst case insdel errors.

**Proof.** Let $c = (c_1, S_1c_1, 0, 0, \ldots, 0, 0, c_n, S_nc_n) \in C''$ and denote by $c^{ID} = ((S_1, c_1), \ldots, (S_n, c_n)) \in C^{ID}$ the corresponding codeword, where $C^{ID}$ is as in the proof of Proposition 2.3. We will follow the same reasoning as in the proof of Proposition 2.3 translate insdel errors in $C''$ to insdel errors in $C^{ID}$, and then apply Theorem 1.16.

Assume first that the corrupted codeword is the zero vector. Then, since the hamming-weight of each nonzero codeword of $C$ is at least $\delta Cn$ and $S_i \neq 0$ for each $i$, the normalized minimum distance of $C''$ is at least $2\delta Cn/(4n - 2) > \delta C/2$. On the other hand,

$$\delta < \frac{1}{4} < \frac{1 + 4\delta + 13\varepsilon}{4} = \frac{\delta C}{2}.$$ 

Hence, the only codeword that would produce this corrupted codeword from $\delta(4n - 2)$ insdel errors is the zero codeword, and Step 3 successfully decodes the zero codeword. Next, we assume that the corrupted codeword is not the zero vector.

Since the minimal distance of $C$ is at least $\delta Cn$, any nonzero $c \in C''$ contains at most $n(1 - \delta C)$ pairs $c_i, S_i c_i$ that are equal to 0, 0. Every such zero pair is interpreted as a deletion in Step 2 of Algorithm 2. These deletions are in addition to those made by the adversary. The adversary, who knows the decoding algorithm, will clearly ignore the zero pairs $c_i, S_i$ for $c_i = 0$, and therefore will either “ruin” nonzero pairs by converting them to nonzero blocks (i.e., blocks with no zeros) of lengths different than 2, or by constructing erroneous pairs.

The most economic way to construct the former is by inserting (deleting) a symbol to (from) an existing nonzero pair, respectively. This increases $\text{ED}(c^{ID}, L)$ by 1. Also,
the adversary can merge, say \( b \geq 2 \) consecutive blocks, into a single block by deleting the buffers between them. This “costs” \( 2(b - 1) \) deletions that translate to an increase to \( \text{ED}(c^{\text{ID}}, L) \) by \( b \). Hence, on average, each deletion or insertion in a nonzero block of length different than 2 increases the edit distance by at most 1.

The construction of the latter, i.e., an erroneous pair, would clearly cost 2 insertions between the zeros of a buffer or by a symbol deletion from an existing nonzero pair, followed by a new nonzero symbol insertion. This is clearly less economical than ruining nonzero pairs, since in this case, on average, in order to increase \( \text{ED}(c^{\text{ID}}, L) \) by 1, the adversary must perform two edit operations.

To conclude, the accounting above indicates that every insdel error made by the adversary increases the edit distance between \( L \) and \( c^{\text{ID}} \) by at most one. It follows that after the adversary performs \( \delta \cdot (4n - 2) \) insdel errors (recall that \( c \in \mathbb{F}_4^{n-2} \)),

\[
\text{ED}(c^{\text{ID}}, L) \leq (1 - \delta_C)n + 4\delta n = (\delta_C - 13\varepsilon)n.
\]

Thus, by Theorem \ref{thm:code_correct} and since the code \( C \) can correct from \( d \) hamming errors and \( e \) erasures where \( 2d + e \leq (\delta_C - \varepsilon)n \), Steps 3 and 4 succeed.

The claim regarding the running time follows exactly as in the proof of Proposition \ref{prop:running_time}.

We now conclude the proof of Theorem \ref{thm:code_correct}

\[\square\]

\textbf{Proof of Theorem \ref{thm:code_correct}.} As before, the proof is immediate from Construction \ref{con:construction} and Proposition \ref{prop:inner_code}. The rate satisfies

\[
R_C' = \frac{R_C}{4} > \frac{1 - \delta_C - \varepsilon}{4} = \frac{1 - 4\delta - 15\varepsilon}{8} \geq \frac{1 - 4\delta}{8} - 2\varepsilon.
\]

\[\square\]

\section{Binary Linear Codes}

In this section we prove Theorem \ref{thm:binary_code}. To ease the reading, we repeat the statement of the theorem.

\textbf{Theorem 1.7.} There exists an explicit linear binary code that can correct from \( \delta < 1/54 \) fraction of worst-case deletions in \( O(n^3) \) time and has the rate \( R = (1 - 54 \cdot \delta)/1216 \).

As explained in Section \ref{sec:construction} our construction concatenates the code of Theorem \ref{thm:code_correct} with an adequately chosen short binary code and then adds buffers between the encoding of different symbols: short buffers between the encoding of \( c_i \) and \( S_i \cdot c_i \) and long buffers between the encodings of \( S_i \cdot c_i \) and \( c_{i+1} \). The specially tailored inner code is a linear binary code that can correct from a small fraction of insdel errors and has the property that, with the exception of the zero word, no codeword has large runs of zeroes. We shall prove that such codes exist and then construct one greedily.

\subsection{The inner code}

The following proposition describes the properties that our inner code should possess and is proved using the probabilistic method. As the code has a fixed length, we shall use the brute force algorithm to construct it.
Proposition 3.1. Set \( \delta_{in} = 1/6 \) and \( \rho = 1/17 \). There exists \( m_0 \in \mathbb{N} \) such that for any \( m > m_0 \), which is a multiple of \( 102^5 \), there is a binary linear code \( C_{in} \subset \{0,1\}^m \) of rate \( R_{in} = \delta_{in}/16 \) such that

1. For any two substrings \( c_s, c'_s \) of any two distinct codewords \( c \neq c' \in C_{in} \) such that \( |c_s|, |c'_s| \geq (1 - 2\delta_{in} + \rho)m \), it holds that \( \text{LCS}(c_s, c'_s) < \min(|c_s|, |c'_s|) - \rho m \).

2. Any substring \( c_{sub} \) of length \( \delta_{in}m \), of any nonzero codeword \( c \in C_{in} \) contains at least \( \rho m + 1 \) ones.

Observe that Proposition 3.1 implies that \( \text{ED}(c_s, c'_s) > 2\rho m \) so in particular we can brute force correct any \( \rho m \) insdel errors in \( C_{in} \) in time \( \exp(m) \).

Proof. Let \( G \in \mathbb{F}_2^{m \times R_{in} m} \) be a uniformly chosen random matrix. \( G \) will serve as a generator matrix for a linear code \( C \), i.e., \( C = \{Gv \mid v \in \mathbb{F}_2^{R_{in} m}\} \). We next prove that the probability that \( C \) does not satisfy any of the properties in the proposition is small.

The proof that Proposition 3.1 holds with high probability relies on the following simple and intuitive claim given in [CGHL21].

Claim 3.2 (Claim 4.1 of [CGHL21]). Let \( C \) be a random linear code and let \( c \neq c' \) be any two distinct codewords. Fix two sets of indices \( \{s_1, \ldots, s_t\}, \{s'_1, \ldots, s'_t\} \subset [n] \). Then,

\[
\Pr[\forall i \in [t], (c)_{s_i} = (c')_{s'_i}] \leq 2^{-t}.
\]

Let \( c \neq c' \in C \) be distinct and \( c_s \) and \( c'_s \) be substrings of \( c \) and \( c' \), such that \( r = \min(|c_s|, |c'_s|) \geq (1 - 2\delta_{in} + \rho)m \). Let \( \{s_1, \ldots, s_{r - \rho m}\} \) and \( \{s'_1, \ldots, s'_{r - \rho m}\} \) be two sequences of indices. The claim implies that,

\[
\Pr[\forall i \in [r - \rho m], (c)_{s_i} = (c')_{s'_i}] \leq 2^{-(r - \rho m)} \leq 2^{-(1 - 2\delta_{in})m}.
\]

By the union bound, the probability that \( c_s \) and \( c'_s \) share a common subsequence of length \( r - \rho m \) is at most

\[
\binom{r}{r - \rho m} \cdot 2^{-(1 - 2\delta_{in})m} \leq 2^{m \cdot (2h(\rho) - (1 - 2\delta_{in}))},
\]

where we used \( \binom{r}{r - \rho m} = \binom{m}{\rho m} \leq \binom{m}{\rho m} \). Now, the number of substrings of \( c \) (\( c' \)) of length \( \geq (1 - 2\delta_{in} + \rho)m \) is at most \( m^2 \cdot (2\delta_{in} - \rho) \) and the number of codewords is \( 2^{R_{in} m} \). Thus, the probability that there exist \( c \neq c' \), and substrings \( c_s \) and \( c'_s \) of \( c \) and \( c' \), respectively, such that \( |c_s|, |c'_s| \geq (1 - 2\delta_{in} + \rho)m \) and they share a common subsequence of length \( r - \rho m \) is at most

\[
2^{m \cdot R_{in}} \cdot m^2 \cdot 2^{-m \cdot (2h(\rho) - (1 - 2\delta_{in}))} = 2^{m \cdot (R_{in} + h(\rho) - (1 - 2\delta_{in})/2 + O(\log m)/m)}.
\]

Thus, as long as

\[
R_{in} + h(\rho) - (1 - 2\delta_{in})/2 < 0,
\]

\(5\)We require this to ensure that both \( \rho m \) and \( \delta_{in} m \) are integers, in order to avoid the use of ceilings and floors.
there exists $m'_0 \in \mathbb{N}$ such that for every integer $m \geq m'_0$, the probability that Proposition 3.1 does not hold is smaller than $1/4$.

To prove that Proposition 3.1 holds with high probability, consider any $0 \neq v \in \mathbb{F}_2^{R_{in}m}$. As $G$ was chosen uniformly at random, $Gv$ is uniform random vector in $\mathbb{F}_2^{m}$. The probability that $Gv$ contains a substring of length $\delta_{in}m$ that has $\leq \rho m$ ones is at most

$$m \cdot \sum_{i=0}^{\rho m} \binom{\delta_{in}m}{i} 2^{-\delta_{in}m} \leq m(\rho m + 1) \cdot \left( \frac{\delta_{in}m}{\rho m} \right)^{\rho m} \leq 2^{\delta_{in}m(-1+h(\frac{\rho}{\delta_{in}})+O(\log(m)))}. $$

Thus, by the union bound, the probability that there exists $v \in \mathbb{F}_2^{R_{in}m} \setminus \{0\}$, such that $Gv$ contains a substring of length $\delta_{in}m$ with $\leq \rho m$ ones is at most

$$2^m(R_{in} - \delta_{in} + \delta_{in}h\left(\frac{\rho}{\delta_{in}}\right) + O(\log(m))).$$

Hence, if

$$R_{in} - \delta_{in} + \delta_{in}h\left(\frac{\rho}{\delta_{in}}\right) < 0 \quad (5)$$

then there exists $m'_0 \in \mathbb{N}$ such that for every integer $m \geq m'_0$, the probability that $C$ does not satisfy this property is $\leq 1/4$.

It can be verified that for $\delta_{in} = 1/6$, $\rho = 1/17$, $R_{in} = \delta_{in}/16$, and $m_0 = \max(m'_0, m'_0')$, inequalities (4) and (5) hold true and therefore the probability that a random code $C$ satisfies both properties is at least $1/2$ and the proposition follows.

Construction and decoding To explicitly construct codes as in Proposition 3.1 we simply go over all possible linear codes and pick one that satisfies both properties. This requires $\exp(m^2)$ many steps. In our final construction we need $m = O(\log(1/\varepsilon_{out}))$ and hence the cost of constructing the inner code is $\exp(\log^2(1/\varepsilon_{out}))$.

Similarly, we decode from deletions using the following brute force algorithm: Set $L'$ to be an empty list. On input $\hat{c}$, the algorithm runs over every codeword $c \in C$ and checks if $\hat{c}$ is a subsequence of $c$. If the answer is yes and $c$ is not in $L'$, then the algorithm adds $c$ to $L'$. If $L'$ contains only $c$, then the algorithm returns $c$. Otherwise, it returns $\perp$. Clearly, the running time of this algorithm is $\exp(m) = \text{poly}(1/\varepsilon_{out})$.

Remark 3.3. An important observation is that our decoding algorithm cannot output a wrong answer. Indeed, if $\hat{c}$ was obtained from $c$ by performing any number of deletions, then $c$ will be one of the codewords in $L'$ (as $\hat{c}$ is a subsequence of $c$).

3.2 Construction of our code

Let $\delta_{out} > 0$ and $\varepsilon_{out} < \delta_{out}/1400$ small enough. Let $C_{out} \subset \mathbb{F}_q^n$ be the code given in Theorem 1.6 with parameters $\delta = \delta_{out}$ and $\varepsilon = \varepsilon_{out}$. Recall that the rate of $C_{out}$ is $R_{out} = (1 - \delta_{out})/4 - \varepsilon_{out}$ and the code is defined over the alphabet $\mathbb{F}_q$ where $q = \text{poly}(1/\varepsilon_{out})$. Denote $k = R_{out} \cdot n$. Let $C_{in} : \{0,1\}^m \rightarrow \{0,1\}^m$ be the code obtained in Section 3.1, where $m$ is such that $R_{in} m = \log(q)$ (we pick $\varepsilon_{out}$ small enough so that $m \geq m_0$ as in Proposition 3.1).

Construction 3.4. The encoding works as follows. Given a message $x \in \mathbb{F}_q^k$ we:
1. Encode $x$ using the outer code $C_{\text{out}}$ to obtain $\sigma = C_{\text{out}}(x)$. Denote
\[
\sigma = ((\sigma_1, S_1 \cdot \sigma_1), \ldots, (\sigma_n, S_n \cdot \sigma_n)).
\]

2. Let $0^{(\text{in})}$ denote a string of $2\delta_{\text{in}}m$ many zeroes. Encode every symbol $(\sigma_i, S_i \cdot \sigma_i)$ using the inner code to obtain $(C_{\text{in}}(\sigma_i), C_{\text{in}}(S_i \cdot \sigma_i))$ and place the string $0^{(\text{in})}$ between $C_{\text{in}}(\sigma_i)$ and $C_{\text{in}}(S_i \cdot \sigma_i)$. We refer to those $0^{(\text{in})}$ strings as inner buffers. At the end of this step we have the string
\[
C_{\text{in}}(\sigma_1) \circ 0^{(\text{in})} \circ C_{\text{in}}(S_1 \cdot \sigma_1) \circ \ldots \circ C_{\text{in}}(\sigma_n) \circ 0^{(\text{in})} \circ C_{\text{in}}(S_n \cdot \sigma_n).
\]

3. Let $0^{(\text{out})}$ denote a string of $5\delta_{\text{in}}m$ many zeroes. Place the string $0^{(\text{out})}$ between every two adjacent symbols of the form $C_{\text{in}}(S_i \cdot \sigma_i) \circ C_{\text{in}}(\sigma_{i+1})$ to get
\[
C_{\text{in}}(\sigma_1) \circ 0^{(\text{in})} \circ C_{\text{in}}(S_1 \cdot \sigma_1) \circ 0^{(\text{out})} \circ \ldots \circ C_{\text{in}}(\sigma_n) \circ 0^{(\text{in})} \circ C_{\text{in}}(S_n \cdot \sigma_n).
\]

We refer to those $0^{(\text{out})}$ strings as outer buffers.

The encoding of $x$ is the string
\[
\text{ENC}(x) = C_{\text{in}}(\sigma_1) \circ 0^{(\text{in})} \circ C_{\text{in}}(S_1 \cdot \sigma_1) \circ 0^{(\text{out})} \circ \ldots \circ C_{\text{in}}(\sigma_n) \circ 0^{(\text{in})} \circ C_{\text{in}}(S_n \cdot \sigma_n).
\]

Rate: The length of the codewords is $2mn + 2\delta_{\text{in}}mn + 5\delta_{\text{in}}m(n - 1)$ bits. Recalling that $\log(q) = m \cdot R_{\text{in}}$ we get
\[
R = \frac{\log(q \cdot R_{\text{out}})}{2mn + 2\delta_{\text{in}}mn + 5\delta_{\text{in}}m(n - 1)} > \frac{R_{\text{in}} \cdot R_{\text{out}}}{2 + 7\delta_{\text{in}}}. \quad (6)
\]

The decoding algorithm is given in Algorithm 3.4.

3.3 Analysis

Proposition 3.5. The code defined in Construction 3.4 can correct from $\rho \delta_{\text{out}}mn$ adversarial deletions, using Algorithm 3.4 in $O(n^3)$ time.

Proof. Let $x \in F_q^k$ be a message and denote by $\sigma := ((\sigma_1, S_1 \cdot \sigma_1), \ldots, (\sigma_n, S_n \cdot \sigma_n))$, the outer codeword corresponding to $x$, i.e., $\sigma = C_{\text{out}}(x)$. We first note that if $x$ is the zero message then since the adversary is allowed to perform only deletions to ENC($x$), the input to the algorithm is a single run of zeros. Therefore the algorithm will output the zero message as required. Thus, from now on, we assume that $x$ is not the zero message.

We will upper bound the edit distance between $\sigma$ and $L$ that is obtained after performing step 3 of Algorithm 3.4. If it holds that $\text{ED}(\sigma, L) \leq \delta_{\text{out}}n$, then the decoding succeeds since our outer code, $C_{\text{out}}$, can correct from $\delta_{\text{out}}n$ insdel errors.

Before we continue with the proof, we note that the outer codeword, $\sigma$, might have zero symbols (which are of the form $(0, 0)$). Note that such a symbol is encoded, by the inner code, to a long run of zeros, which is then interpreted by our algorithm as an outer
**Algorithm 3:** Decoding algorithm for Construction 3.4

**input:** Binary string $y$ which is the output of the deletion adversary on $\text{ENC}(x)$.

**output:** A message $x' \in \mathbb{F}_q^k$.

[0] Set $L$ to be the empty list.

[1] **if** $y$ is a single run of zeros **then**
    **output** $\overline{0} \in \mathbb{F}_q^k$ and return

[2] Every run of zeros of length at least $4\delta_m$ is identified as an outer buffer.
Let $r_1, \ldots, r_t$ be the strings between the outer buffers.

[3] **for every** $r_j$ **do**
    Every run of zeros of length at least $\delta_m$ and less than $4\delta_m$ is identified as an inner buffer.
    **if** exactly 1 inner buffer was identified **then**
    Denote by $c_j$ the string before the inner buffer and by $c'_j$ the string after the inner buffer. In particular $r_j = c_j \circ \text{(identified inner buffer)} \circ c'_j$.
    **if** $m - 2\delta_m < |c_j| \leq m$ and $m - 2\delta_m < |c'_j| \leq m$ **then**
    $a = \text{Dec}(c_j)$ and $b = \text{Dec}(c'_j)$.
    **if** $a$ is not $\perp$ and $b$ is not $\perp$ **then**
    Add to $L$ the tuple $(a, b)$.

buffer. As can be seen in the proof of Theorem 1.6 (see Remark 2.4), we only care about nonzero symbols. Namely, if we denote by $\sigma^0$ the string obtained from $\sigma$ by deleting all the zero symbols, then as long as $\text{ED}(\sigma^0, L) < \delta_{\text{out}}n$, the decoding algorithm succeeds. Thus, we do not need to insert these zero symbols to $L$.

Assume then that $x \neq 0$. In Step 2 the decoding algorithm identifies outer buffers. We say that the algorithm identified correctly the $i$th outer buffer if in Step 2 it identified an outer buffer that contains one of the surviving symbols of the $i$th outer buffer of $\text{ENC}(x)$, and that contains no symbol of any other outer buffer of $\text{ENC}(x)$. We call such an identified outer buffer a **genuine outer buffer**. Observe, that if the $i$th outer symbol is $\sigma_i = (0, 0)$, then the algorithm may identify the entire run between the $(i - 1)$th and the $i$th outer buffers as a single outer buffer. In this case, too we say that this is a genuine outer buffer. The reason for that will become clear during the analysis. In a nutshell, the reason for not treating it as an erroneous buffer follows from the discussion above that shows that our algorithm ignores the zero outer symbol (see Remark 2.4). In all other cases, we say that the decoder identified a **fake outer buffer**. We call an outer buffer that was not identified as an outer buffer (because the adversary deleted many 0s from it) a **corrupted outer buffer**.

After identifying the outer buffers in Step 2 we get $t$ strings $r_1, \ldots, r_t$. We distinguish
between three different types of $r_j$s, depending on the outer buffers that the algorithm identified:

Type-1 $r_j$ – there exists an $i \in [n - 1]$ such that the algorithm identified the $(i - 1)$th genuine outer buffer before $r_j$ and the $i$th genuine outer buffer after $r_j$. If $j = 1 (t)$ then we require the algorithm to identify only the right (left) outer buffer.

Type-2 $r_j$ – if the buffers surrounding $r_j$ are genuine outer buffers that do not correspond to consecutive outer buffers in ENC($x$).

Type-3 $r_j$ – if at least one of the buffers surrounding $r_j$ is a fake outer buffer.

We first study how the adversary can create a Type-1 $r_j$ that is not decoded correctly in Step 3. In what follows, for a substring $s$ of ENC($x$), we denote with $\tilde{s}$ the remaining subsequence of $s$ after the deletions performed by the adversary.

**Type-1 $r_j$** In this case, $r_j$ is the form

$$r_j = \overline{C_{in}(\sigma_i)} \circ \overline{0^{(in)}} \circ \overline{C_{in}(S_i \cdot \sigma_i)},$$

and we assume that the (original) $i$th buffer preceding $r_j$ and the $(i + 1)$th buffer following $r_j$ were identified by the algorithm.

We say that $r_j$ is a surviving outer symbol if a single inner buffer was identified inside $r_j$ (thus $r_j = c_j \circ (\text{identified inner buffer}) \circ c'_j$), and the decoding algorithm of the inner code returns $\sigma_i$ and $S_i \cdot \sigma_i$ when given $c_j$ and $c'_j$, respectively. If in Step 3 the algorithm adds to $L$ the tuple $(a, b) \neq (\sigma_i, S_i \cdot \sigma_i)$, when going over $r_j$, then we call $r_j$ a fake outer symbol. Note that the algorithm can also ignore $r_j$ in Step 3 and in this case, we call $r_j$ an ignored outer symbol. For example, if $r_j$ contains several runs of zeros of length $\geq \delta_{in}m$, then several inner buffers are identified inside $r_j$, in which case the algorithm will not add anything to $L$.

Our objective is to show that the adversary has to perform at least $\rho m + 1$ deletions to $C_{in}(\sigma_i) \circ \overline{0^{(in)}} \circ C_{in}(S_i \sigma_i)$ in order to create a Type-1 $r_j$ that gets ignored by our algorithm and at least $\delta_{in}m + \rho m$ deletions in order to create a Type-1 $r_j$ that is a fake outer symbol. We say that the algorithm identified correctly the inner buffer if exactly one inner buffer was identified inside $r_j$ and at least one of the bits in the identified inner buffer belongs to the original inner buffer.

The following claim shows that if the inner buffer was identified correctly and the adversary performed at most $\rho m$ deletions to each of the inner codewords, then the decoding algorithm of the inner code successfully decodes $c_j$ and $c'_j$.

**Claim 3.6.** Assume that the algorithm identified correctly the inner buffer inside $r_j$ (thus, $r_j = c_j \circ (\text{identified inner buffer}) \circ c'_j$). Then, as long as the adversary performed $\leq \rho m$ deletions to $C_{in}(\sigma_i) \circ C_{in}(S_i \cdot \sigma_i)$, the decoding algorithm of the inner code, outputs correctly $\sigma_i$ ($S_i \cdot \sigma_i$) when given $c_j$ ($c'_j$).

**Proof.** First, note that it may be the case that a string of 0s of an inner codeword (i.e., of $C_{in}(\sigma_i)$ or of $C_{in}(S_i \cdot \sigma_i)$) are identified as a part of the inner or outer buffers. This
is because our algorithm identifies buffers whenever it encounters a long enough run of zeros. Therefore, if $C_{in}(\sigma_i)$ starts with a run of zeros, then this run is identified by our algorithm as part of the first outer buffer. The same phenomenon happens if $C_{in}(\sigma_i)$ ends with a run of zeros, only this time the zeroes are identified as part of the inner buffer. Denote by $C_{in}(\sigma_i)'$ the substring of $C_{in}(\sigma_i)$ obtained by deleting the first and last run of zeros. By Proposition 3.1(2), $C_{in}(\sigma_i)'$ is of length $\geq (1 - 2(\delta_{in} - \rho))m$.

Note that the adversary has the option to delete 1s from the beginning (or end) of $C_{in}(\sigma_i)'$ and as a result, further 0s will be identified as part of a buffer by the algorithm. For example, assume 11010010 to be the first eight bits of $C_{in}(\sigma_i)'$ and further assume that the adversary deletes the first three 1s from the left. In this case, we have 11010010, where the red 1s were deleted by the adversary and the blue 0s are interpreted, by the algorithm, as part of the left outer buffer. Denote by $b_1$ the number of consecutive 1s deleted from the beginning of $C_{in}(\sigma_i)$ and by $e_1$ the number of consecutive 1s deleted from the end of $C_{in}(\sigma_i)$ where $b_1 + e_1 \leq \rho m$, then, the number of zeros merged to the buffer is at most

$$\left\lceil \frac{(b_1 + 1)/(\rho m + 1)}{(\delta_{in}m - \rho m)} \right\rceil \left( \delta_{in}m - \rho m \right) + \left\lceil \frac{(e_1 + 1)/(\rho m + 1)}{(\delta_{in}m - \rho m)} \right\rceil \left( \delta_{in}m - \rho m \right) = 2(\delta_{in}m - \rho m).$$

Denote the resulting string (after removing the first and last runs of 0s that were created by the adversary after deleting $b_1 + e_1$ 1s) by $C_{in}(\sigma_i)''$ and note that $C_{in}(\sigma_i)''$ is a substring of $C_{in}(\sigma_i)$ of length $\geq (1 - 2\delta_{in} + \rho)m$. Now, the adversary can perform another $\rho m - (b_1 + e_1)$ deletions to the rest of the bits of $C_{in}(\sigma_i)''$. In total, LCS($c_j, C_{in}(\sigma_i)''$) $\geq |C_{in}(\sigma_i)''| - \rho m$. Proposition 3.1 guarantees that we decode this corrupted codeword successfully.

Thus, in order for the adversary to make the algorithm ignore $r_j$ or interpret it as a fake outer symbol, it must either

Case 1: delete enough 0s so that no inner buffer is identified, or

Case 2: delete many 1s so that more than one inner buffer is identified, or

Case 3: delete bits so that only a single inner buffer is identified, but that the decoding algorithm fails.

We study each of these cases separately.

Analysis of Case 1: In this case, the adversary must have deleted at least $\delta_{in}m + 1$ bits from the original inner buffer. In this case, $r_j$ is ignored by the algorithm.

Analysis of Case 2: In this case, the algorithm identifies (at least) two inner buffers in $r_j$, and as a result, ignores it. Proposition 3.1 implies that the adversary must delete at least $\rho m + 1$ many 1s from an inner codeword in order to create a second long run of 0s that is interpreted as an inner buffer.

Analysis of Case 3: We now assume that the algorithm identified a single inner buffer. If this inner buffer does not contain any bit of the original inner buffer, then, by the two previous cases, the adversary must have deleted at least $\delta_{in}m + 1$ many 0 from the original inner buffer and additionally at least $\rho m + 1$ many 1s from an inner codeword. In total,
at least \( \delta_i m + \rho m + 2 \) many bits were deleted. In this case, either \( r_j \) is ignored by the algorithm, or it becomes a fake outer symbol.

If the algorithm correctly identified the inner buffer, then Claim 3.6 implies that, for the algorithm to fail to decode, the adversary must have deleted more than \( \rho m \) bits inside \( C_i(\sigma_i) \) or \( C_i(S_i \cdot \sigma_i) \). In particular, the adversary must perform more than \( \rho m \) deletions for the decoding to fail. Notice that in this case, the decoding algorithm of the inner code will output \( \perp \) and will not return a fake outer symbol.

To conclude, if the adversary wishes to create a Type-1 \( r_j \) that is an ignored outer symbol, it needs to perform at least \( \rho m + 1 \) deletions. In order to create a Type-1 \( r_j \) that is a fake outer symbol, the adversary needs to delete at least \( \delta_i m + \rho m + 2 \) many bits.

Observe that an ignored outer symbol increases \( ED(\sigma^0, L) \) by 1 since the corresponding outer symbol, \( (\sigma_i, S_i \cdot \sigma_i) \), was not added to \( L \). A Type-1 \( r_j \) that is a fake outer symbol increases \( ED(\sigma^0, L) \) by 2 since instead of the original outer symbol, a fake outer symbol is added to \( L \). Thus, the number of deletions that the adversary has to “pay” in order to increase \( ED(\sigma^0, L) \) by 1, in the case of Type-1 \( r_j \), is at least

\[
\min \left\{ \rho m + 1, \frac{\delta_i m + \rho m + 2}{2} \right\} = \rho m + 1,
\]

where the equality follows as \( \delta_i > 2.5\rho \). Thus, in the case of Type-1 \( r_j \), it is more “economical” for the adversary to make the algorithm ignore it rather than make it a fake outer symbol.

**Type-2 \( r_j \)** In this case, we assume that \( r_j \) is such that the outer buffer identified before \( r_j \) and the outer buffer identified after \( r_j \) are genuine but not consecutive (and there is no fake outer buffer in between). Assume that the outer buffer before \( r_j \) corresponds to the \( i_1 \)th outer buffer in \( ENC(x) \) and that the outer buffer after \( r_j \) corresponds to the \( i_2 \)th original outer buffer. In particular, the \( i_2 - i_1 - 1 \) outer buffers between the \( i_1 \)th and \( i_2 \)th were corrupted by the adversary.

We now consider how many deletions the adversary had to perform in order for the algorithm to return a fake outer symbol. Note that the substring of the original codeword that starts at the first 1 following the \( i_1 \)th outer buffer and ends at the last 1 preceding the \( i_2 \)th outer buffer is of length at least

\[
2((1 - \delta_i + \rho) + 2\delta_i + 1)m + 5\delta_i m + (i_2 - i_1 - 2)(2 + 7\delta_i)m
= (i_2 - i_1)(2 + 7\delta_i)m - (7\delta_i - 2\rho)m.
\]

Observe that for the algorithm to not ignore \( r_j \) we must have that \( |r_j| < 2m + 4\delta_i m \). It follows that for the algorithm not to ignore \( r_j \), the adversary must have deleted at least

\[
(i_2 - i_1)(2 + 7\delta_i)m - (7\delta_i - 2\rho)m - (2 + 4\delta_i)m = (i_2 - i_1)(2 + 7\delta_i)m - (2 + 11\delta_i - 2\rho)m
\]

many bits. Creating such a fake outer symbol increases \( ED(\sigma^0, L) \) by \( i_2 - i_1 + 1 \) as it corresponds to deleting the outer symbols in locations \( i_1, \ldots, i_2 - 1 \) and an insertion of the fake outer symbol.

If the adversary only corrupted the outer buffers between the \( i_1 \)th and the \( i_2 \)th outer buffers, without creating a fake outer symbol, then it must have deleted at least \((i_2 - i_1 - 20\).
1)(δ_im + 1) many 0s. Indeed, to corrupt a single outer buffer (at least) δ_im + 1 many 0s have to be deleted. Such a behaviour by the adversary increases ED(σ^0, L) by i_2 − i_1 as it is equivalent to deleting the outer symbols in locations i_1, . . . , i_2 − 1.

Thus, the number of deletions that the adversary has to “pay” in order to increase ED(σ^0, L) by 1, in the case of Type-2 r_j is at least

\[
\min \left\{ \frac{(i_2 - i_1)(2 + 7δ_im)m - (2 + 11δ_im - 2ρ)m}{(i_2 - i_1 + 1)}, \frac{(i_2 - i_1 - 1)(δ_im + 1)}{(i_2 - i_1)} \right\}
\]

Observe that \((\frac{(i_2 - i_1 - 1)(δ_im + 1)}{(i_2 - i_1)} > ρm + 1\) and hence the adversary has to make more deletions in the case of Type-2 r_j than in the case of Type-1 r_j in order to increase ED(σ^0, L) by 1.

**Type-3 r_j** Let us assume without loss of generality that the outer buffer to the left of r_j is a fake outer buffer.

To create a fake outer buffer, the adversary has to create a run of 0s of length ≥ 4δ_im m such that all the bits in this run do not belong to any outer buffer in ENC(x) (or that belong to two different outer buffers in ENC(x). We treat this case later). The adversary faces two options; it can either merge many 0s to an inner buffer or create a run of 0s of length ≥ 4δ_im m inside an inner codeword. By Proposition 3.1[2], the second case requires at least 4ρm + 4 many deletions. In the first case, the adversary needs to merge ≥ 2δ_im m many 0s to an inner buffer. We claim that in this case, it must delete more than ρm + 1 many 1s from the inner codewords. Indeed, by Proposition 3.1[2], any δ_im m coordinates of an inner codeword contain at least ρm + 1 many 1s. As at least δ_im m 0s must come from either the inner codeword to the left of the inner buffer or from the one to the right of the inner buffer, the claim follows.

Now that we know the “cost” of creating a fake outer buffer, we shall analyze several cases. Denote with i_1 the index such that the last bit of the fake outer buffer came from the encoding of (σ_i, S_i · σ_i).

1. The outer buffer to the right of r_j is a genuine outer buffer corresponding to the (i_1)th outer buffer in ENC(x): In this case it is not hard to verify that |c_j| + |c_j'| < 2m - 4δ_im m and r_j gets ignored. This increases ED(σ^0, L) by 1, and, by the analysis above, the adversary had to make at least ρm + 1 many deletions.

2. The outer buffer to the right of r_j is a genuine outer buffer, but not the i_1th one: Let us assume that the genuine outer buffer to the right of r_j is the i_2th outer buffer (observe that we must have i_2 > i_1). We now consider two subcases:

   (a) The algorithm ignored r_j: As all the outer buffers between the i_1th and the i_2th were corrupted, the adversary must have deleted at least (i_2 - i_1)(δ_im + 1) many 0s. This increases ED(σ^0, L) by at most i_2 − i_1 + 1 as it causes the deletion of all symbols in locations i_1 + 1, . . . , i_2, and potentially also the i_1th symbol. Thus, the average cost of increasing the edit distance by 1 in this case is at least \(\frac{(i_2 - i_1)(δ_im + 1)}{i_2 - i_1 + 1} > (δ_im + 1)/2 > ρm + 1\).
The algorithm decoded $r_j$ to a fake outer symbol: Similarly to the analysis of Type-2 $r_j$ we see that in this case, as the algorithm has to identify a single inner buffer inside $r_j$, and the length of $r_j$ is $|r_j| \leq 2m + 4\delta_{in} m$, the adversary must have deleted at least

$$(i_2 - i_1)(7\delta_{in} + 2)m - (2 + 4\delta_{in})m = (i_2 - i_1 - 1)(7\delta_{in} + 2)m + 3\delta_{in}m$$

many bits. This increases $\text{ED}(\sigma^0, L)$ by at most $i_2 - i_1 + 2$ since (as in the previous case) this caused at most $i_2 - i_1 + 1$ many deletions and a single insertion. Thus, the average cost of increasing the edit distance by 1 in this case is at least $\frac{(i_2 - i_1 - 1)(7\delta_{in} + 2)m + 3\delta_{in}m}{i_2 - i_1 + 2} \geq \delta_{in}m > \rho_m + 1$.

3. The outer buffer to the right of $r_j$ is also a fake outer buffer: Let us assume that the outer buffer to the right or $r_j$ was created inside the encoding of the $i_2$th outer symbol. We analyze two cases:

(a) $i_2 = i_1$: In this case, it is not hard to see that $r_j$ is too short and hence gets ignored by the algorithm. This increases $\text{ED}(\sigma^0, L)$ by 1. Note that by the analysis above, the adversary had to make at least $(4\rho_m + 4) + (\rho_m + 1) = 5\rho_m + 5$ many deletions.

(b) $i_2 > i_1$: Similar calculations as in the case of Type-2 $r_j$ show that in this case, the adversary has to make more than $\rho_m + 1$ many deletions in order to increase $\text{ED}(\sigma^0, L)$ by 1. Indeed, let us assume that the first bit in the second fake outer buffer came from $(\sigma_{i_2}, S_{i_2} \cdot \sigma_{i_2})$. It follows that in order to corrupt all the outer buffers between the $i_1$th and the $(i_2 - 1)$th outer buffers, the adversary must delete at least $(i_2 - i_1)\delta_{in}m$ many bits. In this case, if $r_j$ is not interpreted as a fake outer symbol, then $\text{ED}(\sigma^0, L)$ grew by at most $i_2 - i_1 + 1$. If $r_j$ was decoded to a fake outer symbol, then we note that it must be the case that at most one inner buffer was identified inside $r_j$. Thus, at least $(i_2 - i_1 - 1)4\delta_{in}m$ many more bits had to be deleted. In addition, we recall that at least $\rho_m + 1$ deletions occurred to create the outer buffer to the left of $r_j$ (we do not charge anything for the right one in order to avoid double-counting). Calculating, we see that the average cost of increasing the edit distance by 1 in either of the cases is larger than $\rho_m + 1$.

Finally, we note that if the fake outer buffer before $r_j$ contains bits from two different original outer buffers, the $i_1$th and the $i_2$th, then at least $2(i_2 - i_1)(1 - \delta + \rho)m$ many 1s had to be deleted. Such an operation increases the edit distance by at most $i_2 - i_1$. In addition, we have to repeat the analysis above and take into consideration the cost of creating the buffer to the right of $r_j$, and the additional effect of $r_j$ on the edit distance (i.e., whether $r_j$ was ignored or decoded as a fake outer symbol, etc.). It is clear that in this case, the cost of increasing the edit distance by 1 is much larger than $\rho_m + 1$.

In conclusion, in all cases, in order to increase $\text{ED}(\sigma^0, L)$ by 1, the adversary has to make at least $\rho_m + 1$ many deletions. Since the adversary can make at most $\delta_{out}mn$ deletions, it follows that $\text{ED}(\sigma^0, L) < \delta_{out}n$. Hence, by the assumption on the outer code, Step 4 of Algorithm 3 returns the correct message. This completes the correctness.
part of Proposition 3.5. All that is left is to analyze the running time complexity of the algorithm.

Running time: The claim about the running time follows by first noting that Step 2, in which we identify the outer buffers, runs in linear time. Secondly, for each \( r_j \), the runtime of Step 3 is determined by the cost of the brute force decoding algorithm. This algorithm runs in exponential time in \( m \), where \( m = \text{poly}(1/\varepsilon_{\text{out}}) \). Hence, Step 3 runs in time \( n \cdot \text{poly}(1/\varepsilon_{\text{out}}) \). Finally, according to Theorem 1.6, the decoding algorithm of the outer code runs in time \( O(n^3) \). In conclusion, the running time of the decoding algorithm is \( O(n^3) \). This concludes the proof of Proposition 3.5.

3.4 Proof of Theorem 1.7

Proposition 3.5 implies that the code constructed in Construction 3.4 can decode from \( \rho \delta_{\text{out}} mn \) many deletions. By Equation (6), its rate is \( \frac{R_{\text{in}} R_{\text{out}}}{2 + 7 \delta_{\text{in}}} \).

Recall that \( \varepsilon_{\text{out}} < \delta_{\text{out}}/1400 \), \( \delta_{\text{in}} = 1/6 \), \( \rho = 1/17 \), \( R_{\text{out}} = (1 - \delta_{\text{out}})/4 - \varepsilon_{\text{out}} \) and \( R_{\text{in}} = \delta_{\text{in}}/16 \). It follows that the rate of our code is

\[
R \geq \frac{R_{\text{in}} R_{\text{out}}}{2 + 7 \delta_{\text{in}}} = \frac{1}{304} \cdot \left( \frac{1 - \delta_{\text{out}} - \varepsilon_{\text{out}}}{4} \right) \\
\geq \frac{1}{304} \cdot \left( \frac{1 - 1.0029 \delta_{\text{out}}}{4} \right),
\]

and it can correct from more than \( \delta = \frac{\delta_{\text{out}} \rho}{2 + 7 \delta_{\text{in}}} > \frac{\delta_{\text{out}}}{53.84} \) fraction of worst-case deletions. Thus, we conclude that the final rate-error trade-off is

\[
R \geq \frac{1 - 5.4 \cdot \delta}{1216}.
\]

4 Reed-Solomon codes achieving the half-Singleton bound

In this section, we prove our results concerning RS-codes. Specifically, we prove that RS-codes achieve the half-Singleton bound and give some explicit constructions. The proofs will follow by standard analysis of the LCS between any two distinct codewords.

We begin by reformulating the condition on the maximum length of an LCS as an algebraic condition (invertibility of certain matrices). Then we show that an RS-code that satisfies this condition would have the maximum possible edit distance and hence would be able to decode from the maximum number of insdel errors. We remark that a similar approach already appeared in [SNW02 Section 2.2] and we shall repeat some of the details here.
4.1 An equivalent algebraic condition

The following proposition is the main result of this section as it provides a necessary and sufficient condition for an RS-code to recover from the maximum number of insdel errors. We first make the following definitions: We say that a vector of indices $I \in [n]^s$ is an increasing vector if its coordinates are monotonically increasing, i.e., for any $1 \leq i < j \leq s$, $I_i < I_j$, where $I_i$ is the $i$th coordinate of $I$. For a codeword $c$ of length $n$ and an increasing vector $I$, let $c_I$ be the restriction of $c$ to the coordinates with indices in $I$, i.e., $c_I = (c_{I_1}, \ldots, c_{I_s})$. For two vectors $I, J \in [n]^{2k-1}$ with distinct coordinates we define the following (variant of a) Vandermonde matrix of order $(2k - 1) \times (2k - 1)$ in the formal variables $X = (X_1, \ldots, X_n)$:

$$V_{I,J}(X) = \begin{pmatrix} 1 & X_{I_1} & \cdots & X_{I_1}^{k-1} & X_{J_1} & \cdots & X_{J_1}^{k-1} \\ 1 & X_{I_2} & \cdots & X_{I_2}^{k-1} & X_{J_2} & \cdots & X_{J_2}^{k-1} \\ \vdots & \vdots & \ddots & \vdots & \vdots & \vdots & \vdots \\ 1 & X_{I_{2k-1}} & \cdots & X_{I_{2k-1}}^{k-1} & X_{J_{2k-1}} & \cdots & X_{J_{2k-1}}^{k-1} \end{pmatrix}. \quad (7)$$

Proposition 4.1. Consider the $[n,k]$ RS-code defined by an evaluation vector $\alpha = (\alpha_1, \ldots, \alpha_n)$. The code can correct any $n-2k+1$ insdel errors if, and only if, for every two increasing vectors $I, J \in [n]^{2k-1}$ that agree on at most $k-1$ coordinates, $\det(V_{I,J}(\alpha)) \neq 0$.

Proof. We first prove that if the condition on the determinant holds, then the code can correct any $n-2k+1$ insdel errors. Assume that the claim does not hold; therefore, there exist two distinct codewords $c \neq c'$ whose LCS is at least $2k - 1$, i.e., $c_I = c'_I$ for two increasing vectors $I, J \in [n]^{2k-1}$. Assume further that $c$ and $c'$ are the encodings of the degree $k-1$ polynomials $f = \sum_{i=0}^{k-1} f_i x^i$ and $g = \sum_{i=0}^{k-1} g_i x^i$, respectively. If $I_\ell = J_\ell$ for at least $k$ coordinates, then for every such $\ell$

$$f(\alpha_{I_\ell}) = c_{I_\ell} = c'_{J_\ell} = g(\alpha_{I_\ell}).$$

Hence $f \equiv g$, in contradiction to the fact that $c \neq c'$. Thus, we can assume that $I, J$ agree on at most $k-1$ coordinates. In this case, $V_{I,J}(\alpha)$ is singular, since the vector $(f_0 - g_0, f_1, \ldots, f_{k-1} - g_1, \ldots, -g_{k-1})^t$ is in its right kernel, which contradicts our assumption. From Lemma 1.3 it follows that the code can correct $n-2k+1$ insdel errors.

The same argument also shows that this is a necessary condition. \qed

In [SNW02] Safavi-Naini and Wang identified (almost) the same condition (see Remark 4.2 below) and used it in their construction of traitor tracing schemes. Interestingly, the later work of [TSN07], which gave a construction of RS-codes capable of decoding from $\log(n+1) - 1$ insdel errors, did not use this condition. In particular, as far as we know, prior to this work the condition in Proposition 4.1 was not used in order to show the existence of optimal RS-codes.

The following remark explains the difference between Proposition 4.1 and the condition in [SNW02].

Remark 4.2. The main difference between the condition presented in [SNW02] and ours, is that they considered a $2k \times 2k$ matrix and a generalized RS-code. Given evaluation
points \((\alpha_1, \ldots, \alpha_n)\) and a vector with nonzero coordinates \((v_1, \ldots, v_n) \in \mathbb{F}_q^n\), the generalized \([n,k]_q\) RS-code is defined as the set of all vectors \((v_1 \cdot f(\alpha_1), \ldots, v_n \cdot f(\alpha_n))\), such that \(\deg(f) < k\). The matrix studied in [SNW02] is:

\[
V_{I,J}(X) = \begin{pmatrix}
v_{I_1} & v_{I_1} \cdot X_{I_1} & \ldots & v_{I_1} \cdot X_{I_1}^{k-1} & v_{J_1} & v_{J_1} \cdot X_{J_1} & \ldots & v_{J_1} \cdot X_{J_1}^{k-1} \\
v_{I_2} & v_{I_2} \cdot X_{I_2} & \ldots & v_{I_2} \cdot X_{I_2}^{k-1} & v_{J_2} & v_{J_2} \cdot X_{J_2} & \ldots & v_{J_2} \cdot X_{J_2}^{k-1} \\
\vdots & \vdots & \ldots & \vdots & \vdots & \vdots & \ldots & \vdots \\
v_{I_{2k}} & v_{I_{2k}} \cdot X_{I_{2k}} & \ldots & v_{I_{2k}} \cdot X_{I_{2k}}^{k-1} & v_{J_{2k}} & v_{J_{2k}} \cdot X_{J_{2k}} & \ldots & v_{J_{2k}} \cdot X_{J_{2k}}^{k-1}
\end{pmatrix}.
\] (8)

In our matrix, we saved a coordinate (which leads to optimal codes) as we did not have two columns for the free terms of \(f\) and \(g\) (as defined in the proof). In contrast, the matrix (8) has a column for the free term of \(f\) (the first) and a column for the free term of \(g\) (the column \((v_{J_1}, \ldots, v_{J_{2k}})\)). This also leads to the requirement that \(I\) and \(J\) are of length \(2k\) (they can still agree on at most \(k - 1\) indices).

### 4.2 Optimal Reed-Solomon codes exist

In this section, we show that over large enough fields, there exist RS-codes that attain the half-Singleton bound. Specifically, we show that there exist RS-codes that can decode from a \(\delta\) fraction of insdel errors and have rate \(R = (1 - \delta)/2 + o(1)\). For convenience, we repeat the statement of Theorem 1.8.

**Theorem 1.8.** Let \(k\) and \(n\) be positive integers such that \(2k - 1 \leq n\). For \(q = O(n^{4k-2})\) there exists an \([n,k]_q\) RS-code defined by \(n\) distinct evaluation points \(\alpha_1, \ldots, \alpha_n \in \mathbb{F}_q\), that can recover from \(n - 2k + 1\) adversarial insdel errors.

For a vector \(I\) and an element \(a\), we write \(a \in I\) if \(a\) appears in one of the coordinates of \(I\); otherwise, we write \(a \notin I\).

**Lemma 4.3.** Let \(s \geq 2\) be an integer and \(I, J \in [n]^s\) two increasing vectors that do not agree on any coordinate, i.e., \(I_i \neq J_i\) for all \(1 \leq i \leq s\). Then, there are two distinct indices \(i \neq j \in [s]\) such that \(I_i \notin J\) and \(J_j \notin I\).

**Proof.** W.l.o.g. assume that \(I_1 < J_1\). Since \(J\) is an increasing vector, \(I_1 \notin J\). In addition, some coordinate among \(\{J_1, \ldots, J_s\}\) does not appear in \(\{I_2, \ldots, I_s\}\), and any such coordinate is clearly different from \(I_1\). \(\square\)

**Proposition 4.4.** Let \(I, J \in [n]^{2k-1}\) be two increasing vectors that agree on at most \(k - 1\) coordinates. Then, in the expansion of \(\det(V_{I,J}(X))\) as a sum over permutations, there is a monomial that is obtained at exactly one of the \((2k - 1)!\) different permutations. In particular, its coefficient is \(\pm 1\), depending on the sign of its corresponding permutation. Consequently, \(\det(V_{I,J}(X)) \neq 0\).

**Proof.** The result will follow by applying induction on \(k\). For \(k = 1\), \(V_{I,J}(X) = 1\) and the result follows. For the induction step, assume it holds for \(k - 1\), and we prove it for \(k \geq 2\). Consider two coordinates \(i, j\), determined as follows. If \(I\) and \(J\) agree on some coordinate, say \(j\), then we set \(i\) to be such that \(I_i \notin J\). If they do not agree on any coordinate, then we let \(i, j\) be the two coordinates guaranteed by Lemma 4.3.
Next, in the determinant expansion of $V_{i,j}$ as a sum of $(2k - 1)!$ monomials, collect all the monomials that are divisible by $X_{i}^{k-1}X_{j}^{k-1}$, and write them together as

$$X_{i}^{k-1}X_{j}^{k-1}f(X),$$

for some polynomial $f$ in the variables $(X_{i} : i \in (I \setminus \{I_{i}\}) \cup (J \setminus \{J_{j}\}))$. Note that the choice of $i$ and $j$ guarantees that such monomials exist. Observe that any monomial in the determinant expansion of $V_{i,j}$ that is divisible by $X_{i}^{k-1}X_{j}^{k-1}$ must be obtained by picking the $(i,k)$ and the $(j, 2k - 1)$ entries in the matrix $[I,J]$. Hence, $f$ equals the determinant of the submatrix $V'_{i,j}$ obtained by removing rows $i, j$ and columns $k, 2k - 1$ from $V_{i,j}$. Note that $V'_{i,j}$ is a matrix satisfying the conditions of the claim: it is a $(2k - 3) \times (2k - 3)$ matrix defined by two increasing vectors of length $2k - 3$ that agree on at most $k - 2$ coordinates. Indeed, $i$ and $j$ were chosen so that by removing them we remove one agreement, if such existed.

Hence, by the induction hypothesis $\det(V'_{i,j})$ has a monomial $m$ (with a $\pm 1$ coefficient) that is uniquely obtained among the $(2k - 3)!$ different monomials. Therefore, $X_{i}^{k-1}X_{j}^{k-1}m$ is a monomial of $X_{i}^{k-1}X_{j}^{k-1}f$ with a $\pm 1$ coefficient. Since there is no other way to obtain this monomial in the determinant expansion of $V_{i,j}$, this monomial is uniquely obtained in $\det(V_{i,j})$, and the result follows. 

We proceed to prove Theorem 1.8 by a standard application of the Schwartz-Zippel lemma.

**Proof of Theorem 1.8** Define

$$F(X) = \prod_{i<j}(X_i - X_j) \prod_{I,J}\det(V_{i,j}(X)),$$

where the second product runs over all possible pairs of increasing vectors that agree on no more than $k-1$ coordinates. Clearly, by Proposition 1.4, $F(X)$ is a nonzero polynomial in the ring $\mathbb{Z}[X]$. Next, we make two observations regarding the polynomial $F$. First, since there are $\binom{n}{2k-1}$ increasing vectors, and the degree of each $\det(V_{i,j}(X))$ is at most $k(k-1)$, it follows that

$$\deg(F) \leq n^2 + \left(\frac{n}{2k-1}\right)^2 \cdot k(k-1) < n^{4k-2}.$$

Second, as each $\det(V_{i,j}(X))$ is a nonzero polynomial with nonzero coefficients bounded in absolute values by $(2k - 1)!$, the absolute value of any nonzero coefficient of $F$ is at most

$$\left((2k - 1)\right)! \left(\frac{n}{2k-1}\right)^2 \leq \left((2k - 1)\right)! \left(\frac{n^{4k-2}}{(2k-1)}\right)^2 < e^{n^{4k-2}}.$$

We claim that there is a prime $q$ in the range $[n^{4k-2}, 2n^{4k-2}]$ that does not divide at least one of the nonzero coefficients of the polynomial $F$. Indeed, consider a nonzero coefficient of $F$, and assume towards a contradiction that it is divisible by all such primes. Then, by the growth rate of the primorial function, the absolute value of the coefficient is $\Omega(e^{n^{4k-2}(1+o(1))})$, in contradiction. Now, it is easy to verify that $F$ is also a nonzero polynomial in $F_q[X]$, since the monomial whose nonzero coefficient is not divisible by $q$
Theorem 4.6

Consider a polynomial representation of each field element requires a super polynomial number of bits. This assignment clearly corresponds to \( n \) distinct evaluation points, which by Proposition 4.1, define an \([n, k]\) RS-code that can correct any \( n \) distinct evaluation points over a field of size \( q = O(n^{k-2}) \). Further, the above argument is a standard union bound over all variable assignments that make the matrix defined in (7) to be singular. This by no means implies that such a large finite field is necessary. For example, a similar union-bound argument that shows the existence of MDS codes would require an exponentially large field for codes with a constant rate. In contrast, it is well-known that MDS codes over linear field size exist (e.g., RS-codes). It would be interesting to explicitly construct codes with the same or even better parameters than the ones given in Theorem 1.8. Unfortunately, we could not construct such codes, and this is left as an open question for further research.

Remark 4.5. The downside of this construction is the field size \( q = n^{O(k)} \), which renders it to run in polynomial time only for \( k = O(\log(n)/\log(\log(n))) \). For larger values of \( k \), the representation of each field element requires a super polynomial number of bits.

4.3 Deterministic construction for any \( k \)

In this section, we give our main construction of an \([n, k]\) RS-code that can correct any \( n - 2k + 1 \) insdel errors. Specifically, we prove Theorem 1.9 which is restated for convenience

**Theorem 1.9.** Let \( k \) and \( n \) be positive integers, where \( 2k - 1 \leq n \). There is a deterministic construction of an \([n, k]\) RS-code that can correct from \( n - 2k + 1 \) insdel errors where \( q = O\left(n^{k^2/(2k)!^2}\right) \). The construction runs in polynomial time for \( k = O(\log(n)/\log(\log(n))) \).

**Remark 4.5.** The downside of this construction is the field size \( q = n^{O(k)} \), which renders it to run in polynomial time only for \( k = O(\log(n)/\log(\log(n))) \). For larger values of \( k \), the representation of each field element requires a super polynomial number of bits.

The Mason-Stothers theorem [Mas85, Sto81] is a result about polynomials that satisfy a non-trivial linear dependence, which is analogous to the well-known abc conjecture in number theory [Mas85, Oes88]. Our main tool is one of the many extensions in the literature to the Mason-Stothers theorem. For stating the theorem we need the following notation: For a polynomial \( Y(x) \in \mathbb{F}[x] \) over a field with \( \text{char}(\mathbb{F}) = p \neq 0 \), denote by \( \nu(Y(x)) \) the number of distinct roots of \( Y(x) \) with multiplicity not divisible by \( p \).

**Theorem 4.6** (“Moreover part” of Proposition 5.2 in [VW03]). Let \( m \geq 2 \) and \( Y_0(x) = Y_1(x) + \ldots + Y_m(x) \) with \( Y_j(x) \in \mathbb{F}_p[x] \). Suppose that \( \gcd(Y_0(x), \ldots, Y_m(x)) = 1 \), and that \( Y_1(x), \ldots, Y_m(x) \) are linearly independent over \( \mathbb{F}_p(x^p) \). Then,

\[
\deg(Y_0(x)) \leq -\left(\frac{m}{2}\right) + (m - 1) \sum_{j=0}^{m} \nu(Y_j(x)).
\]

\( \mathbb{F}_p(x^p) \) is the field of rational functions in \( x^p \). Namely, its elements are \( f(x^p)/g(x^p) \) where \( f(x), g(x) \in \mathbb{F}_p[x] \) and \( g(x) \neq 0 \).
Construction 4.7. Let $k$ be a positive integer and set $\ell = ((2k)!)^2$. Fix a finite field $\mathbb{F}_p$ for a prime $p > k^2 \cdot \ell$ and let $n$ be an integer such that $2k - 1 < n \leq p$. Let $\mathbb{F}_q$ be a field extension of $\mathbb{F}_p$ of degree $k^2 \cdot \ell$ and let $\gamma \in \mathbb{F}_q$ be such that $\mathbb{F}_q = \mathbb{F}_p(\gamma)$. Hence, each element of $\mathbb{F}_q$ can be represented as a polynomial in $\gamma$, of degree less than $k^2 \ell$, over $\mathbb{F}_p$.

Define the $[n,k]_q$ RS-code by setting $\alpha_i := (\gamma - i)^{\ell}$ for $1 \leq i \leq n$.

Proposition 4.8. The $[n,k]_q$ RS-code defined in Construction 4.7 can correct any $n - 2k + 1$ worst case insdel errors.

Proof. Let $I, J \subseteq [n]^{2k-1}$ be two increasing vectors that agree on at most $k-1$ coordinates. By Proposition 4.1 it is enough to show that $V_{I,J}(\alpha)$ is non-singular, for every such $I, J$. By the Leibniz formula, $\det(V_{I,J}(\alpha))$ is a sum of $(2k - 1)!$ terms corresponding to the different permutations. Denote these terms as $P_i(\gamma)$ for $i = 0, \ldots, (2k - 1)! - 1$. Each of the terms is a product of the sign of the corresponding permutation with some $2k - 1$ elements of the form $(\gamma - s)^{\ell_j}$, for some $s \in I \cup J$ and $0 \leq j \leq k - 1$. Assume towards a contradiction that $\det(V_{I,J}(\alpha)) = 0$ in $\mathbb{F}_q$, i.e.,

$$\det(V_{I,J}(\alpha)) = P_0(\gamma) + \ldots + P_{(2k-1)!-1}(\gamma) = 0,$$

in $\mathbb{F}_q$. By viewing every term in (9) as a univariate polynomial in $\gamma$ over $\mathbb{F}_p$, one can verify that, for any $j$, $\deg(P_j) = \ell \cdot k(k-1) < k^2 \ell$. As $\mathbb{F}_q$ is an extension of $\mathbb{F}_p$ of degree $k^2 \ell$, it follows that (9) holds also in $\mathbb{F}_p[\gamma]$, the ring of polynomials in the variable $\gamma$ over $\mathbb{F}_p$. By Proposition 4.4 the determinant of the variable matrix (7) has a monomial that is uniquely obtained and therefore has a $\pm 1$ coefficient. Assume, without loss of generality, that $P_0$ is the image of this monomial under the mapping defined by the assignment $X_i \mapsto (\gamma - i)^{\ell}$. Note that since this mapping is injective on the set of monomials, no other monomial is mapped to a scalar multiple of $P_0$. In other words, $P_0$ and $P_i$ are linearly independent for any $i \geq 1$. Assume further that (without loss of generality) $P_1, \ldots, P_m$ is a minimal subset among $\{P_i\}_{i \geq 1}$ that spans $P_0$ over $\mathbb{F}_p$. The existence of such a set follows from (9). Hence, we can write

$$P_0 = \sum_{i=1}^{m} a_i P_i,$$

where $a_i \in \mathbb{F}_p \setminus \{0\}$.

Clearly, by minimality, $P_1, \ldots, P_m$ are linearly independent over $\mathbb{F}_p$. Further, $m \geq 2$, since otherwise there would be an $i > 0$ such that $P_i$ is a multiple of $P_0$.

Since the $P_i$’s are of degree $(k(k-1))$, and $P_0$ was obtained from a unique monomial in the determinant expansion, it follows that the greatest common divisor $Q := \gcd(P_0, \ldots, P_m)$ has degree at most $\ell(k(k-1)) - 1$. By dividing (10) by $Q$ we have

$$\overline{P}_0 = \sum_{i=1}^{m} a_i \overline{P}_i,$$

where $\overline{P}_i = P_i/Q$. We will need the following claim, whose proof is deferred to the end of this section.

Claim 4.9. The polynomials $\overline{P}_1, \ldots, \overline{P}_m$ are linearly independent over $\mathbb{F}_p(\gamma^p)$. 

28
The contradiction will follow by invoking Theorem 4.6. Towards this end note that (i) By Claim 4.9 the polynomials $P_1, \ldots, P_m$ are linearly independent of $\mathbb{F}_p(\gamma^p)$ (ii) $\gcd(P_0, \ldots, P_m) = 1$, and (iii) $\nu(P_j) \leq 2k - 2$, as $P_j$ is the multiplication of $2k - 2$ non-constant polynomials, each having a single root. Thus, by (11) and Theorem 4.6

$$\ell \leq \deg(P_0) - \deg(Q) = \deg(P_0) \leq -\left(\frac{m}{2}\right) + (m - 1) \cdot \sum_{i=1}^{m} \nu(P_j)$$

$$< m^2(2k - 2)$$

$$\leq ((2k - 1)!)^2 \cdot (2k - 2),$$

which is a contradiction by the choice of $\ell$. This completes the proof.

It remains to prove Claim 4.9.

Proof of Claim 4.9. Assume towards a contradiction that there exist $\lambda_1, \ldots, \lambda_m \in \mathbb{F}_p(\gamma^p)$ not all zero, such that

$$\sum_{j=1}^{m} \lambda_j(\gamma^p)P_j(\gamma) = 0.$$  \hspace{1cm} (12)

By clearing the denominators of the $\lambda_j$’s and any common factor they might have, we can assume that the $\lambda_j$’s are polynomials in the variable $\gamma^p$ with no common factors. Since $\deg(P_j) \leq \deg(P_j) < p$, we get by reducing (12) modulo $\gamma^p$ that

$$\sum_{j=1}^{m} \lambda_j(0)P_j(\gamma) = 0.$$  \hspace{1cm} (12)

Note that $\lambda_j(0) \neq 0$ for some $j$, since otherwise $\gamma^p$ would be a common factor of the $\lambda_i$’s. Hence, $P_1, \ldots, P_m$ are linearly dependent over $\mathbb{F}_p$, which contradicts the fact that $P_1, \ldots, P_m$ are linearly independent over $\mathbb{F}_p$.

By setting $n = p$ in Construction 4.7 it follows that the field size of Construction 4.7 is roughly $n^{O(k)}$ which is much worse than the field size guaranteed by the existential result in Theorem 1.8. Note, however, that the construction runs in polynomial time for RS-codes with dimension $O(\log(n)/\log(\log(n)))$. The proof of Theorem 1.9 immediately follows.

4.4 Explicit construction for $k = 2$ with quartic field size

In this section we prove Theorem 1.10, which is restated for convenience.

Theorem 1.10. For any $n \geq 4$, there exists an explicit $[n, 2]_q$ RS-code that can correct from $n - 3$ insdel errors, where $q = O(n^4)$.

The proof of Theorem 1.10 requires the notion of and relies on constructions of Sidon spaces. This notion was introduced in a work of Bachoc, Serra and Zémor [BSZ17] in the study of an analogue of Vosper’s theorem for finite fields. Later, Roth, Raviv and Tamo gave an explicit construction of Sidon spaces and used it to provide a construction of cyclic subspace codes [RRT17]. Our construction relies on the construction of Sidon
spaces of \[\text{[RRT17]},\] which was also recently used in \[\text{[RLT21]}\] to construct a public-key cryptosystem. We believe that Sidon spaces in general, and specifically the construction of \[\text{[RRT17]}\], might find more applications in coding theory and cryptography in the future. We begin with a formal definition of a Sidon space.

**Definition 4.10.** An $\mathbb{F}_q$ linear subspace $S \subseteq \mathbb{F}_q^n$ is called a Sidon space if for any nonzero elements $a, b, c, d \in S$ such that $ab = cd$, it holds that that 

\[
\{a \mathbb{F}_q, b \mathbb{F}_q\} = \{c \mathbb{F}_q, d \mathbb{F}_q\},
\]

where $xF = \{x \cdot \alpha : \alpha \in \mathbb{F}_q\}$.

A Sidon space $S$ has the following interesting property, from which it draws its name: Given the product $a \cdot b$ of two nonzero elements $a, b \in S$, one can uniquely factor it to its two factors $a, b$ from $S$, up to a multiplication by a scalar from the base field. Clearly, this is the best one can hope for, since for any nonzero $\alpha \in \mathbb{F}_q$ the product of the elements $\alpha \cdot a, b/\alpha \in S$ also equals $a \cdot b$. A Sidon space can be viewed as a multiplicative analogue to the well-known notion of *Sidon sets*, which is a common object of study in combinatorics, see e.g. \[\text{[ET41]}\].

We proceed to present the construction of a Sidon space given in \[\text{[RRT17]}\].

**Theorem 4.11** (Construction 15, Theorem 16 in \[\text{[RRT17]}\]). Let $q \geq 3$ be a prime power, $m \in \mathbb{N}$, and $n = 2m$. Then, there exists an explicit $\gamma \in \mathbb{F}_q^n$ such that 

\[
S = \{u + u \gamma : u \in \mathbb{F}_q^m\}
\]

is an $m$-dimensional Sidon space over $\mathbb{F}_q$.

Another component in our construction is the “long” ternary code with minimum distance of at least 5, given in \[\text{[GS86]}\]. We note that we could also use the codes given in \[\text{[DD08]}\].

**Theorem 4.12.** \[\text{[GS86]}\] For every $m \geq 1$, there exits an explicit $[(3^m + 1)/2, (3^m + 1)/2 - 2m]_3$ linear code with minimum distance at least 5.

We next combine the above two algebraic objects and construct an RS-code with the desired properties.

**Construction 4.13.** For $q = 3$ and $m \in \mathbb{N}$. Let $S \subset \mathbb{F}_{3^m}$ be a $2m$-dimensional Sidon space over $\mathbb{F}_3$ as guaranteed by Theorem \[\text{4.11}\]. Let $s_1, \ldots, s_{2m}$ be a basis of $S$. Let $H = (h_{i,j})$ be a $(2m) \times ((3^m + 1)/2)$ parity check matrix of the code given in Theorem \[\text{4.12}\]. Our $[n, 2]_{3^m}$ RS-code of length $n = (3^m + 1)/2$ is defined by the evaluation points 

\[
\alpha_j = \sum_{i=1}^{2m} s_i h_{i,j} \text{ for } 1 \leq j \leq (3^m + 1)/2.
\]

In other words, we can think of our evaluation points as the $n$ coordinates of the vector $

\alpha = (s_1, \ldots, s_{2m}) \cdot H.

The following property of the evaluation points $\alpha_j$ follows easily from Theorem \[\text{4.12}\].

**Lemma 4.14.** Any four distinct $\alpha_j$’s are linearly independent over $\mathbb{F}_3$. 

30
Proof. Consider four distinct $\alpha_j$’s, say $\alpha_1, \alpha_2, \alpha_3, \alpha_4$, and assume towards a contradiction that there exist $\beta_1, \ldots, \beta_4 \in \mathbb{F}_3$ not all zero, such that $\sum_{i=1}^{4} \beta_i \alpha_i = 0$. Then

$$0 = \sum_{i=1}^{4} \beta_i \alpha_i = \sum_{i=1}^{4} \beta_i \sum_{j=1}^{2m} s_j h_{j,i} = \sum_{j=1}^{2m} \sum_{i=1}^{4} \beta_i s_j h_{j,i}.$$  

Since the $s_j$’s are linearly independent over $\mathbb{F}_3$ it follows that $\sum_{i=1}^{4} \beta_i h_{j,i} = 0$ for every $j = 1, \ldots, 2m$. Hence, the four columns $h_1, h_2, h_3, h_4$ of $H$ are linearly dependent over $\mathbb{F}_3$, which contradicts the fact that the minimum distance of the code checked by $H$ is at least 5.

We proceed to prove that the constructed RS-code can decode from the maximum number of insdel errors.

**Theorem 4.15.** The $[n, 2]_{3m}$ RS-code given in Construction 4.13 can correct any $n - 3$ worst case insdel errors.

**Proof.** Assume towards a contradiction that this is not the case. Proposition 4.1 implies that there must exist two triples of distinct evaluation points $(x_1, x_2, x_3), (y_1, y_2, y_3)$, that agree on at most one coordinate, such that

$$\begin{vmatrix}
1 & x_1 & y_1 \\
1 & x_2 & y_2 \\
1 & x_3 & y_3 \\
\end{vmatrix} = 0.$$  

Equivalently, $(y_1 - y_2)(x_2 - x_3) = (y_2 - y_3)(x_1 - x_2)$. Since the $x_i$’s are distinct elements of the Sidon space $S$, $x_2 - x_3$ and $x_1 - x_2$ are nonzero elements in $S$. Similarly, $y_1 - y_2$ and $y_2 - y_3$ are nonzero elements in $S$. By definition of Sidon spaces, there exists a nonzero $\lambda \in \mathbb{F}_3$ such that

$$\lambda(y_1 - y_2) = y_2 - y_3 \text{ or } \lambda(y_1 - y_2) = x_1 - x_2,$$

which contradicts Lemma 4.14. Indeed, each of the equations implies a nontrivial linear dependence over $\mathbb{F}_3$ between at least three and at most four evaluation points (here we used the facts that the elements of each triple are distinct and that the two triples agree on at most one coordinate).

We conclude this section with the proof of Theorem 1.10.

**Proof of Theorem 1.10.** By Theorem 4.15, the code given in Construction 4.13 is an RS-code of length $n = (3^m + 1)/2$, defined over the field $\mathbb{F}_{3^m}$, which is of order $O(n^4)$, as claimed.

### 4.5 A lower bound on the field size

In Section 4.2, we proved the existence of optimal $[n, k]_q$ RS-codes for worst-case insdel errors over fields of size $q = n^{O(k)}$. This section complements this result by providing a lower bound on the field size for such codes. Specifically, we ask how large must $q$ be in an $[n, k]_q$ RS-code that can correct from $n - 2k + 1$ worst-case insdel errors. We prove the following.
Proposition 1.11. Any \([n, k]_q\) RS-code that can correct from \(n - 2k + 1\) worst case insdel errors must satisfy

\[
q \geq \frac{1}{2} \cdot \left( \frac{n}{(2k - 1)(k - 1)} \right)^{2k - 1 - 1}.
\]

Proof. Consider an \([n, k]_q\) RS-code, defined by evaluation points \(\alpha_1, \ldots, \alpha_n\), that can correct any \(n - 2k + 1\) insdel errors. For a non-constant polynomial \(f\) of degree less than \(k\) let \(V_f\) be the set of all subsequences of the codeword corresponding to \(f\), of length \(2k - 1\):

\[
V_f = \{ (f(\alpha_{i_1}), \ldots, f(\alpha_{i_{2k-1}})) : 1 \leq i_1 < \ldots < i_{2k-1} \leq n \} \subseteq \mathbb{F}_q^{2k-1}.
\]

By Lemma 1.3 since the code can decode from any \(n - 2k + 1\) insdel errors, the sets \(V_f\) and \(V_g\) for two distinct polynomials \(f, g\), are disjoint. Therefore, \(^8\)

\[
\sum_{1 \leq \deg(f) < k} |V_f| \leq q^{2k - 1}.
\]

Next, we provide a lower bound on the size of \(V_f\). For any non-constant polynomial \(f\), of degree less than \(k\), and any \(a \in \mathbb{F}_q\) there are at most \(k - 1\) indices \(i\) such that \(f(\alpha_i) = a\). Thus, for a fixed vector \((a_1, \ldots, a_{2k-1}) \in V_f\) there are at most \((k - 1)^{2k-1}\) increasing vectors of indices \((i_1, \ldots, i_{2k-1})\) such that

\[
(f(\alpha_{i_1}), \ldots, f(\alpha_{i_{2k-1}})) = (a_1, \ldots, a_{2k-1}).
\]

Therefore \(|V_f| \geq (\frac{n}{(2k - 1)(k - 1)})^{(2k - 1)}\). Combined with (13) we have

\[
\left( \frac{1}{k - 1} \right)^{2k - 1} \cdot \left( \frac{n}{2k - 1} \right) \cdot (q^k - q) \leq q^{2k - 1},
\]

By rearranging and the fact that \(q^{2k - 1}/(q^k - q) \leq 2q^{k - 1}\) for \(q, k \geq 2\), we have

\[
\left( \frac{1}{2} \right)^{k - 1} \cdot \left( \frac{n}{(2k - 1)(k - 1)} \right)^{2k - 1} \leq q
\]

As one can easily verify, this bound is rather weak, as it provides an improvement over the trivial lower bound of \(q \geq n\) only for the vanishing rate regime of \(k = O(n^{1/4})\). For codes of dimension 2, the bound implies \(q = \Omega(n^3)\), and it slowly degrades as one increases \(k\). Nevertheless, it is always at least \(\Omega(n^3)\) for any constant \(k\). It is interesting to note that by combining Proposition 1.11 and Theorem 4.15 it follows that an \([n, 2]_q\) RS-code that can decode from \(n - 3\) insdel errors requires that \(\Omega(n^3) \leq q \leq O(n^4)\). Determining the minimum possible value of \(q\) for this case is an interesting open problem.

\(^8\)This equation remains true also if we include the constant polynomials.
5 Conclusions and Open Question

In this paper, we studied linear codes that can handle insdel errors. We focused on two different problems. The first is constructing such codes over small finite fields, and the second is understanding the behavior of RS-codes against insdel errors. The main goal is, naturally, to construct codes that get close (or match) the half-Singleton bound. We proved that RS-codes could meet this bound, and for small rate, we gave explicit constructions of such RS-codes. As far as we know, this is the first explicit construction that matches this bound. Over small alphabets, we constructed linear codes that have relatively high rate compared to previous constructions. Our work leaves many open problems. We mention a few of them below:

We still do not have explicit constructions of linear codes over small fields that achieve the half-Singleton bound. As far as we know, Theorem 1.5 is the best explicit construction over small fields.

Construction 4.7 is not optimal in terms of the field size. It is a fascinating open question to find an RS-code with an optimal field size. Specifically, the challenge is to construct an RS-code that can correct from any \( n - 2k + 1 \) insdel errors, over a field of size \( O(n^{O(k)}) \) (Theorem 1.8 proves the existence of such codes).

The lower bound on the field size proved in Proposition 1.11 is far from giving a full picture of the tradeoff between dimension and field size. The natural open question is to significantly improve our lower bound or provide a better upper bound.

Finally, another interesting question is to provide an efficient decoding algorithm for our constructions of RS-codes.
