Abstract

We address the problem of model selection for the finite horizon episodic Reinforcement Learning (RL) problem where the transition kernel $P^*$ belongs to a family of models $\mathcal{P}^*$ with finite metric entropy. In the model selection framework, instead of $P^*$, we are given $M$ nested families of transition kernels $\mathcal{P}_1 \subset \mathcal{P}_2 \subset \ldots \subset \mathcal{P}_M$. We propose and analyze a novel algorithm, namely Adaptive Reinforcement Learning (General) (ARL-GEN) that adapts to the smallest such family where the true transition kernel $P^*$ lies. ARL-GEN uses the Upper Confidence Reinforcement Learning (UCRL) algorithm with value targeted regression as a blackbox and puts a model selection module at the beginning of each epoch. Under a mild separability assumption on the model classes, we show that ARL-GEN obtains a regret of $\tilde{O}(d^*_E H^2 + \sqrt{d^*_E M^*_H T})$, with high probability, where $H$ is the horizon length, $T$ is the total number of steps, $d^*_E$ is the Eluder dimension and $M^*_H$ is the metric entropy corresponding to $\mathcal{P}^*$. Note that this regret scaling matches that of an oracle that knows $P^*$ in advance. We show that the cost of model selection for ARL-GEN is an additive term in the regret having a weak dependence on $T$. Subsequently, we remove the separability assumption and consider the setup of linear mixture MDPs, where the transition kernel $P^*$ has a linear function approximation. With this low rank structure, we propose novel adaptive algorithms for model selection, and obtain (order-wise) regret identical to that of an oracle with knowledge of the true model class.

1 Introduction

A Markov decision process (MDP) [1] is a classical framework to model a reinforcement learning (RL) environment, where an agent interacts with the environment by taking successive decisions and observes rewards. One of the objectives in RL is to maximize the total reward accumulated over multiple rounds, or equivalently minimize the regret in comparison with an optimal policy [2]. Regret minimization is useful in several sequential decision-making problems such as portfolio allocation and sequential investment, dynamic resource allocation in communication systems, recommendation systems, etc. In these settings, there is no separate budget to purely explore the unknown environment; rather, exploration and exploitation need to be carefully balanced.

In many applications (e.g., AlphaGo, robotics), the space of states and actions can be very large or even infinite, which makes RL challenging, particularly in generalizing learnt knowledge across

* Equal contribution.

Preprint. Under review.
unseen states and actions. In recent years, we have witnessed an explosion in the RL literature to tackle this challenge, both in theory (see, e.g., [3–7]), and in practice (see, e.g., [8,9]). The most related work to ours is by Ayoub et al. [5], which proposes an algorithm, namely UCRL-VTR, for model-based RL without any structural assumptions, and it is based on the upper confidence RL and value-targeted regression principles. The regret of UCRL-VTR depends on the eluder dimension [10] and the metric entropy corresponding the family of distributions $\mathcal{P}$ in which the unknown transition model $P^*$ lies. In most practical cases, however, the class $\mathcal{P}$ given to (or estimated by) the RL agent is quite pessimistic; meaning that $P^*$ actually lies in a small subset of $\mathcal{P}$ (e.g., in the game of Go, the learning is possible without the need for visiting all the states [11]). This issue becomes more interpretable in the setup where $P^*$ assumes a low-rank structure via a linear model (see, e.g., [12–15]). RL problems with linear function approximation are often parameterized by a $\theta^* \in \mathbb{R}^d$. In this setting, the regret usually depends on (a) the norm $||\theta^*||$ and (b) the dimension $d$. In particular, Jia et al. [14] show that the UCRL-VTR algorithm, when instantiated in the linear setting, achieves a regret of $O(bd\sqrt{H^3 T})$, where $b$ is an upper bound over $||\theta^*||$, $H$ is the horizon length and $T$ is the total number of steps. In this setting, the choice of $||\theta^*||$ and dimension or sparsity of $\theta^*$ is crucial. If these quantities are under-specified, the regret bounds may fail to hold, and the learning algorithms may incur linear regret. Furthermore, if these quantities are over-specified (which is the case in most RL applications, e.g., the linear quadratic regulators [16]), the regret bounds are unnecessarily large. Hence, one needs algorithms that exploit the structure of the problem and adapt to the problem complexity with high confidence.

The problem of model selection can be formally stated as follows – we are given a family of $M$ nested hypothesis classes $\mathcal{P}_1 \subset \mathcal{P}_2 \subset \ldots \subset \mathcal{P}_M$, where each class posits a plausible model class for the underlying RL problem. The true model $P^*$ lies in a model class $\mathcal{P}_{m^*}$, which is assumed to be contained in the family of nested classes. Model selection guarantees refer to algorithms whose regret scales in the complexity of the smallest model class containing the true model $P^*$, even though the algorithm is not aware of that a priori. Model selection is well studied in the contextual bandit setting. In this setting, minimax optimal regret guarantees can be obtained by exploiting the structure of the problem along with an eigenvalue assumption [17,19]. Another line of work focuses on the coralling framework of [20]. These algorithms treat each of the $M$ model classes as a bandit arm and provide a meta algorithm to minimize regret [21,22].

In this work, we address the problem of model selection in RL environments. We consider both the setups where the underlying transition distribution has no structural assumption as well as when it admits a low rank function approximation. In the RL framework, the question of model selection has received little attention. Recently, Lee et al. [23] study the problem of model selection in RL with function approximation. Similar to the active-arm elimination technique employed in standard multi-armed bandit (MAB) problems [24], the authors eliminate the model classes that are dubbed misspecified, and obtain a regret of $O(T^{2/3})$. On the other hand, our framework is quite different in the sense that we consider model selection for RL with general transition structure. Moreover, our regret scales as $O(\sqrt{T})$.

Outline and contributions: The first part of the paper deals with the setup where we consider any general model class that are totally bounded, i.e., for arbitrary precision, the metric entropy is bounded. Notice that this encompasses a significantly larger class of problems compared to the problems with function approximation. Assuming a nested family of transition kernels, we propose an adaptive algorithm, namely Adaptive Reinforcement Learning-General (ARL-GEN). Assuming the transition families are well-separated, ARL-GEN constructs a test statistic and thresholds it to identify the correct family. We show that this simple scheme achieves the regret $O(d_\epsilon^2 H^2 + \sqrt{d_\epsilon^2 M^* H^2 T})$, where $d_\epsilon^2$ is the eluder dimension and $M^*$ is the metric entropy corresponding to the transition family $\mathcal{P}_{m^*}$ in which the true model $P^*$ lies. The regret bound shows that ARL-GEN adapts to the true problem complexity, and moreover, the cost of model section is only $O(\log T)$, which is minimal compared to the total regret. In the second part of the paper, we focus on the linear function approximation framework, where the transition kernel is parameterized by a vector $\theta^* \in \mathbb{R}^d$. With norm ($||\theta^*||$) and sparsity ($||\theta^*||_0$) as problem complexity parameters, we propose two algorithms, namely Adaptive Reinforcement Learning-Linear (norm) and Adaptive Reinforcement Learning-Linear (dim), respectively, that adapt to these complexities – meaning that the regret depends on the actual problem complexities $||\theta^*||$ and $||\theta^*||_0$. In these settings also, the costs of model selection are shown to be minor lower order terms.
1.1 Related work

Model selection in online learning: Model selection in the framework of bandits are only recently being studied \[23\] [17]. These works aim to identify whether a given problem instance comes from contextual or standard MAB. In the linear contextual bandit framework, with the dimension of the underlying parameter as a complexity measure, \[18, 19\] propose efficient algorithms that adapts to the true dimension of the problem. While \[18\] obtains a regret of \(O(T^{2/3})\), \[19\] obtains a \(O(\sqrt{T})\) regret (however, the regret of \[19\] depends on several problem dependent quantities and hence not instance uniform). The algorithm Corral was proposed in \[20\], where the optimal algorithm for each model classes is casted as an expert, and the forecaster obtains low regret with respect to the best expert (best model class). The generality of this framework has rendered it fruitful in a variety of different settings; for example \[20, 21\] considered unstructured MABs, which was then extended to both linear and contextual bandits and linear reinforcement learning in a series of works \[26, 22\] and lately to reinforcement learning \[23\], as mentioned previously. However, the price for this versatility is that the regret rates the cost of model selection is multiplicative rather than additive. In particular, for the special case of linear bandits and linear reinforcement learning, the regret scales as \(\sqrt{T}\) in time with an additional multiplicative factor of \(\sqrt{M}\), while the regret scaling with time is strictly larger than \(\sqrt{T}\) in the general contextual bandit.

RL with function approximation: Regret minimization in RL under function approximation is first considered in \[5\]. It makes explicit model-based assumptions and the regret bound depends on the eluder dimensions of the models. In contrast, \[13\] considers a low-rank linear transition model for the special case of linear bandits and linear reinforcement learning, the regret scales as \(1/\sqrt{T}\) in the general contextual bandit.

1.2 Preliminaries

Notations: For a positive integer \(n\), by \([n]\) we denote the set of integers \(\{1, 2, \ldots, n\}\). \(|\cdot|\) and \(\langle\cdot, \cdot\rangle\) denote \(L^2\) norm and inner product, respectively, unless otherwise specified. \(\gamma_{\text{min}}(A)\) denotes the minimum eigenvalue of the matrix \(A\). \(B^1_d\) denotes the unit ball in \( \mathbb{R}^d \) and \(S^d\) denotes the set of all \(d \times d\) positive definite matrices. For functions \(f, g : \mathcal{X} \rightarrow \mathbb{R}\), we denote \((f - g)(x) := f(x) - g(x)\) and \((f - g)^2(x) := (f(x) - g(x))^2\) for any \(x \in \mathcal{X}\). For any \(P : \mathcal{Z} \rightarrow \Delta(\mathcal{X})\), we denote \((Pf)(z) := \int_{\mathcal{X}} f(x)P(x|z)dx\) for any \(z \in \mathcal{Z}\), where \(\Delta(\mathcal{X})\) denotes the set of signed distributions over \(\mathcal{X}\).

Regret minimization in episodic MDPs: An episodic MDP is denoted by \(\mathcal{M}(S, A, H, P^\star, r)\), where \(S\) is the state space, \(A\) is the action space (both possibly infinite), \(H\) is the length of each episode, \(P^\star : S \times A \rightarrow \Delta(S)\) is an (unknown) transition kernel (a function mapping state-action pairs to signed distribution over the state space) and \(r : S \times A \rightarrow [0, 1]\) is a (known) reward function. In episodic MDPs, a (deterministic) policy \(\pi\) is given by a collection of \(H\) functions \((\pi_1, \ldots, \pi_H)\), where each \(\pi_h : S \rightarrow A\) maps a state \(s\) to an action \(a\). In each episode, an initial state \(s_1\) is first picked by the environment (assumed to be fixed and history independent). Then, at each step \(h \in [H]\), the agent observes the state \(s_h\), picks an action \(a_h\) according to \(\pi_h\), receives a reward \(r(s_h, a_h)\), and then transitions to the next state \(s_{h+1}\), which is drawn from the conditional distribution \(P^\star|s_{h+1}\) and \((s_h, a_h)\). The episode ends when \(s_{H+1}\) is reached. For each state-action pair \((s, a) \in S \times A\) and step \(h \in [H]\), we define action values \(Q_h^\pi(s, a)\) and and state values \(V_h^\pi(s)\) corresponding to a policy \(\pi\) as

\[
Q_h^\pi(s, a) := r(s, a) + \mathbb{E}\left[ \sum_{h'=h+1}^H r(s_{h'}, \pi_{h'}(s_{h'})) \mid s_h = s, a_h = a \right], \quad V_h^\pi(s) := Q_h^\pi(s, \pi_h(s)),
\]

where the expectation is with respect to the randomness of the transition distribution \(P^\star\). It is not hard to see that \(Q_h^\pi\) and \(V_h^\pi\) satisfy the Bellman equations:

\[
Q_h^\pi(s, a) = r(s, a) + (P^\star V_{h+1}^\pi)(s, a) \quad \forall h \in [H], \quad \text{with} \quad V_{H+1}^\pi := 0.
\]

A policy \(\pi^\star\) is said to be optimal if it minimizes the value for all states \(s\) and step \(h\) simultaneously, and the corresponding optimal value function is denoted by \(V_h^\pi(s) = \min_\pi V_h^\pi(s)\) for all \(h \in [H]\), where the supremum is over all (non-stationary) policies. The agent interacts with the environment for \(K\) episodes to learn the unknown transition kernel \(P^\star\) and thus, in turn, the optimal policy
π∗. At each episode k ≥ 1, the agent chooses a policy πk := (πh1k, . . . , πHk) and a trajectory (sh, ah, rh, sh+1)h∈[H] is generated. The performance of the learning agent is measured by the cumulative (pseudo) regret accumulated over K episodes, defined as

\[ R(T) := \sum_{k=1}^{K} \left[ V^∗_1(s^k_1) - V^π_k(s^k_1) \right], \]

where T = KH denotes the total number of steps in K episodes.

2 Model selection in general MDPs

In this section, we consider general MDPs without any structural assumption on the unknown transition kernel P∗. In the standard setting [5], it is assumed that P∗ belongs to a known family of transition models P. Here, in contrast to the standard setting, we do not have the knowledge of P. Instead, we are given M nested families of transition kernels P1 ⊂ P2 ⊂ . . . ⊂ PM. The smallest such family where the true transition kernel P∗ lies is denoted by Pm∗, where m∗ ∈ [M]. However, we do not know the index m∗, and our goal is to propose adaptive algorithms such that the regret depends on the complexity of the family Pm∗. In order to achieve this, we need a separability condition on the nested models. To this end, we let, for each m ∈ [M], Vm := {Vϕ,m : P ∈ Pm, h ∈ [H]} denote the set of all optimal value functions under the transition family Pm.

Assumption 1 (Separability). There exists a Δ > 0 such that for any transition kernel P ∈ Pm∗−1, value function V ∈ Vm and state-action pair (s, a), we have

\[ ((PV)(s, a) - (P∗V)(s, a)) ≥ Δ. \]

Note that separability condition is quite standard in statistics, specifically in the area of clustering and latent variable modelling [30–32]. Model selection without a separability condition is kept as an interesting future work. We also assume that given a state-action pair (s, a), the conditional variance of optimal value functions corresponding to all the model classes is bounded.

Assumption 2 (Bounded variance). There exists a σ < ∞ such that for any state-action pair (s, a) ∈ S × A and value function V ∈ VM, we have

\[ \int_S P^∗(s'|s, a) (V(s') - (P∗V)(s, a))^2 ds' = \sigma^2. \]

Note that this assumption is also quite mild and equivalent conditions appear in the context of distributed optimization [33] as well as stochastic optimization (SGD) literature [34–35]. Furthermore, in Remark [2], we show how can one relax this assumption.

2.1 Algorithm: Adaptive Reinforcement Learning - General (ARL-GEN)

In this section, we provide a novel model selection algorithm (Algorithm 1) that use successive refinements over episodes. We use UCRL-VTR algorithm of [5] as our base algorithm, and add a model selection module at the beginning of each epoch. In other words, over multiple episodes, we successively refine our estimates of the proper model class where the true transition kernel P∗ lies.

The base algorithm: UCRL-VTR, in its general form, takes a family of transition models P and a confidence level δ ∈ (0, 1] as its input. At each episode k, it maintains a (high-probability) confidence set Bk−1 ⊂ P for the unknown model P∗ and use it for optimistic planning. First, it finds the transition kernel \( P_k = \text{argmax}_{P \in B_{k-1}} V^∗_{P,k}(s^k_1) \). It then computes, at each step h, the optimal value function \( V^k_h := V^∗_{P_k,h} \) under the kernel \( P_k \) using dynamic programming. Starting with \( V^k_{H+1}(s, a) = 0 \) for all pairs (s, a), UCRL-VTR defines for all steps h = H down to 1,

\[ Q^k_h(s, a) = r(s, a) + (P_k V^k_{h+1})(s, a), \text{ and } V^k_h(s) = \max_{a \in A} Q^k_h(s, a). \tag{1} \]

It then, at each step h, takes the action that maximizes the Q-function estimate, i.e. it chooses \( a^k_h = \text{argmax}_{a \in A} Q^k_h(s^k_h, a) \). Now, the confidence set is updated using all the data gathered in the episode. First, UCRL-VTR computes an estimate of P∗ by employing a non-linear value-targeted regression model. The data of the nonlinear regression model is given by the tuple (s^k_h, a^k_h, y^k_h) j∈[k],h∈[H], where for any (h, k), we define \( y^k_h := V^k_{h+1}(s^k_{h+1}) \). Note that \( y^k_h \in [0, H] \) almost surely and \( \mathbb{E}[y^k_h | G^k_h] = (P^∗V^k_{h+1})(s^k_h, a^k_h) \) for all (h, k), where \( G^k_h \) denotes the σ-field summarizing the information available just before \( s^k_{h+1} \) is observed. This naturally leads to the estimate

\[ \hat{P}_k = \arg\min_{P \in P} \mathcal{L}_k(P), \text{ where } \mathcal{L}_k(P) := \sum_{j=1}^{H} \sum_{h=1}^{H} \left( V^j_{h+1}(s^j_{h+1}) - (P^∗V^j_{h+1})(s^j_{h+1}, a^j_{h+1}) \right)^2. \tag{2} \]
Then, with probability at least $1 - \delta$, nested function classes $\mathcal{P}_1 \subset \mathcal{P}_2 \subset \ldots \subset \mathcal{P}_M$, threshold $\gamma$.

To do model selection, we first obtain upper bounds on the test statistics

**Proof sketch.**

**Algorithm 1:** Adaptive Reinforcement Learning - General – ARL-GEN

1. **Input:** Confidence parameter $\delta$, nested function classes $\mathcal{P}_1 \subset \mathcal{P}_2 \subset \ldots \subset \mathcal{P}_M$, threshold $\gamma$
2. **for** epochs $i = 1, 2, \ldots$
3. **Set** $\tau_{i-1} = \sum_{j=1}^{i-1} k_j$
4. **for** function classes $m = 1, 2, \ldots, M$
5. **Compute** $\hat{F}_m^{(i)} = \arg\min_{P \in \mathcal{P}_m} \sum_{k=1}^{\tau_{i-1}} H \sum_{h=1}^{k} \left(V_{h+1}^k(s_h^k + (PV_{h+1}^k)(a_h^k))^2 - (\hat{P}_k V_{h+1}^k(s_h^k, a_h^k))^2\right)$
6. **Compute** $T_m^{(i)} = \frac{1}{\tau_{i-1} H} \sum_{k=1}^{\tau_{i-1}} H \sum_{h=1}^{k} \left(\sum_{j=1}^{\tau_{i-1}} H \sum_{h=1}^{k} \left(V_{h+1}^k(s_h^k + (PV_{h+1}^k)(a_h^k))^2 - (\hat{P}_k V_{h+1}^k(s_h^k, a_h^k))^2\right)\right)$
7. **end for**
8. **Set** $m^{(i)} = \min\{m \in [M] : T_m^{(i)} \leq \gamma\}$, $k_i = 2^i$ and $\delta_i = \delta/2^i$
9. **Run** UCRL-VTR for the family $\mathcal{P}_{m^{(i)}}$ for $k_i$ episodes with confidence level $\delta_i$.
10. **end for**

The confidence set is then updated as

$$B_k = \left\{ P \in \mathcal{P} \left| \sum_{j=1}^{k} \sum_{h=1}^{H} \left(\sum_{j=1}^{\tau_{i-1}} H \sum_{h=1}^{k} \left(V_{h+1}^k(s_h^k + (PV_{h+1}^k)(a_h^k))^2 - (\hat{P}_k V_{h+1}^k(s_h^k, a_h^k))^2\right)\right) \leq \beta_k(\delta) \right\}. $$

Here $\beta_k(\delta) := 8H^2 \log \left(\frac{2N(P_m, M, \alpha, \|\cdot\|_{\infty, 1})}{\delta}\right) + 4H^2 \left(2 + \sqrt{2\log \left(\frac{4kH(KH+1)}{\delta}\right)}\right)$ is the confidence width, where, for any $\alpha > 0$, $\mathcal{N}(P_m, M, \alpha, \|\cdot\|_{\infty, 1})$ denotes the $(\alpha, \|\cdot\|_{\infty, 1})$-covering number of $\mathcal{P}_m$.

Then, one can show that $P^*$ lies in the confidence set $B_k$ in all episodes $k$ with probability at least $1 - \delta$. Here, we consider a slightly different expression of $\beta_k(\delta)$ as compared to [5], but the proof essentially follows the same technique (deferred to the appendix).

**Our approach:** We consider doubling epochs - at each epoch $i \geq 1$, UCRL-VTR is run for $k_i = 2^i$ episodes. At the beginning of $i$-th epoch, using all the data of previous epochs, we add a model selection module as follows. First, we compute, for each family $\mathcal{P}_m$, the transition kernel $\hat{F}_m^{(i)}$, that minimizes the empirical loss $L_{\tau_{i-1}}(P)$ over all $P \in \mathcal{P}_m$ (see (2)), where $\tau_{i-1} := \sum_{j=1}^{\tau_{i-1}} k_j$ denotes the total number of episodes completed before epoch $i$. Next, we compute the average empirical loss $T_m^{(i)} := \frac{1}{\tau_{i-1} H} \sum_{h=1}^{\tau_{i-1}} H \left(\sum_{j=1}^{\tau_{i-1}} H \sum_{h=1}^{k} \left(V_{h+1}^k(s_h^k + (PV_{h+1}^k)(a_h^k))^2 - (\hat{P}_k V_{h+1}^k(s_h^k, a_h^k))^2\right)\right)$ for the model $\hat{F}_m^{(i)}$. Finally, we compare $T_m^{(i)}$ to a pre-calculated threshold $\gamma$, and pick the transition family for which $T_m^{(i)}$ falls below such threshold (with smallest $m$, see Algorithm 1). After selecting the family, we run UCRL-VTR for this family with confidence level $\delta_i = \frac{\delta}{2^i}$, where $\delta \in (0, 1]$ is a parameter of the algorithm.

**2.2 Analysis of ARL-GEN**

First, we present the main result of this section which states that the model selection procedure of ARL-GEN (Algorithm 1) succeeds with high probability after a certain number of epochs.

**Lemma 1 (Model selection of ARL-GEN).** Fix a $\delta \in (0, 1]$ and $\alpha > 0$. Suppose, Assumptions 1 and 2 hold and we set the threshold $\gamma = \sigma^2 + c_0/6$, where $c_0$ is a (arbitrary) small constant. Also, suppose that the separation $\Delta$ satisfies

$$\Delta \geq c_0 + \alpha \left(2H^2 \sqrt{2\log \left(\frac{2K(HH+1)}{\delta}\right)} + 4H^2\right).$$

Then, with probability at least $1 - 3M\delta$, ARL-GEN identifies the correct model class $\mathcal{P}_{m^*}$ from epoch $i \geq i^*$ when the number of episodes completed before epoch $i^*$ satisfies

$$\tau_{i^*-1} \geq C \max \left\{ H^3 \log K \log(1/\delta), H \log \left(\frac{N(\mathcal{P} M, \alpha, \|\cdot\|_{\infty, 1})}{\delta}\right) \right\},$$

where $C > 1$ is a sufficiently large universal constant.

**Proof sketch.** In order to do model selection, we first obtain upper bounds on the test statistics $T_m^{(i)}$ for model classes that includes $P^*$. We accomplish this by carefully defining a martingale difference

---

1. For any $\alpha > 0$, we call $\mathcal{P}^\alpha$ an $(\alpha, \|\cdot\|_{\infty, 1})$ cover of the family of transition kernels $\mathcal{P}$ if for any $P \in \mathcal{P}$ there exists an $P^\alpha$ in $\mathcal{P}^\alpha$ such that $\|P^\alpha - P\|_{\infty, 1} := \sup_{P, a} \int_{s'} |P^\alpha(s'|s, a) - P(s'|s, a)| ds' \leq \alpha$.

2. We have similar results for finite transition families ($|\mathcal{P}_m| < \infty$), which are deferred to the appendix.
sequence that depends on the value function estimates $V^k_{h+1}$, and invoking Azuma-Hoeffding in conjunction with Assumption[2]. We then obtain a lower bound on $T_m^{(i)}$ for model classes not containing $\mathcal{P}^*$ via leveraging Assumption[1](separability) along with Assumption[2]. Combining the above two bounds yields the desired result.

\[\text{Regret bound:} \quad \text{In order to present our regret bound, we define, for each model model class } \mathcal{P}_m, \text{ a collection of functions } f : S \times A \times V_m \to \mathbb{R} \text{ as} \]

\[\mathcal{F}_m \colon= \{ f \mid \exists P \in \mathcal{P}_m \text{ s.t. for any } (s, a, V) \in S \times A \times V_m, \ f(s, a, V) = (PV)(s, a) \}, \]

where $V_m$ is the set of optimal value functions under the transition family $\mathcal{P}_m$. By one-to-one correspondence, we have $\mathcal{F}_1 \subset \mathcal{F}_2 \subset \ldots \subset \mathcal{F}_M$, and the complexities of these function classes determine the learning complexity of the RL problem under consideration. We characterize the complexity of each function class $\mathcal{F}_m$ by its \textit{eluder dimension}, which is defined as follows.

**Definition 1** (Eluder dimension). The $\varepsilon$-eluder dimension $\dim_{\varepsilon}(\mathcal{F}_m, \varepsilon)$ of the function class $\mathcal{F}_m$ is the length of the longest sequence $\{(s_i, a_i, V_i)\}_{i=1}^{n} \subseteq S \times A \times V_m$ of state-action-optimal value function tuples under the transition family $\mathcal{P}_m$, such that for some $\varepsilon' \geq \varepsilon$ and for each $i \in \{2, \ldots, n\}$,

\[\sup_{f_1, f_2 \in \mathcal{F}_m} \left\{ (f_1 - f_2)(s_i, a_i, V_i) \mid \sqrt{\sum_{j=1}^{i-1} (f_1 - f_2)^2(s_j, a_j, V_j)} \leq \varepsilon' \right\} > \varepsilon'. \]

The notion of eluder dimension was first introduced in [10] to characterize the complexity of function classes, and since then it has been widely used [3,5,6]. We denote by $d^*_\varepsilon = \dim_{\varepsilon}(\mathcal{F}_m, 1/T)$, the $(1/T)$-eluder dimension of the function class $\mathcal{F}_m$ corresponding to the (realizable) family $\mathcal{P}_m$, where $T = KH$ denotes the total number of steps after $K$ episodes. Furthermore, we denote by $M^* = \log(\mathcal{N}(\mathcal{P}_m, 1/T, \|\cdot\|_{\infty,1}))$ the metric entropy (with scale $1/T$) of the family $\mathcal{P}_m$. Then, armed with Lemma[1] we obtain the following regret bound for ARL-GEN[4].

**Theorem 1** (Cumulative regret of ARL-GEN). Suppose the condition of Lemma[1] holds. Then, for any $\delta \in (0, 1]$, running ARL-GEN for $K$ episodes yields a regret bound

\[R(T) \leq \mathcal{O} \left( \max \left\{ H^4 \log K \log(1/\delta), H^2 \log \left( \frac{\mathcal{N}(\mathcal{P}_m, 1/T, \|\cdot\|_{\infty,1})}{\delta} \right) \right\} \right) + \mathcal{O} \left( H^2 d^*_\varepsilon \log K + H \sqrt{Td^*_\varepsilon (M^* + \log(1/\delta)) \log K (T/\delta)} \right), \]

with probability at least $1 - 3M \delta - 2\delta$.

**Remark 1.** We retain the regret bound of UCRL-VTR (see [5]), and the cost of model selection is given by the first term in the above regret expression, which has a logarithmic dependence on the total number of episodes $K$. So model selection is essentially free upto log factors.

**Remark 2.** If we relax Assumption[2] with $\int_S P^*(s'|s, a) (V(s') - (P^*V)(s, a))^2 ds' \leq \sigma^2$, then, provided $\Delta \geq c_0 + \sigma^2 + \alpha \left( 2H^2 \sqrt{2 \log \left( \frac{2KH(KH+1)}{\sigma} \right)} + 4H^2 \right)$, we retain the same regret guarantee as in Theorem[1].

### 3 Model selection in linear kernel MDPs

In this section, we consider a special class of MDPs called \textit{linear kernel MDPs} (a.k.a., linear mixture MDPs) [14]. Roughly speaking, it means that the transition kernel $P^*$ can be represented as a linear function of a given feature map $\phi : S \times A \times S \to \mathbb{R}^d$. Formally, we have the following definition.

**Definition 2** (Linear kernel MDP). An MDP $\mathcal{M} = (S, A, H, P^*, r)$ is called a $b$-bounded linear kernel MDP if there exists a known feature mapping $\phi : S \times A \times S \to \mathbb{R}^d$ and an unknown vector $\theta^* \in \mathbb{R}^d$ with $\|\theta^*\| \leq b$ such that $P^*(s'|s, a) = \langle \phi(s, a, s'), \theta^* \rangle$ for any $(s, a, s') \in S \times A \times S$.

In this setting, we do not need any separability condition like Assumption[1]. Instead, we make the following assumptions on the feature map $\phi$. To this end, for any function $f : S \to \mathbb{R}$ and any

\[\text{For ease of representation, we assume the transition kernel } P^* \text{ to be fixed for all steps } h. \text{ Our results extends naturally to the setting, where there are } H \text{ different kernels, one for each step } h. \text{ This would only add a multiplicative } \sqrt{H} \text{ factor in the regret bound (see [12]). Moreover, our results can be extended to the setting when the reward function is also unknown and model selection needs to be done for that also.} \]
We propose and analyze an algorithm (Algorithm 2), that adapts to the problem complexity.

Algorithm 2: Adaptive Reinforcement Learning - Linear (norm) – ARL-LIN(n)orm

1: **Input:** An upper bound \( b \) of \( \| \theta^* \| \), initial epoch length \( k_1 \), confidence level \( \delta \in (0, 1] \)
2: Initialize estimate of \( \| \theta^* \| \) as \( b^{(1)} = b \), set \( \delta_1 = \delta \)
3: for epochs \( i = 1, 2 \ldots \) do
4: Play UCRL-VTR-LIN with norm estimate \( b^{(i)} \) for \( k_i \) episodes with confidence level \( \delta_i \)
5: Refine estimate of \( \| \theta^* \| \) as \( b^{(i+1)} = \max_{\theta \in B_{k_i}} \| \theta \| \)
6: Set \( k_{i+1} = 2k_i \), \( \delta_{i+1} = \frac{\delta_i}{2} \)
7: end for

We emphasize that similar assumptions have featured in model selection for stochastic contextual bandits \([17–19]\). The assumption ensures that the confidence ball of the estimate of \( \theta^* \) shrinks at a certain rate, which is crucial for model selection. In fact removing such spectral assumption is an open problem \([33]\), and model selection without it remains an interesting future direction. Now, in the learning problem, the MDP is parameterized by the unknown parameter \( \theta^* \) and we denote the MDP by \( \mathcal{M}_{\theta^*} \). In what follows, we define two natural complexity measure of \( \mathcal{M}_{\theta^*} \): (a) norm \( \| \theta^* \| \), and (b) sparsity (number of non-zero coordinates) \( \| \theta^* \|_0 \), of the unknown parameter \( \theta^* \).

### 3.1 Norm as complexity measure

In this section, we define \( \| \theta^* \| \) as a natural measure of complexity of the problem. In linear kernel MDPs, if \( \theta^* \) is close to 0 (with small \( \| \theta^* \| \)), the set of states \( s^i \) for the next step will have a small cardinality. Similarly, when \( \theta^* \) is away from 0 (with large \( \| \theta^* \| \)), the above-mentioned cardinality will be quite large. We mention here, via the same set of arguments, that the sparsity of \( \theta^* \) also serves as a natural measure of complexity. We consider this in the next section.

#### 3.1.1 Algorithm: Adaptive Reinforcement Learning - Linear (norm) – ARL-LIN(n)orm

We propose and analyze an algorithm (Algorithm 2), that adapts to the problem complexity \( \| \theta^* \| \), and as a result, the regret obtained will depend on \( \| \theta^* \| \). In prior work \([14]\), usually it is assumed that \( \theta^* \) lies in a norm ball with known radius, i.e., \( \| \theta^* \| \leq b \). This is a non-adaptive algorithm and the algorithm uses \( b \) as a proxy for the problem complexity, which can be a huge over-estimate. In sharp contrast, we start with this over estimate of \( \| \theta^* \| \), and successively refine this estimate over multiple epochs. We show that this refinement strategy yields a consistent sequence of estimates of \( \| \theta^* \| \), and as a consequence, our regret bound depends on \( \| \theta^* \| \), but not on its upper bound \( b \).

The base algorithm: We take the algorithm of \([14]\) as our base algorithm, which is an adaptation of UCRL-VTR for linear kernel MDPs (henceforth, denoted as UCRL-VTR-LIN). UCRL-VTR-LIN takes the upper bound \( b \) of \( \| \theta^* \| \) and a confidence level \( \delta \in (0, 1] \) as its inputs. Now, let us have a look at how UCRL-VTR-LIN constructs the confidence ellipsoid at the \( k \)-th episode. Observe that at any step \( h \) of the \( k \)-th episode, the following holds:

\[
\langle P^*V_{h+1}^k(s_h^k, a_h^k) = \int_S V_{h+1}^k(s') \phi(s_h^k, a_h^k, s', \theta^*) ds' = \langle \phi_{V_{h+1}^k}(s_h^k, a_h^k, \theta^*) \rangle
\]

\(^4\)Note that one can also take UCRL-VTR \(^+\) algorithm of \([13]\) as a baseline algorithm since the regret of the same is near optimal. In particular, UCRL-VTR \(^+\) tracks the variance of the value function estimates along with a careful estimation of covariance matrix corresponding to the embeddings \( \phi_{V}(-) \).
where $V_{h+1}^k$ is an estimate of the value function constructed using data received before episode $k$. This naturally leads to the following estimate of $\theta^*$:

$$\hat{\theta}_k = \arg\min_{\theta \in \mathbb{R}^d} \sum_{j=1}^k \sum_{h=1}^H \left( V_{h+1}^j(s_h^j) - \langle \phi_{V_h}^j(s_h^j, a_h^j), \theta \rangle \right)^2 + \|\theta\|^2. \quad (3)$$

It is easy to see that $\hat{\theta}_k$ has a closed form expression. The confidence ellipsoid is then constructed as

$$B_k = \left\{ \theta \in \mathbb{R}^d : \|\Sigma_k^{1/2} \left( \theta - \hat{\theta}_k \right) \| \leq \beta_k(\delta) \right\},$$

where the shape parameter $\Sigma_k = I + \sum_{j=1}^k \sum_{h=1}^H \phi_{V_h}^j(s_h^j, a_h^j)\phi_{V_h}^j(s_h^j, a_h^j)^\top$ and the radius $\beta_k(\delta) = O \left((b^2 + H^2 d \log(kH)) \log^2(k^2H/\delta)\right)$. Since the confidence sets are ellipsoids, the Q-function estimates (see (1)) of UCRL-VTR-LIN at the $k$-th episode take the form

$$Q^k_h(s, a) = r(s, a) + \langle \phi_{V_h}^k(s, a), \hat{\theta}_{k-1} \rangle + \sqrt{\beta_{k-1}(\delta)} \left\| \Sigma_{k-1}^{-1/2} \phi_{V_h}^k(s, a) \right\|.$$

Using these, UCRL-VTR-LIN defines the value estimates as $V^k_h(s) = \min_{a \in A} Q^k_h(s, a)$ to keep those bounded. Then, Jia et al. [14] show that $\theta^*$ lies in the confidence ellipsoid $B_k$ in all episodes $k$ with probability at least $1 - \delta$.

**Our approach:** Similar to ARL-GEN, we consider doubling epochs - at each epoch $i \geq 1$, UCRL-VTR-LIN is run for $k_i = 2^{i-1}k_1$ episodes with confidence level $\delta_i = \frac{\delta}{\gamma_{\text{init}}}$. Suppose the hypothesis of Lemma 3 holds. Then, with probability at least $1 - \delta$ uniformly over all $k \in \{\tau_{\text{min}}(\delta), \ldots, K\}$, we have $\gamma_{\text{min}}(\Sigma_k) \geq 1 + \frac{k_{\text{in}}H}{2}$, where $\tau_{\text{min}}(\delta) := \frac{8}{\rho_{\text{min}}} \log \left( \frac{2dH \delta}{\delta} \right)$.

Now, we are in a position to present the main result of this section. We show that the norm estimates $b^{(i)}$ computed by ARL-LIN (norm) (Algorithm 2) indeed converges to the true norm $\|\theta^*\|$ at an exponential rate with high probability.

**Lemma 3 (Convergence of norm estimates).** Suppose Assumption [3] holds. Also, suppose that, for any $\delta \in (0, 1]$, the length of the initial epoch satisfies

$$k_1 \geq \max \left\{ \tau_{\text{min}}(\delta) \log (1 + K/k_1), C (b \max\{p, q\})^2 \right\},$$

where $p \approx O \left( \frac{1}{\sqrt{\rho_{\text{min}}} \delta} \right)$, $q \approx O \left( \sqrt{\frac{H \log(kH) \log^2(k^2H/\delta)}{\rho_{\text{min}}} \frac{1}{\rho_{\text{min}}}} \right)$, $\tau_{\text{min}}(\delta)$ is as defined in Lemma 2, and $C > 1$ is some sufficiently large universal constant. Then, with probability exceeding $1 - 4\delta$, the sequence $\{b^{(i)}\}_{i=1}^\infty$ converges to $\|\theta^*\|$ at a rate $O \left( \left( \frac{\delta}{2^{i/2}} \right)^{i/2} \right)$, and $b^{(i)} \leq c_1 \|\theta^*\| + c_2$, where $c_1, c_2 > 0$ are universal constants.

Armed with the above lemma, we finally focus on the regret bound for ARL-LIN (norm).

**Theorem 2 (Cumulative regret of ARL-LIN (norm)).** Fix any $\delta \in (0, 1]$, and suppose that the hypothesis of Lemma 3 holds. Then, with probability exceeding $1 - 6\delta$, ARL-LIN (norm) enjoys the regret bound

$$R(T) = O \left( \|\theta^*\| d \sqrt{H^3 T \log(k_1H) \log(k_1^2H/\delta)} \text{polylog}(K/k_1) \right),$$

where $T = KH$ denotes the total number of rounds completed after $K$ episodes.

**Remark 3 (Complexity adaptive bound).** The regret depends on $\|\theta^*\|$, the norm of the unknown parameter, instead of an upper-bound on it. Hence, our algorithm adapts to the problem complexity.
We have the following concentration result on the estimates $\hat{\theta}$

**Algorithm 3:** Adaptive Reinforcement Learning - Linear (dim) – ARL-LIN (dim)

1. **Input:** Initial phase length $k_0$, confidence level $\delta \in (0, 1]$, norm upper bound $b$
2. Initialize estimate of $\theta^*$ as $\hat{\theta}^{(0)} = 1$
3. for epochs $i = 0, 1, 2 \ldots$ do
4. Set $k_i = 3^i k_0$ and $\delta_i = \frac{\delta}{2^i}$
5. Refine estimate of non-zero coordinates: $D(i) := \{i : |\hat{\theta}^{(i)}| \geq (0.5)^i+1\}$
6. Play UCRL-VTR-LIN only restricted to $D(i)$ co-ordinates for $k_i$ episodes with norm upper bound $b$ and confidence level $\delta_i$
7. Play UCRL-VTR-LIN in full dimension for $6^i \lceil \sqrt{k_0} \rceil$ episodes starting from where we left off in epoch $i-1$ with norm upper bound $b$ and confidence level $\delta$
8. Compute an estimate of $\theta^*$ as $\hat{\theta}^{(i+1)} = \hat{\theta}_{\tau_i}$ using (3), where $\tau_i = \sum_{j=0}^{i} 6^j \lceil \sqrt{k_0} \rceil$
9. end for

**Remark 4** (Cost of model selection). Note that the regret bound here matches to that of the regret of UCRL-VTR-LIN (see [14]), and so the model selection is (order-wise) free, in terms of regret.

### 3.2 Dimension/sparsity as complexity measure

In this section, we consider the linear MDP, with dimension as a measure of complexity. We propose and analyze an adaptive algorithm that tailors to the sparsity of $\theta^*$. We denote $\bar{d}^* = \|\theta^*\|_0$.

#### 3.2.1 Algorithm: Adaptive Reinforcement Learning - Linear (dim) – ARL-LIN (dim)

Our proposed algorithm (Algorithm 3) works over multiple epochs, and we use diminishing thresholds to estimate the support of $\theta^*$. The algorithm is parameterized by the initial phase length $k_0$, and the confidence level $\delta \in (0, 1]$. ARL-LIN (Dim) proceeds in epochs numbered 0, 1, ..., increasing with time. Each epoch $i$ is divided into two phases - (i) a regret minimization phase lasting $36^i k_0$ episodes, (ii) followed by a support estimation phase lasting $6^i \lceil \sqrt{k_0} \rceil$ episodes. Thus, each epoch $i$ lasts for a total of $36^i k_0 + 6^i \lceil \sqrt{k_0} \rceil$ episodes. At the beginning of epoch $i \geq 0$, $D(i) \subseteq [d]$ denotes the set of ‘active coordinates’, namely the estimate of the non-zero coordinates of $\theta^*$, and by initialization, $D(0) = [d]$. In the regret minimization phase of epoch $i$, a fresh instance of UCRL-VTR-LIN is spawned, with the dimensions restricted only to the set $D(i)$ and confidence level $\delta_i := \frac{\delta}{2^i}$.

On the other hand, in the support estimation phase, we continue running the UCRL-VTR-LIN algorithm in full dimension, from the point where we left off in epoch $i-1$. Concretely, one should think of the support estimation phases over epochs as a single run of UCRL-VTR-LIN in the full dimension with confidence level $\delta$ and norm upper bound $b$. At the end of each epoch $i \geq 0$, let $\tau_i := \sum_{j=0}^{i} 6^j \lceil \sqrt{k_0} \rceil$ denotes total number episodes run in the support estimation phases. Then, ARL-LIN (Dim) forms an estimate of $\theta^*$ as $\hat{\theta}^{(i+1)} := \hat{\theta}_{\tau_i}$, where, for any $k \geq 1$, $\hat{\theta}_k$ is as defined in (3). The active coordinate set $D(i+1)$ for the next epoch is then the coordinates of $\hat{\theta}^{(i+1)}$ with magnitude exceeding $(0.5)^{i+1}$. By this careful choice of exploration periods and thresholds, we show that the estimated support of $\theta^*$ is equal to the true support, for all but finitely many epochs. Thus, after a finite number of epochs, the true support of $\theta^*$ locks-in, and thereafter the agent incurs the regret that an oracle knowing the true support would incur. Hence, the extra regret we incur with respect to an oracle (which knows the support of $\theta^*$) is small. We formalize these results in the next section.

#### 3.2.2 Regret Guarantee of ARL-LIN (dim)

We have the following concentration result on the estimates $\hat{\theta}^{(i)}$, which essentially implies that the support estimation phase succeeds with high probability after a certain number of epochs.

**Lemma 4.** Suppose Assumption 2 holds. Also, suppose that, for any $\delta \in (0, 1]$, the initial phase length $k_0$ satisfies $\sqrt{k_0} = \tau_{\text{min}}(\delta) + O \left(\frac{\mu^H \ln \log(2K^2/\delta) \ln(2K)}{\rho_{\text{min}}(0.5)^2} \right)$, where $\tau_{\text{min}}(\delta)$ is as defined in Lemma 2. Then, for all epochs $i \geq 10$, we have $\mathbb{P} \left(\|\hat{\theta}^{(i)} - \theta^*\|_\infty \geq (0.5)^i \right) \leq \frac{\delta}{\bar{d}^*}$. 

Armed with the above lemma, we have the following regret bound for ARL-LIN (dim).
Theorem 3 (Cumulative regret of ARL-LIN(dim)). Suppose ARL-LIN(dim) is run with parameter $k_0$ chosen above and $\delta \in (0,1)$ for $K$ episodes. Then, with probability at least $1 - 3\delta$, its regret is

$$ R(T) = O\left( \frac{H}{\gamma} k_0 + \left( bd^* \sqrt{H T} + b d H^{2} K^{1/4} \right) \operatorname{polylog}(K/k_0) \operatorname{polylog}(T/\delta) \right), $$

where $\gamma = \min \{ |\theta^*(j)| : \theta^*(j) \neq 0 \}$, where $\theta^*(j)$ denotes the $j$-th coordinate of $\theta^*$.

Remark 5 (Cost of model selection). We observe that the cost of model selection is $\tilde{O}(\frac{H}{\gamma} k_0 + b d H^2 K^{1/4})$, which has a weaker dependence on $K$ than the leading term, and hence is minor.

Remark 6. Note that the regret depends on $\gamma$, and hence it is a problem instance dependent bound.

Remark 7. In Theorem 3, we haven’t optimized over the choice of epoch lengths and dependence on $\gamma$. E.g., choosing the support estimation period as $2^{\lceil \sqrt{k_0} \rceil}$, the regret minimization period as $4^{k_0}$ and the threshold as $(0.9)^t$, one can ensure the support locks in after only $2$ epochs. However, the dependence on $\gamma$ in this case becomes worse. The support estimation period, regret minimization period and threshold selection may be kept as tuning parameters.

4 Conclusion

We address the problem of model selection for reinforcement learning problems with general model classes. We use the separability assumption crucially, and propose a provable algorithm for model selection. Moreover, for structured classes, like linear model classes, we propose algorithms with provable and sharp regret guarantees. An immediate future work is to obtain a provable model selection algorithm for reinforcement learning without separability condition. Also, we believe the $H$ dependence in the model selection cost is sub-optimal. We keep this as our future endeavors.

Appendix

A Details for Section 2

A.1 Confidence sets in UCRL-VTR

We first describe how the confidence sets are constructed in UCRL-VTR. Note that the procedure is similar to that done in [5], but with a slight difference. Specifically, we define the confidence width as a function of complexity of the transition family $P$ on which $P^*$ lies; rather than the complexity of a value-dependent function class induced by $P$ (as done in [5]). We emphasize that this small change makes the model selection procedure easier to understand without any effect on the regret.

Let us define, for any two transition kernels $P, P' \in \mathcal{P}$ and any episode $k \geq 1$, the following

$$L_k(P) = \sum_{j=1}^{k} \sum_{h=1}^{H} \left( V^j_{h+1}(s^j_{h+1}) - (P V^j_{h+1})(s^j_{h}, a^j_{h}) \right)^2,$$

$$L_k(P, P') = \sum_{j=1}^{k} \sum_{h=1}^{H} \left( (P V^j_{h+1})(s^j_{h}, a^j_{h}) - (P' V^j_{h+1})(s^j_{h}, a^j_{h}) \right)^2.$$

Then, the confidence set at the end of episode $k$ is constructed as

$$B_k = \left\{ P \in \mathcal{P} \mid L_k(P, \hat{P}_k) \leq \beta_k(\delta) \right\},$$

where $\hat{P}_k = \arg\min_{P \in \mathcal{P}} L_k(P)$ denotes an estimate of $P^*$ after $k$ episodes. The confidence width $\beta_k(\delta) \equiv \beta_k(P, \delta)$ is set as

$$\beta_k(\delta) := \begin{cases} 8H^2 \log \left( \frac{|\mathcal{P}|}{\delta} \right) & \text{if } \mathcal{P} \text{ is finite}, \\ 8H^2 \log \left( \frac{2N(P, \frac{1}{kH}, \|\cdot\|_{\infty})}{\delta} \right) + 4H^2 \left( 2 + \sqrt{2 \log \left( \frac{4kH(k+1)}{\delta} \right)} \right) & \text{if } \mathcal{P} \text{ is infinite}. \end{cases}$$
Lemma 5 (Concentration of $P^*$). For any $\delta \in (0, 1]$, with probability at least $1 - \delta$, uniformly over all episodes $k \geq 1$, we have $P^* \in B_k$.

Proof. First, we define, for any fixed $P \in \mathcal{P}$ and $(h, k) \in [H] \times [K]$, the quantity

$$Z_{h,k} := 2 \left((P^* V_{h+1}^k)(s_h^k, a_h^k) - (P V_{h+1}^k)(s_h^k, a_h^k)\right) (V_{h+1}^k(s_{h+1}^k) - (P^* V_{h+1}^k)(s_{h}^k, a_{h}^k)).$$

Then, we have

$$L_k(\hat{P}_k) = L_k(P^*) + L_k(P^*, \hat{P}_k) + \sum_{j=1}^{H} \sum_{h=1}^{k} Z_{h,j}^k \hat{P}_h.$$  \hfill (4)

Using the notation $y_h^k = V_{h+1}^k(s_h^k)$, we can rewrite $Z_{h,k}^P$ as

$$Z_{h,k}^P := 2 \left((P^* V_{h+1}^k)(s_h^k, a_h^k) - (P V_{h+1}^k)(s_h^k, a_h^k)\right) (y_h^k - \mathbb{E}[y_h^k|\mathcal{G}_{h-1}]).$$

where $\mathcal{G}_{h-1}$ denotes the $\sigma$-field summarising all the information available just before $s_{h+1}$ is observed. Note that $Z_{h,k}^P$ is $\mathcal{G}_{h-1}$-measurable. Moreover, since $V_{h+1}^k \in [0, H]$, $Z_{h,k}^P$ is $2H[P^* V_{h+1}^k](s_h^k, a_h^k) - (P V_{h+1}^k)(s_h^k, a_h^k)]$-sub-Gaussian conditioned on $\mathcal{G}_{h-1}$. Therefore, for any $\lambda < 0$, with probability at least $1 - \delta$, we have

$$\forall k \geq 1, \sum_{j=1}^{H} \sum_{h=1}^{k} Z_{h,j}^P \geq \frac{1}{\lambda} \log(1/\delta) + \frac{\lambda}{2} \cdot 4H^2 \sum_{j=1}^{H} \sum_{h=1}^{k} ((P^* V_{h+1}^k)(s_h^k, a_h^k) - (P V_{h+1}^k)(s_h^k, a_h^k))^2.$$  \hfill (5)

Setting $\lambda = -1/(4H^2)$, we obtain for any fixed $P \in \mathcal{P}$, the following:

$$\forall k \geq 1, \sum_{j=1}^{H} \sum_{h=1}^{k} Z_{h,j}^P \geq -4H^2 \log \left(\frac{1}{\delta}\right) - \frac{1}{2} L_k(P^*, P).$$  \hfill (6)

with probability at least $1 - \delta$. By construction, $\hat{P}_k \in \mathcal{P}$ and $L_k(\hat{P}_k) \leq L_k(P^*)$. Therefore, from (4), we have

$$\forall k \geq 1, L_k(P^*, \hat{P}_k) \leq 8H^2 \log \left(\frac{\|P\|}{\delta}\right)$$

with probability at least $1 - \delta$, which proves the result for finite $\mathcal{P}$.

Case 1 – finite $\mathcal{P}$: We take a union bound over all $P \in \mathcal{P}$ in (5) to obtain that

$$\forall k \geq 1, \forall P \in \mathcal{P}, \sum_{j=1}^{H} \sum_{h=1}^{k} Z_{h,j}^P \geq -4H^2 \log \left(\frac{\|P\|}{\delta}\right) - \frac{1}{2} L_k(P^*, P).$$  \hfill (7)

with probability at least $1 - \delta$. By construction, $\hat{P}_k \in \mathcal{P}$ and $L_k(\hat{P}_k) \leq L_k(P^*)$. Therefore, from (4), we have

$$\forall k \geq 1, L_k(P^*, \hat{P}_k) \leq 8H^2 \log \left(\frac{\|P\|}{\delta}\right)$$

with probability at least $1 - \delta$, which proves the result for finite $\mathcal{P}$.

Case 2 – infinite $\mathcal{P}$: Fix some $\alpha > 0$. Let $\mathcal{P}^\alpha$ denotes an $(\alpha, \|\cdot\|_{\infty, 1})$ cover of $\mathcal{P}$, i.e., for any $P \in \mathcal{P}$, there exists an $P^\alpha$ in $\mathcal{P}^\alpha$ such that $\|P^\alpha - P\|_{\infty, 1} := \sup_{s,a} \int_{s'} |P^\alpha(s'|s, a) - P(s'|s, a)| ds' \leq \alpha$.

Now, we take a union bound over all $P^\alpha \in \mathcal{P}^\alpha$ in (5) to obtain that

$$\forall k \geq 1, \forall P^\alpha \in \mathcal{P}^\alpha, \sum_{j=1}^{H} \sum_{h=1}^{k} Z_{h,j}^{P^\alpha} \geq -4H^2 \log \left(\frac{\|P^\alpha\|}{\delta}\right) - \frac{1}{2} L_k(P^*, P^\alpha).$$

with probability at least $1 - \delta$, and thus, in turn,

$$\forall k \geq 1, \forall P \in \mathcal{P}, \sum_{j=1}^{H} \sum_{h=1}^{k} Z_{h,j}^P \geq -4H^2 \log \left(\frac{\|P\|}{\delta}\right) - \frac{1}{2} L_k(P^*, P) + \zeta_k^\alpha(P).$$  \hfill (7)

with probability at least $1 - \delta$, where $\zeta_k^\alpha(P)$ denotes the discretization error:

$$\zeta_k^\alpha(P) = \sum_{j=1}^{H} \sum_{h=1}^{k} \left(Z_{h,j}^P - Z_{h,j}^{P^\alpha}\right) + \frac{1}{2} L_k(P^*, P) - \frac{1}{2} L_k(P^*, P^\alpha)$$

$$= \sum_{j=1}^{H} \sum_{h=1}^{k} \left(2y_h^k \left((P^* V_{h+1}^j)(s_h^j, a_h^j) - (P V_{h+1}^j)(s_h^j, a_h^j)\right) + \frac{1}{2} (P V_{h+1}^j)^2(s_h^j, a_h^j) - \frac{1}{2} (P^* V_{h+1}^j)^2(s_h^j, a_h^j)\right).$$

13
Since \( \|P - P^\alpha\|_{\infty,1} \leq \alpha \) and \( \|V^{k}_{h+1}\|_{\infty} \leq H \), we have
\[
\left| (P^\alpha V^{k}_{h+1})(s, a) - (PV^{k}_{h+1})(s, a) \right| \leq \alpha H ,
\]
which further yields
\[
\left| (P^\alpha V^{k}_{h+1})^2(s, a) - (PV^{k}_{h+1})^2(s, a) \right| \leq \max_{|\xi| \leq \alpha H} \left| (PV^{k}_{h+1})(s, a) + \xi \right|^2 - (PV^{k}_{h+1})(s, a)^2 \leq 2\alpha H^2 + \alpha^2 H^2 .
\]
Therefore, we can upper bound the discretization error as
\[
|\xi^\alpha(P)| \leq 2\alpha H \sum_{j=1}^{k} \sum_{h=1}^{H} |y^{j}_{h}| + \sum_{j=1}^{k} \sum_{h=1}^{H} \left( \alpha H^2 + \frac{\alpha^2 H^2}{2} \right) \leq 2\alpha H \sum_{j=1}^{k} \sum_{h=1}^{H} |y^{j}_{h} - \mathbb{E}[y^{j}_{h}|G^{k}_{h-1}]| + \sum_{j=1}^{k} \sum_{h=1}^{H} \left( 3\alpha H + \frac{\alpha^2 H^2}{2} \right) .
\]
Since \( y^{k}_{h} - \mathbb{E}[y^{k}_{h}|G^{k}_{h-1}] \) is \( \delta \)-sub-Gaussian conditioned on \( G^{k}_{h-1} \), we have
\[
\forall k \geq 1, \forall h \in [H], \ |y^{k}_{h} - \mathbb{E}[y^{k}_{h}|G^{k}_{h-1}]| \leq H \sqrt{2 \log \left( \frac{2kH(kH+1)}{\delta} \right) } \]
with probability at least \( 1 - \delta \). Therefore, with probability at least \( 1 - \delta \), the discretization error is bounded for all episodes \( k \geq 1 \) as
\[
|\xi^\alpha(P)| \leq kH \left( 2\alpha H \sqrt{2 \log \left( \frac{2kH(kH+1)}{\delta} \right) } + 3\alpha H + \frac{\alpha^2 H^2}{2} \right) \leq \alpha kH \left( 2H^2 \sqrt{2 \log \left( \frac{2kH(kH+1)}{\delta} \right) } + 4H^2 \right) ,
\]
where the last step holds for any \( \alpha \leq 1 \). Therefore, from (7), we have
\[
\forall k \geq 1, \forall P \in \mathcal{P}, \sum_{j=1}^{k} \sum_{h=1}^{H} Z^{j,P}_{h} \geq -4H^2 \log \left( \frac{|P^\alpha|}{\delta} \right) - \frac{1}{2} \mathcal{L}_k(P^*, P) - \frac{1}{2} \mathcal{L}_k(P^*, \hat{P}_k) \leq 8H^2 \log \left( \frac{2M}{\delta} \right) + 4H^2 \left( 2 + \sqrt{2 \log \left( \frac{4kH(kH+1)}{\delta} \right) } \right) ,
\]
with probability at least \( 1 - \delta \), which proves the result for infinite \( \mathcal{P} \). \( \square \)

A.2 Model selection in ARL-GEN

First, we find concentration bounds on the test statistics \( T_i^m \) for all epochs \( i \geq 1 \) and class indexes \( m \in [M] \), which are crucial to prove the model selection guarantee (Lemma3 of ARL-GEN).

1. Realizable model classes: Fix a class index \( m \geq m^* \). In this case, the true model \( P^* \in \mathcal{P}_m \).

Therefore, we can upper bound the empirical at epoch \( i \) as
\[
T_i^m \leq \frac{1}{\tau_{i-1} - H} \sum_{k=1}^{\tau_{i-1}} \sum_{h=1}^{H} \left( V^{k}_{h+1}(s^{k}_{h+1}) - (PV^{k}_{h+1})(s^{k}_{h+1}, a^{k}_{h}) \right)^2 = \frac{1}{\tau_{i-1} - H} \sum_{k=1}^{\tau_{i-1}} \sum_{h=1}^{H} \left( y^{k}_{h} - \mathbb{E}[y^{k}_{h}|G^{k}_{h-1}] \right)^2 .
\]

Now, we define the random variable \( m^{k}_{h} := (y^{k}_{h} - \mathbb{E}[y^{k}_{h}|G^{k}_{h-1}])^2 \). By Assumption2, we have \( \mathbb{E}[m^{k}_{h}|G^{k}_{h-1}] = \text{var}[y^{k}_{h}|G^{k}_{h-1}] = \sigma^2 \). Moreover, note that \( (m^{k}_{h} - \mathbb{E}[m^{k}_{h}|G^{k}_{h-1}])_{k,h} \) is a martingale difference sequence adapted to the filtration \( G^{k}_{h} \), with absolute values \( m^{k}_{h} - \mathbb{E}[m^{k}_{h}|G^{k}_{h-1}] \leq H^2 \) for
all \( k, h \). Therefore, by the Azuma-Hoeffding inequality, with probability at least \( 1 - \delta / 2^i \),

\[
\sum_{k=1}^{\tau_i-1} \sum_{h=1}^{H} m^k_h \leq \sum_{k=1}^{\tau_i-1} \sum_{h=1}^{H} E[m^k_h | G_{h-1}^k] + H^2 \sqrt{2\tau_i-1H \log(2^i/\delta)}.
\]

Now, using a union bound, with probability at least \( 1 - \delta \), for any class index \( m \geq m^* \), we have

\[
\forall i \geq 1, \quad T^{(i)}_m \leq \sigma^2 + H^{3/2} \sqrt{\frac{2\log(2^i/\delta)}{\tau_i-1}}.
\]  \((9)\)

2. **Non-realizable model classes:** Fix a class index \( m < m^* \). In this case, the true model \( P^* \notin \mathcal{P}_m \).

We can decompose the empirical risk at epoch \( i \) as \( T^{(i)}_m = T^{(i)}_{m,1} + T^{(i)}_{m,2} + T^{(i)}_{m,3} \), where

\[
T^{(i)}_{m,1} = \frac{1}{\tau_i-1H} \sum_{k=1}^{\tau_i-1} \sum_{h=1}^{H} \left( V_{h+1}^k(s^k_{h+1}) - (P^*_V)^k(s^k_{h+1}, a^k_h) \right)^2,
\]

\[
T^{(i)}_{m,2} = \frac{1}{\tau_i-1H} \sum_{k=1}^{\tau_i-1} \sum_{h=1}^{H} \left( (P^*_V)^k(s^k_{h+1}, a^k_h) - (\hat{P}^{(i)}_m)^k(s^k_{h+1}, a^k_h) \right)^2,
\]

\[
T^{(i)}_{m,3} = \frac{1}{\tau_i-1H} \sum_{k=1}^{\tau_i-1} \sum_{h=1}^{H} 2 \left( (P^*_V)^k(s^k_{h+1}, a^k_h) - (\hat{P}^{(i)}_m)^k(s^k_{h+1}, a^k_h) \right) \left( V_{h+1}^k(s^k_{h+1}) - (P^*_V)^k(s^k_{h+1}, a^k_h) \right).
\]

First, using a similar argument as in \((9)\), with probability at least \( 1 - \delta \), we obtain

\[
\forall i \geq 1, \quad T^{(i)}_{m,1} \geq \sigma^2 - H^{3/2} \sqrt{\frac{2\log(2^i/\delta)}{\tau_i-1}}.
\]

Next, by Assumption \[ \[ \] \] we have

\[
\forall i \geq 1, \quad T^{(i)}_{m,2} \geq \Delta.
\]

Now, we turn to bound the term \( T^{(i)}_{m,3} \). We consider both the cases – when \( \mathcal{P} \) is finite and when \( \mathcal{P} \) is infinite.

**Case 1 – finite model classes:** Note that \( \hat{P}^{(i)}_m \in \mathcal{P}_m \). Then, from \((8)\), we have

\[
\forall i \geq 1, \quad T^{(i)}_{m,3} \geq -\frac{4H}{\tau_i-1} \log \left( \frac{|\mathcal{P}_m|}{\delta} \right) - \frac{1}{2} T^{(i)}_{m,2}
\]

with probability at least \( 1 - \delta \). Now, combining all the three terms together and using a union bound, we obtain the following for any class index \( m \leq m^* - 1 \):

\[
\forall i \geq 1, \quad T^{(i)}_m \geq \sigma^2 + \frac{1}{2} \Delta - H^{3/2} \sqrt{\frac{2\log(2^i/\delta)}{\tau_i-1}} - \frac{4H}{\tau_i-1} \log \left( \frac{|\mathcal{P}_m|}{\delta} \right).
\]  \((10)\)

with probability at least \( 1 - 2\delta \).

**Case 2 – infinite model classes:** We follow a similar procedure, using \((8)\), to obtain the following for any class index \( m \leq m^* - 1 \):

\[
\forall i \geq 1, \quad T^{(i)}_m \geq \sigma^2 + \frac{1}{2} \Delta - H^{3/2} \sqrt{\frac{2\log(2^i/\delta)}{\tau_i-1}} - \frac{4H}{\tau_i-1} \log \left( \frac{\mathcal{N}(\mathcal{P}_m, \alpha, \|\cdot\|_{\infty,1})}{\delta} \right) - \alpha \left( 2H^2 \sqrt{2\log(2\tau_i-1H(\tau_i-1H+1)/\delta)} + 4H^2 \right)
\]

with probability at least \( 1 - 3\delta \).

A.2.1 **Proof of Lemma \[ \[ \] \]**

We are now ready to prove Lemma \[ \[ \] \] which presents the model selection Guarantee of ARL-GEN for infinite model classes \( \{\mathcal{P}_m\}_{m \in [M]} \). Here, at the same time, we prove a similar (and simpler) result for finite model classes also.
First, note that we consider doubling epochs \( k_i = 2^i \), which implies \( \tau_{i-1} = \sum_{j=1}^{i-1} k_j = \sum_{j=1}^{i-1} 2^j = 2^i - 1 \). With this, the number of epochs is given by \( N = \lfloor \log_2(K+1) - 1 \rfloor = \mathcal{O}(\log K) \). Let us now consider finite model classes \( \{P_m\}_{m \in [M]} \).

**Case 1 – finite model classes:** First, we combine (9) and (10), and take a union bound over all \( m \in [M] \) to obtain

\[
\forall m \geq m^*, \forall i \geq 1, \quad T_m^{(i)} \leq \sigma^2 + H^{3/2} \sqrt{\frac{2N \log(2/\delta)}{\tau_{i-1}}} \quad \text{and}
\]

\[
\forall m \leq m^* - 1, \forall i \geq 1, \quad T_m^{(i)} \geq \sigma^2 + \frac{1}{2} \Delta - H^{3/2} \sqrt{\frac{2N \log(2/\delta)}{\tau_{i-1}}} - \frac{4H}{\tau_{i-1}} \log \left( \frac{|P_M|}{\delta} \right)
\]

with probability at least \( 1 - 2M\delta \), where we have used that \( \log(2^i/\delta) \leq N \log(2/\delta) \) for all \( i \) and \( |P_m| \leq |P_M| \) for all \( m \). Now, suppose for some epoch \( i^* \), we have

\[
\tau_{i^* - 1} \geq C \max \left\{ 2H^3 \log K \log(2/\delta), 4H \log \left( \frac{|P_M|}{\delta} \right) \right\}
\]

where \( C > 1 \) is a sufficiently large universal constant. Then, we have

\[
\forall m \geq m^*, \forall i \geq i^*, \quad T_m^{(i)} \leq \sigma^2 + \frac{1}{\sqrt{C}} \quad \text{and}
\]

\[
\forall m \leq m^* - 1, \forall i \geq i^*, \quad T_m^{(i)} \geq \sigma^2 + \frac{1}{2\sqrt{C}} - \frac{1}{C} \geq \sigma^2 + \frac{1}{2} \Delta - \frac{2}{\sqrt{C}}
\]

with probability at least \( 1 - 2M\delta \). Note that provided, \( \Delta \geq \frac{6}{\sqrt{C}} \), and defining a threshold \( \gamma = \sigma^2 + \frac{1}{\sqrt{C}} \), we have

\[
\forall m \geq m^*, \forall i \geq i^*, \quad T_m^{(i)} \leq \gamma \quad \text{and}
\]

\[
\forall m \leq m^* - 1, \forall i \geq i^*, \quad T_m^{(i)} \geq \gamma
\]

with probability at least \( 1 - 2M\delta \). The above equation implies that \( m^{(i)} = m^* \) for all epochs \( i \geq i^* \), which, along with the choice \( c_0 = 6/\sqrt{C} \), proves an analogous result of Lemma 1 for finite model classes.

Now, we focus on infinite model classes \( \{P_m\}_{m \in [M]} \), for which Lemma 1 is stated.

**Case 2 – infinite model classes:** First, we combine (9) and (11), and take a union bound over all \( m \in [M] \) to obtain

\[
\forall m \geq m^*, \forall i \geq 1, \quad T_m^{(i)} \leq \sigma^2 + H^{3/2} \sqrt{\frac{2N \log(2/\delta)}{\tau_{i-1}}} \quad \text{and}
\]

\[
\forall m \leq m^* - 1, \forall i \geq 1, \quad T_m^{(i)} \geq \sigma^2 + \frac{1}{2} \Delta - H^{3/2} \sqrt{\frac{2N \log(2/\delta)}{\tau_{i-1}}} - \frac{4H}{\tau_{i-1}} \log \left( \frac{N(P_M, \alpha, \|\cdot\|_{\infty,1})}{\delta} \right)
\]

\[
- \alpha \left( 2H^2 \sqrt{2 \log \left( \frac{2KH(KH+1)}{\delta} \right)} + 4H^2 \right)
\]

with probability at least \( 1 - 3M\delta \). Suppose for some epoch \( i^* \), we have

\[
\tau_{i^* - 1} \geq C \max \left\{ 2H^3 \log K \log(2/\delta), 4H \log \left( \frac{N(P_M, \alpha, \|\cdot\|_{\infty,1})}{\delta} \right) \right\}
\]
where $C > 1$ is a sufficiently large universal constant. Then, we have
\[
\forall m \geq m^*, \forall i \geq i^*, \quad T_m^{(i)} \leq \sigma^2 + \frac{1}{\sqrt{C}} \quad \text{and}
\]
\[
\forall m \leq m^* - 1, \forall i \geq i^*, \quad T_m^{(i)} \geq \sigma^2 + \frac{1}{2}\Delta - \frac{1}{\sqrt{C}} - \frac{1}{C} - \alpha \left( 2H^2 \sqrt{2 \log \left( \frac{2KH(KH+1)}{\delta} \right)} + 4H^2 \right)
\]
\[
\geq \sigma^2 + \frac{1}{2}\Delta - \frac{2}{\sqrt{C}} - \alpha \left( 2H^2 \sqrt{2 \log \left( \frac{2KH(KH+1)}{\delta} \right)} + 4H^2 \right)
\]
with probability at least $1 - 3M\delta$. Note that provided,
\[
\forall m \geq m^*, \forall i \geq i^*, \quad T_m^{(i)} \leq \gamma \quad \text{and}
\forall m \leq m^* - 1, \forall i \geq i^*, \quad T_m^{(i)} \geq \gamma
\]
with probability at least $1 - 3M\delta$. The above equation implies that $m^{(i)} = m^*$ for all epochs $i \geq i^*$, which along with the choice $c_0 = 6/\sqrt{C}$, proves Lemma 1.

A.3 Regret bound of ARL-GEN (Proof of Theorem 1)
Lemma 1 implies that as soon as we reach epoch $i^*$, ARL-GEN identifies the model class with high probability, i.e., for each $i \geq i^*$, we have $m^{(i)} = m^*$. However, before that, we do not have any guarantee on the regret performance of ARL-GEN. Since at every episode the regret can be at most $H$, the cumulative regret up until the $i^*$ epoch is upper bounded by $\tau_{i^*} H$, which is at most $O \left( \max \left\{ H^4 \log(K) \log(1/\delta), H^2 \log \left( \frac{N(\mathcal{P}_m, \mathcal{F}_m)}{\delta} \right) \right\} \right)$, if the model classes are infinite, and $O \left( \max \left\{ H^4 \log(K) \log(1/\delta), H^2 \log \left( \frac{|\mathcal{P}_m|}{\delta} \right) \right\} \right)$, if the model classes are finite. Note that this is the cost we pay for model selection.

Now, let us bound the regret of ARL-GEN from epoch $i^*$ onward. Let $R_{\text{UCRL-VTR}}^{(i)}(k_i, \delta, \mathcal{P}_m^{(i)})$ denote the cumulative regret of UCRL-VTR, when it is run for $k_i$ episodes with confidence level $\delta_i$ for the family $\mathcal{P}_m^{(i)}$. Now, using the result of Ayoub et al. [5], we have
\[
R_{\text{UCRL-VTR}}^{(i)}(k_i, \delta, \mathcal{P}_m^{(i)}) \leq 1 + H^2 \dim \left( \mathcal{F}_m^{(i)}, \frac{1}{k_i H} \right) + 4 \sqrt{\beta_{k_i} \left( \mathcal{P}_m^{(i)}, \delta_i \right) \dim \left( \mathcal{F}_m^{(i)}, \frac{1}{k_i H} \right)} k_i H + H \sqrt{2k_i H \log(1/\delta_i)}
\]
with probability at least $1 - 2\delta_i$. With this and Lemma 1 the regret of ARL-GEN after $K$ episodes (i.e., after $T = KH$ timesteps) is given by
\[
R(T) \leq \tau_{i^* - 1} H + \sum_{i=i^*}^N R_{\text{UCRL-VTR}}^{(i)}(k_i, \delta, \mathcal{P}_m^{(i)}) \leq \tau_{i^* - 1} H + N + \sum_{i=i^*}^N H^2 \dim \left( \mathcal{F}_{m^*}, \frac{1}{k_i H} \right) + 4 \sum_{i=i^*}^N \sqrt{\beta_{k_i} \left( \mathcal{P}_{m^*}, \delta_i \right) \dim \left( \mathcal{F}_{m^*}, \frac{1}{k_i H} \right)} k_i H + \sum_{i=i^*}^N H \sqrt{2k_i H \log(1/\delta_i)}
\]
The above expression holds with probability at least $1 - 3M\delta - 2 \sum_{i=i^*}^N \delta_i$ for infinite model classes, and with probability at least $1 - 2M\delta - 2 \sum_{i=i^*}^N \delta_i$ for finite model classes.
Let us first compute the last term in the above expression. Substituting $\delta_i = \delta/2^i$, we have
\[
\sum_{i=1}^{N} H \sqrt{2k_i H \log(1/\delta_i)} = \sum_{i=1}^{N} H \sqrt{2k_i H \log(2/\delta)}
\]
\[
\leq H \sqrt{2HN \log(2/\delta)} \sum_{i=1}^{N} \sqrt{k_i}
\]
\[
= \mathcal{O} \left( H \sqrt{KHN \log(1/\delta)} \right) = \mathcal{O} \left( H \sqrt{T \log K \log(1/\delta)} \right),
\]
where we have used that the total number of epochs $N = \mathcal{O}(\log K)$, and that
\[
\sum_{i=1}^{N} \sqrt{k_i} = \sqrt{k_N} \left(1 + \frac{1}{\sqrt{2}} + \frac{1}{2} + \ldots + N\text{-th term} \right)
\]
\[
\leq \sqrt{k_N} \left(1 + \frac{1}{\sqrt{2}} + \frac{1}{2} + \ldots \right) = \frac{\sqrt{2}}{\sqrt{2} - 1} \sqrt{k_N} \leq \frac{\sqrt{2}}{\sqrt{2} - 1} K.
\]
Next, we can upper bound the third to last term in the regret expression as
\[
\sum_{i=1}^{N} H^2 \dim_{\mathcal{E}} \left( \mathcal{F}_{m^*}, \frac{1}{k_i H} \right) \leq H^2 N \dim_{\mathcal{E}} \left( \mathcal{F}_{m^*}, \frac{1}{KH} \right) = \mathcal{O} \left( H^2 d^* \log K \right).
\]
Now, notice that, by substituting $\delta_i = \delta/2^i$, we can upper bound $\beta_{k_i}(\mathcal{P}_{m^*}, \delta_i)$ as follows:
\[
\beta_{k_i}(\mathcal{P}_{m^*}, \delta_i) = \mathcal{O} \left( H^2 i \log \left( \frac{N(\mathcal{P}_{m^*}, \frac{1}{KH}, \|\cdot\|_{\infty,1})}{\delta} \right) \right) + H^2 \left( 1 + \sqrt{i \log \frac{kh_i}{k_i H + 1}} \right)
\]
\[
\leq \mathcal{O} \left( H^2 N \log \left( \frac{N(\mathcal{P}_{m^*}, \frac{1}{KH}, \|\cdot\|_{\infty,1})}{\delta} \right) \right) + H^2 \left( 1 + \sqrt{N \log \frac{KH}{\delta}} \right)
\]
\[
\leq \mathcal{O} \left( H^2 \log K \log \left( \frac{N(\mathcal{P}_{m^*}, \frac{1}{KH}, \|\cdot\|_{\infty,1})}{\delta} \right) \right) + H^2 \sqrt{\log K \log(K/\delta)}
\]
for infinite model classes, and $\beta_{k_i}(\mathcal{P}_{m^*}, \delta_i) = \mathcal{O} \left( H^2 \log K \log \left( \frac{|\mathcal{P}_{m^*}|}{\delta} \right) \right)$ for finite model classes.

With this, the second to last term in the regret expression can be upper bounded as
\[
\sum_{i=1}^{N} 4 \sqrt{\beta_{k_i}(\mathcal{P}_{m^*}, \delta_i)} \dim_{\mathcal{E}} \left( \mathcal{F}_{d_i}, \frac{1}{k_i H} \right) k_i H
\]
\[
\leq \mathcal{O} \left( H \sqrt{\log K \log \left( \frac{N(\mathcal{P}_{m^*}, \frac{1}{KH}, \|\cdot\|_{\infty,1})}{\delta} \right) \log(K/\delta)} \right)
\]
\[
\leq \mathcal{O} \left( H \sqrt{\log K \log \left( \frac{N(\mathcal{P}_{m^*}, \frac{1}{KH}, \|\cdot\|_{\infty,1})}{\delta} \right) \log \left( \frac{KH}{\delta} \right)} \right)
\]
\[
= \mathcal{O} \left( H \sqrt{T d^* (\mathcal{M^*} + \log(1/\delta)) \log K \log(T/\delta)} \right)
\]
for infinite model classes. Similarly, for finite model classes, we can upper bound this term by
\[
\mathcal{O} \left( H \sqrt{T d^* (|\mathcal{P}_{m^*}|/\delta) \log K \log(T/\delta)} \right).
\]

Hence, for infinite model classes, the final regret bound can be written as
\[
R(T) = \mathcal{O} \left( \max \left\{ H^4 \log(K) \log(1/\delta), H^2 \log \left( \frac{N(\mathcal{P}_{M^*}, \frac{1}{T}, \|\cdot\|_{\infty,1})}{\delta} \right) \right\} \right)
\]
\[
+ \mathcal{O} \left( H^2 d^* \log K + H \sqrt{T d^* (\mathcal{M^*} + \log(1/\delta)) \log K \log(T/\delta)} \right).
\]
The above regret bound holds with probability greater than
\[ 1 - 3M\delta - \sum_{i=t+i}^{N} \frac{\delta}{2i-1} \geq 1 - 3M\delta - \sum_{i \geq 1} \frac{\delta}{2i-1} = 1 - 3M\delta - 2\delta, \]
which completes the proof of Theorem 1.

Similarly, for finite model classes, the final regret bound can be written as
\[
R(T) = O\left( \max \left\{ H^4 \log(K) \log(1/\delta), H^2 \log \left( \frac{|P_M|}{\delta} \right) \right\} \right) \\
+ O\left( H^2 d_z^2 \log K + H \sqrt{T d_z^2 \log \left( \frac{|P_m|}{\delta} \right) \log K} \right),
\]
which holds with probability greater than \( 1 - 2M\delta - 2\delta \).

B Details for Section 3

B.1 Proof of Lemma 2

We follow a similar proof technique as used in [17] in the setting of contextual linear bandits using Assumption 3 and the matrix Freedman inequality. First, note that by Assumption 3, we have \( \| \phi_{V_{h+1}}(s^k_h, a^k_h) \| \leq 1 \), and \( \mathbb{E}[\phi_{V_{h+1}}(s^k_h, a^k_h)\phi_{V_{h+1}^\top}(s^k_h, a^k_h)^\top | \mathcal{G}_{k-1}^h] = \Sigma \geq \rho_{\min} I \) for all \( h \in [H] \) and \( k \in [K] \). Now, fix an \( h \in [H] \), and define the following matrix martingale
\[
Z_{h,k} = \sum_{j=1}^{k} \phi_{V_{h+1}}(s^j_{h}, a^j_{h})\phi_{V_{h+1}^\top}(s^j_{h}, a^j_{h})^\top - k\Sigma,
\]
with \( Z_{h,0} = 0 \). Next, consider the martingale difference sequence
\[
Y_{h,k} = Z_{h,k} - Z_{h,k-1} = \phi_{V_{h+1}}(s^k_h, a^k_h)\phi_{V_{h+1}^\top}(s^k_h, a^k_h)^\top - \Sigma.
\]
Since \( \| \phi_{V_{h+1}}(s^k_h, a^k_h) \| \leq 1 \), we have
\[
\| \Sigma \|_{op} = \| \mathbb{E}[\phi_{V_{h+1}}(s^k_h, a^k_h)\phi_{V_{h+1}^\top}(s^k_h, a^k_h)^\top | \mathcal{G}_{k-1}^h] \|_{op} \leq 1,
\]
and as a result
\[
\| Y_{h,k} \|_{op} = \| \phi_{V_{h+1}}(s^k_h, a^k_h)\phi_{V_{h+1}^\top}(s^k_h, a^k_h)^\top - \Sigma \|_{op} \leq 2.
\]
Furthermore, a simple calculation yields
\[
\| \mathbb{E}[Y_{h,k} Y_{h,k}^\top | \mathcal{G}_{k-1}^h] \|_{op} = \| \mathbb{E}[Y_{h,k}^\top Y_{h,k} | \mathcal{G}_{k-1}^h] \|_{op} \\
= \| \mathbb{E}[\| \phi_{V_{h+1}}(s^k_h, a^k_h)\phi_{V_{h+1}^\top}(s^k_h, a^k_h)^\top | \mathcal{G}_{k-1}^h] - \Sigma^2 \| \leq 2.
\]
Now, applying matrix Freedman inequality (Theorem 13 of [17]) with \( R = 2, \omega^2 = 2k, u = \rho_{\min} k/2 \), we obtain
\[
\mathbb{P} \left[ \| Z_{h,k} \|_{op} \geq \frac{\rho_{\min} k}{2} \right] \leq \frac{\delta}{KH},
\]
for any \( k \geq \left( \frac{16}{\rho_{\min}^2} + \frac{8}{\rho_{\min}} \right) \log(2dKH/\delta) \). Note that the above concentration bound holds for any \( h \in [H] \). Now, we define \( Z_k = \sum_{h=1}^{H} Z_{h,k} \). Then, applying a union bound, we obtain
\[
\| Z_k \|_{op} \leq \sum_{h=1}^{H} \| Z_{h,k} \|_{op} \leq \frac{\rho_{\min} kH}{2}
\]
for a given \( k \in \{ \tau_{\min}(\delta), \ldots, K \} \), with probability at least \( 1 - \delta/K \). By Assumption 3 we have \( \gamma_{\min}(kH\Sigma) \geq \rho_{\min} kH \). Hence, using Weyl’s inequality, we obtain
\[
\gamma_{\min}\left( \sum_{j=1}^{k} \sum_{h=1}^{H} \phi_{V_{h+1}}(s^j_{h}, a^j_{h})\phi_{V_{h+1}^\top}(s^j_{h}, a^j_{h})^\top \right) \geq \rho_{\min} Hk/2
\]
for a given \( k \in \{\tau_\text{min}(\delta), \ldots, K\} \), with probability at least \( 1 - \delta/K \). Now, the result follows by taking a union bound, and by noting that \( \Sigma_k = I + \sum_{j=1}^{k} \sum_{h=1}^{H} \phi_{v_{k+1}}(s_h^b, a_h) \phi_{v_{k+1}}(s_h^b, a_h)^\top \).

### B.2 Model selection in ARL-LIN (norm) (Proof of Lemma 3)

We consider doubling epochs, with epoch lengths \( k_i = 2^{i-1}k_1 \) for \( i \in \{1, \ldots, N\} \), where \( k_1 \) is the initial epoch length and \( N \) is the number of epochs. From the doubling principle, we obtain

\[
\sum_{i=1}^{N} 2^{i-1}k_1 = K \Rightarrow N = \log_2 \left( 1 + \frac{K}{k_1} \right) = O\left( \log(K/k_1) \right).
\]

Now, let us consider the \( i \)-th epoch, and let \( \hat{\theta}_{k_i} \) be the least square estimate of \( \theta^* \) at the end of epoch \( i \), which is the estimate computed by UCRL-VTR-LIN after \( k_i \) episodes. The confidence interval at the end of epoch \( i \), i.e., after UCRL-VTR-LIN is run with a norm estimate \( b^{(i)} \) for \( k_i \) episodes with confidence level \( \delta_i \), is given by

\[
B_{k_i} = \left\{ \theta \in \mathbb{R}^d : \|\theta - \hat{\theta}_{k_i}\|_{\Sigma_{k_i}} \leq \sqrt{\beta_{k_i}(\delta_i)} \right\}.
\]

Here \( \beta_{k_i}(\delta_i) \) denotes the radius and \( \Sigma_{k_i} \) denotes the shape of the ellipsoid. Using Lemma 2 one can rewrite \( B_{k_i} \) as

\[
B_{k_i} = \left\{ \theta \in \mathbb{R}^d : \|\theta - \hat{\theta}_{k_i}\| \leq \frac{\sqrt{\beta_{k_i}(\delta_i)}}{1 + \rho_{\text{min}}Hk_i/2} \right\},
\]

with probability at least \( 1 - \delta_i = 1 - \delta/2^{i-1} \). Here, from Lemma 2 we use the fact that \( \tau_\text{min}(\Sigma_{k_i}) \geq 1 + \rho_{\text{min}}Hk_i/2 \), provided \( k_i \geq \tau_\text{min}(\delta/2^{2i-1}) \). To ensure this condition, we take (the sufficient condition) \( k_1 \geq \tau_\text{min}(\delta)N \). Hence, with \( k_1 \) satisfying \( k_1 \geq \tau_\text{min}(\delta) \log_2 \left( 1 + \frac{N}{k_1} \right) \), we ensure that \( \gamma\text{min}(\Sigma_{k_i}) \geq 1 + \rho_{\text{min}}Hk_i/2 \).

Also, we know that \( \theta^* \in B_{k_i} \), with probability at least \( 1 - \delta_i \). Hence, we obtain

\[
\|\hat{\theta}_{k_i}\| \leq \|\theta^*\| + \frac{\sqrt{\beta_{k_i}(\delta_i)}}{1 + \rho_{\text{min}}Hk_i/2}
\]

with probability at least \( 1 - 2\delta_i \). Now, recall that at the end of the \( i \)-th epoch, ARL-LIN (norm) set the estimate of \( \|\theta^*\| \) to

\[
b^{(i+1)} = \max_{\theta \in B_{k_i}} \|\theta\|.
\]

From the definition of \( B_{k_i} \), we obtain

\[
b^{(i+1)} = \|\hat{\theta}_{k_i}\| + \frac{\sqrt{\beta_{k_i}(\delta_i)}}{1 + \rho_{\text{min}}Hk_i/2} \leq \|\theta^*\| + 2\frac{\sqrt{\beta_{k_i}(\delta_i)}}{1 + \rho_{\text{min}}Hk_i/2}
\]

with probability exceeding \( 1 - 2\delta_i \). Let us now look at the confidence radius

\[
\beta_{k_i}(\delta_i) = O \left( (b^{(i)})^2 + H^2d\log(k_iH)\log^2(k_i^2H/\delta_i) \right).
\]

We now substitute \( k_i = 2^{i-1}k_1 \) and \( \delta_i = \frac{\delta}{2^{i-1}} \) to obtain

\[
\sqrt{1 + \rho_{\text{min}}Hk_i/2} \geq \frac{2^{i-2}}{\sqrt{\rho_{\text{min}}Hk_1}},
\]

and

\[
\frac{\sqrt{\beta_{k_i}(\delta_i)}}{1 + \rho_{\text{min}}Hk_i/2} \leq \frac{C_1}{2} \frac{b^{(i)}}{2^{i-2} \sqrt{\rho_{\text{min}}Hk_1}} + \frac{C_2}{2} \frac{\beta^{3/2}}{2^{i-2} \sqrt{\rho_{\text{min}}Hk_1}} \left( H \sqrt{d\log(k_iH)\log^2(k_i^2H/\delta_i)} \right)
\]

for some universal constants \( C_1, C_2 \). Using this, we obtain

\[
b^{(i+1)} \leq \|\theta^*\| + C_1 \frac{b^{(i)}}{2^{i-2} \sqrt{\rho_{\text{min}}Hk_1}} + C_2 \frac{\beta^{3/2}}{2^{i-2} \sqrt{\rho_{\text{min}}Hk_1}} \left( H \sqrt{d\log(k_iH)\log^2(k_i^2H/\delta_i)} \right)
\]

\[
= \|\theta^*\| + b^{(i)} \sqrt{\frac{1}{k_1}} + \frac{\beta^{3/2}q}{2^{i-2} \sqrt{k_1}},
\]

\[20\]
with probability at least $1 - 2\delta_i$, where
\[ p = \frac{C_1}{\sqrt{p_{\min}H}} \quad \text{and} \quad q = \frac{C_2}{\sqrt{p_{\min}}} \sqrt{H \log(k_1 H) \log^2(k_1^2 H / \delta_1)}. \]

Hence, we obtain, with probability at least $1 - 2\delta_i$,
\[ b^{(i+1)} - b^{(i)} \leq \|\theta^*\| - \left(1 - \frac{p}{2} \frac{1}{K_1} b^{(i)}\right) + \frac{\delta^{3/2} q}{2} \frac{d}{k_1}. \]

By construction, $b^{(i)} \geq \|\theta^*\|$ (since $\theta^* \in B_{k_i}$). Hence, provided $k_1 > \frac{4p^2}{\delta}$, we have
\[ b^{(i+1)} - b^{(i)} \leq \frac{p}{2} \frac{1}{k_1} \|\theta^*\| + \frac{\delta^{3/2} q}{2} \frac{d}{k_1} \]
with probability at least $1 - 2\delta_i$. From the above expression, we have
\[ \sup_i b^{(i)} < \infty \]
with probability greater than or equal to
\[ 1 - \sum_i 2\delta_i = 1 - \sum_i 2\delta / 2^{i-1} = 1 - 4\delta. \]

From the expression of $b^{(i+1)}$ and using the above fact in conjunction yield
\[ \lim_{i \to \infty} b^{(i)} = \|\theta^*\|. \]

However, by construction $b^{(i)} \geq \|\theta^*\|$. Using this, along with the above equation, we obtain
\[ \lim_{i \to \infty} b^{(i)} = \|\theta^*\|. \]
with probability exceeding $1 - 4\delta$. So, the sequence $\{b^{(1)}, b^{(2)}, \ldots\}$ converges to $\|\theta^*\|$ with probability at least $1 - 4\delta$, and hence our successive refinement algorithm is consistent.

**Rate of Convergence:** Since
\[ b^{(i+1)} - b^{(i)} = O\left(\frac{\delta^{3/2}}{2^i}\right), \]
with high probability, the rate of convergence of the sequence $\{b^{(i)}\}_{i=1}^\infty$ is exponential in the number of epochs.

**Uniform upper bound on $b^{(i)}$:** We now compute a uniform upper bound on $b^{(i)}$ for all $i$. Consider the sequences $\left\{\frac{\delta^{3/2}}{2^i}\right\}_{i=1}^\infty$ and $\left\{\frac{1}{2^i}\right\}_{i=1}^\infty$, and let $t_j$ and $u_j$ denote the $j$-th term of the sequences respectively. It is easy to check that $\sup_i t_i < \infty$ and $\sup_i u_i < \infty$, and that the sequences $\{t_i\}_{i=1}^\infty$ and $\{u_i\}_{i=1}^\infty$ are convergent. With this new notation, we have
\[ b^{(2)} \leq \|\theta^*\| + u_1 \frac{p b^{(1)}}{\sqrt{k_1}} + u_2 \frac{q \sqrt{d}}{\sqrt{k_1}} \]
with probability at least $1 - 2\delta$. Similarly, for $b^{(3)}$, we have
\[ b^{(3)} \leq \|\theta^*\| + u_2 \frac{p b^{(2)}}{\sqrt{k_1}} + u_3 \frac{q \sqrt{d}}{\sqrt{k_1}} \]
\[ \leq \left(1 + u_2 \frac{p}{\sqrt{k_1}}\right) \|\theta^*\| + \left(u_1 u_2 \frac{p}{\sqrt{k_1}} + u_3 \frac{q \sqrt{d}}{\sqrt{k_1}}\right) + \left(1 + u_2 \frac{p}{\sqrt{k_1}}\right) \|\theta^*\| + \left(u_1 u_2 \frac{p}{\sqrt{k_1}} + u_3 \frac{q \sqrt{d}}{\sqrt{k_1}}\right) \]
with probability at least $1 - 2\delta - \delta = 1 - 3\delta$. Similarly, we write expressions for $b^{(4)}$, $b^{(5)}$, .... Now, provided $k_1 \geq C \left(\max\{p, q\} b^{(1)} \right)^2$, where $C$ is a sufficiently large constant, the expression for $b^{(i)}$ can be upper-bounded as
\[ b^{(i)} \leq c_1 \|\theta^*\| + c_2 \]
for all $i$, where $c_1, c_2 > 0$ are some universal constants, which are obtained from summing an infinite geometric series with decaying step size. The above expression holds with probability at least $1 - \sum_i 2\delta_i = 1 - 4\delta$, which completes the proof.

**B.3 Regret of ARL-LIN(norm) (Proof of Theorem 2)**

The cumulative regret is given by

$$R(T) \leq \sum_{i=1}^{N} R_{\text{UCRL-VTR-LIN}}(k_i, \delta_i, b^{(i)}),$$

where $N$ denotes the total number of epochs $R_{\text{UCRL-VTR-LIN}}(k_i, \delta_i, b^{(i)})$ denotes the cumulative regret of UCRL-VTR-LIN, when it is run with confidence level $\delta_i$ and norm upper bound $b^{(i)}$ for $k_i$ episodes. Using the result of Jia et al. [14], we have

$$R_{\text{UCRL-VTR-LIN}}(k_i, \delta_i, b^{(i)}) = \mathcal{O}\left(b_i d H^2 \sqrt{k_i \log(k_i H)} \log(k_i^2 H/\delta_i)\right)$$

with probability at least $1 - \delta_i$. Now, using Lemma 3, we obtain

$$R(T) \leq (c_1 \|\theta^*\| + c_2) \sum_{i=1}^{N} \mathcal{O}\left(d H^2 \sqrt{k_i \log(k_i H)} \log(k_i^2 H/\delta_i)\right)$$

with probability at least $1 - 4\delta - \sum_i \delta_i$. Substituting $k_i = 2^i - 1$ and $\delta_i = \frac{\delta}{2^i}$, we obtain

$$R(T) \leq (c_1 \|\theta^*\| + c_2) \sum_{i=1}^{N} \mathcal{O}\left(d H^2 \sqrt{k_i} \cdot \text{poly}(i) \log(k_i H) \log(k_i^2 H/\delta)\right)$$

with probability at least $1 - 4\delta - 2\delta = 1 - 6\delta$. Using the above expression, we obtain

$$R(T) \leq (c_1 \|\theta^*\| + c_2) \mathcal{O}\left(d H^2 \log(k_i H) \log(k_i^2 H/\delta)\right) \sum_{i=1}^{N} \text{poly}(i) \sqrt{k_i}$$

$$\leq (c_1 \|\theta^*\| + c_2) \mathcal{O}\left(d H^2 \log(k_i H) \log(k_i^2 H/\delta)\right) \mathcal{O}(N) \sum_{i=1}^{N} \sqrt{k_i}$$

$$\leq (c_1 \|\theta^*\| + c_2) \mathcal{O}\left(d H^2 \log(k_i H) \log(k_i^2 H/\delta)\right) \text{polylog}(K/k_1) \sum_{i=1}^{N} \sqrt{k_i}$$

$$\leq (c_1 \|\theta^*\| + c_2) \mathcal{O}\left(d H^2 \log(k_i H) \log(k_i^2 H/\delta)\right) \text{polylog}(K/k_1) \sqrt{K}$$

$$= \mathcal{O}\left(\|\theta^*\| d^{1/2} H^2 T \log(k_i H) \log(k_i^2 H/\delta) \text{polylog}(K/k_1)\right),$$

where we have used that $N = \mathcal{O}\left(\log(K/k_1)\right)$, $\sum_{i=1}^{N} \sqrt{k_i} = \mathcal{O}(\sqrt{K})$, and $T = KH$. The above regret bound holds with probability greater than or equal to $1 - 6\delta$, which completes the proof.

**B.4 Model selection in ARL-LIN(dim)**

First, we need the following concentration result on the estimates of $\theta^*$ in the sup-norm, which is important in designing the model selection procedure of ARL-LIN(dim).

**Lemma 6.** Suppose, Assumption 3 holds. Also, suppose that $\hat{\theta}_\tau$ is the estimate of $\theta^*$ after running UCRL-VTR-LIN in full d-dimensional for $\tau$ episodes with norm upper bound $b$ and confidence level $\delta$, where $\tau \in \{\tau_{\min}(\delta), \ldots, K\}$ and $\tau_{\min}(\delta) = \left(\frac{16}{\rho_{\min}^2} + \frac{8}{\rho_{\min}}\right) \log(2dKH/\delta)$. Furthermore, for any $\varepsilon \in (0, 1)$, let $\tau = \Omega\left(\frac{b^2 H d \log^2(K^2 H/\delta) \log(KH)}{\rho_{\min}^2 \varepsilon^2}\right)$. Then, we have

$$\mathbb{P}\left[\left\|\hat{\theta}_\tau - \theta^*\right\|_{\infty} \geq \varepsilon\right] \leq 2\delta.$$

**Proof.** By Lemma 2 and the properties of UCRL-VTR-LIN, we obtain for all $\tau \in \{\tau_{\min}(\delta), \ldots, K\}$,

$$\left\|\hat{\theta}_\tau - \theta^*\right\|_{\infty} \leq \left\|\hat{\theta}_\tau - \theta^*\right\| \leq \frac{\sqrt{\beta_\tau(\delta)}}{\sqrt{1 + \rho_{\min} H \tau/2}}.$$
with probability at least $1 - 2\delta$. Let us now look at the confidence radius

$$\beta_r(\delta) = O \left( b^2 + H^2 d \log(\tau H) \log^2(\tau^2 H / \delta) \right) \leq C b^2 H^2 d \log(KH) \log^2(K^2 H / \delta).$$

for some positive constant $C$. With this, the above equation can be written as

$$\|\hat{\theta}_r - \theta^*\|_\infty \leq \sqrt{C} \frac{bH \sqrt{d \log(KH) \log^2(K^2 H / \delta)}}{\rho_{\min} H \tau / 2}.$$

Now setting $\tau \geq 2C b^2 H d \log^2(K^2 H / \delta) \log(KH) / \rho_{\min}^2$, and using the fact that $\tau < K$, we get the result. \(\square\)

We shall now apply this result to prove Lemma 4.

**Proof of Lemma 4.** Note that, for each epoch $i \geq 1$, $\hat{\theta}^{(i)}$ is computed by considering the samples of UCRL-VTR-LIN over $\tau_i - 1$ episodes, where $\tau_i - 1 = \sum_{j=0}^{i-1} \theta^j \sqrt{k_0}$. If $\tau_{\min}(\delta) \leq \tau_i - 1 \leq K$ and $\tau_i - 1 = \Omega \left( b^2 H d \log^2(K^2 H^2 / \delta) \log(KH) \right)$, then by Lemma 6 we have

$$\mathbb{P} \left[ \|\hat{\theta}^{(i)} - \theta^*\|_\infty \geq (0.5)^i \right] \leq \frac{\delta}{2i-1}.$$

Consider the epoch $i = 1$. In this case, $\hat{\theta}^{(1)}$ is computed by samples of UCRL-VTR-LIN over $\tau_0 = \lceil \sqrt{k_0} \rceil$ episodes. Then, the choice $\sqrt{k_0} = \tau_{\min}(\delta) + O \left( b^2 H d \log^2(K^2 H^2 / \delta) \log(KH) \right)$ (we have added $\tau_{\min}(\delta)$ to make the calculations easier), ensures that

$$\mathbb{P} \left[ \|\hat{\theta}^1 - \theta^*\|_\infty \geq 0.5 \right] \leq \delta.$$

Note that, we require $\tau_{i-1} \geq i 4^i \lceil \sqrt{k_0} \rceil$. The proof is concluded if we can show that this holds for epochs $i \geq 10$. To this end, we note that

$$\tau_{i-1} = \sum_{j=0}^{i-2} \theta^j \sqrt{k_0} = \sqrt{k_0} \left( \frac{6^i - 1}{5} \right) \geq i 4^i \lceil \sqrt{k_0} \rceil,$$

where the last inequality holds for all $i \geq 10$. \(\square\)

**B.5 Regret of ARL-LIN (dim) (Proof of Theorem 3)**

We first calculate the probability of the event $\mathcal{E} = \left\{ \bigcap_{i=10} \left\{ \|\hat{\theta}^{(i)}(\gamma) - \theta^*\|_\infty \leq (0.5)^i \right\} \right\}$, which follows from Lemma 4 by a straightforward union bound. Specifically, we have

$$\mathbb{P} [\mathcal{E}] = \mathbb{P} \left[ \bigcap_{i=10} \left\{ \|\hat{\theta}^{(i)} - \theta^*\|_\infty \leq (0.5)^i \right\} \right] = 1 - \mathbb{P} \left[ \bigcup_{i=10} \left\{ \|\hat{\theta}^{(i)} - \theta^*\|_\infty \geq (0.5)^i \right\} \right]$$

$$\geq 1 - \sum_{i=10} \mathbb{P} \left[ \|\hat{\theta}^{(i)} - \theta^*\|_\infty \geq (0.5)^i \right]$$

$$\geq 1 - \sum_{i=10} \frac{\delta}{2i-1} \geq 1 - \sum_{i=10} \frac{\delta}{2i-1} = 1 - \delta.$$ 

Now, consider the phase $i(\gamma) := \max \left\{ 10, \log_2 \left( \frac{1}{\delta} \right) \right\}$. Note that when event $\mathcal{E}$ holds, then for all epochs $i \geq i(\gamma)$, $D^{(i)}$ is the correct set of $d^*$ non-zero coordinates of $\theta^*$. Thus, with probability at least $1 - \delta$, the cumulative regret of ARL-LIN (dim) after $K$ episodes is given by

$$R(T) \leq H \sum_{j=0}^{i(\gamma)-1} 36^j k_0 + \sum_{j=i(\gamma)}^N R^{\text{UCRL-VTR-LIN}} (36^j k_0, \delta_j, b) + R^{\text{UCRL-VTR-LIN}} \left( \sum_{j=0}^N 6^j \lceil \sqrt{k_0} \rceil, \delta, b \right),$$

where $N$ denotes the total number of epochs. Note that $N = O \left( \log_{36} \left( \frac{K}{k_0} \right) \right)$, and hence

$$\sum_{j=0}^N 6^j \lceil \sqrt{k_0} \rceil = O \left( \sqrt{K} \right).$$

Then, the third term in the above regret expression can be upper
bounded by $R_d^{\text{UCRL-VTR-LIN}}(\sqrt{K}, \delta, b)$. Here, the subscript $d$ denotes that UCRL-VTR-LIN in full $d$-coordinates during the support estimation phases of all epochs $j \geq 0$. Thus, using the result of Jia et al. [14], the regret suffered by $\text{ARL-LIN(dim)}$ during all the support estimation phases can be upper bounded as

$$R_d^{\text{UCRL-VTR-LIN}} \left( \sum_{j=0}^{N} 6^j [\sqrt{k_0}], \delta, b \right) \leq R_d^{\text{UCRL-VTR-LIN}}(\sqrt{K}, \delta, b)$$

with probability at least $1 - \delta$.

Now, we turn to upper bound the second term of the regret expression. Here, the subscript $d^*$ denotes that UCRL-VTR-LIN is run in only $d^*$-coordinates (with high probability) during the regret minimization phases of all epochs $j \geq i(\gamma)$. Now, using the result of Jia et al. [14], for all epochs $j \geq i(\gamma)$, we have

$$R_d^{\text{UCRL-VTR-LIN}}(36^j k_0, \delta_j, b) = O \left( b d^* H^2 \sqrt{36^j k_0} \log(36^j k_0 H) \log(36^j k_0^2 H/\delta_j) \right)$$

with probability at least $1 - \delta_j$. Substituting $\delta_j = \delta/2^j$, the regret suffered by $\text{ARL-LIN(dim)}$ during all the regret minimization phases can be upper bounded as

$$\sum_{j=i(\gamma)}^{N} R_d^{\text{UCRL-VTR-LIN}}(36^j k_0, \delta_j, b) = \sum_{j=i(\gamma)}^{N} O \left( b d^* H^2 \sqrt{36^j k_0} \log(k_0 H) \log(k_0^2 H/\delta) \right)$$

$$\leq O \left( b d^* H^2 \log(N) \log(k_0 H) \log(k_0^2 H/\delta) \right) \sum_{j=i(\gamma)}^{N} 6^j [\sqrt{k_0}]$$

$$= O \left( b d^* H^2 \sqrt{K} \log(k_0 H) \log(k_0 H) \log(k_0^2 H/\delta) \right)$$

with probability at least $1 - \sum_{j \geq i(\gamma)}^{N} \delta_j/2^j \geq 1 - \delta$. Here, we have used that the total number of epochs $N = O \left( \log_{36} \left( \frac{K}{k_0} \right) \right) = O(\log(K/k_0))$.

Putting everything together, the regret of $\text{ARL-LIN(dim)}$ is upper bounded as

$$R(T) \leq H k_0 \log^{(i(\gamma))} + O \left( b d^* \sqrt{H^3 T} \log(k_0 H) \log(k_0^2 H/\delta) \right)$$

$$+ O \left( b d H^2 K^{1/4} \log(\sqrt{K H}) \log(K H/\delta) \right)$$

$$= O \left( \frac{H}{\gamma_{5.18}} k_0 + \left( b d^* \sqrt{H^3 T} + b d H^2 K^{1/4} \right) \log(k_0 H) \log(T/\delta) \right)$$

with probability at least $1 - 3\delta$. Here, in the last step, we have used that $36 \leq 2^{5.18}$, which completes the proof.
