Investigations of clathrate structures have gained a new impetus with the recent discovery of room-temperature superconductivity in metal hydrides. Here we report the finding, through density functional theory calculations, of a clathrate phase in the fullerite C_{60} system. Intermolecular bonds of the type 5/5 2+3 cycloadition are induced between each C_{60} molecule and its twelve nearest neighbors in the face centered cubic lattice. Remarkably, this bonding creates on octahedral sites new C_{60} cages, identical to the original ones, and on tetrahedral sites distorted sodalite-like cages. The resulting carbon clathrate has a Pm\bar{3} simple cubic structure with half of the original face centered cubic lattice. Eighty per cent of its atoms are sp^{3}-hybridized, driving a narrow-gap semiconducting behavior, a moderate bulk modulus of 268GPa and an estimated hardness of 21.6GPa. This new phase is likely to be prepared by subjecting C_{60} to high pressure and high temperature conditions.

Clathrates are open-framework structures with face-sharing polyhedral cages that can contain guest species, atoms or molecules. Hydrates are an important group of clathrate structures, being the focus of intense investigations on the possibility of greenhouse gases storage. Group IV elemental solids can also form clathrates and, in particular, silicon and germanium clathrates have been synthesized in both guest and guest-free forms. Their properties can be tuned by inserting or exchanging guest atoms inside the polyhedral cages. The stunning recent discovery of room-temperature superconductivity at high pressure in metal hydrides, in which the metal atoms are located inside the hydrogen cages, has fueled the investigations on clathrate structures.

Carbon has exceptional flexibility as shown by the profusion of allotropes with distinct physical and chemical properties. Despite the large number of geometries carbon constructs may adopt, no carbon clathrate has been synthesized so far, in contrast to other group IV elements. There have been several theoretical studies discussing the stability of different carbon clathrates, such as C_{46}, C_{34} and C_{24}, whose construction is based on polyhedral cages and arrangements exhibited by clathrates of other chemical elements. A significant step towards the synthesis of carbon clathrates has been done recently with the high-pressure synthesis of mixed carbon-boron clathrates, where metal atoms, strontium or lanthanum, are trapped inside ordered sodalite-like cages formed by carbon and boron.

Notable candidates for the realization of carbon clathrates are some of the three-dimensional (3D) C_{60} polymers prepared at high pressure and high temperature. However, the crystal structures reported so far involve isolated C_{60} cages bonded to each other through sp^{3} carbons. Here we show, through density functional theory (DFT) calculations, that indeed fullerite C_{60} can also form an all-carbon clathrate structure through 3D polymerization of the molecules in the face centered cubic (fcc) lattice that creates two new polyhedral cages, sharing faces with each other and with the original C_{60} molecules. This carbon clathrate structure is statically and dynamically stable, being somewhat less stable than the known 3D C_{60} polymers, and is a narrow-gap semiconductor with a predicted indirect gap of 0.68eV. Despite a high ratio, eighty percent, of sp^{3} carbons, it displays moderate elastic moduli and a moderate hardness of 21.6GPa, probably a consequence of the elastic flexibility of the big C_{60} cages.

DFT calculations were performed using the Vienna ab initio simulation package (VASP). Perdew-Burke-Ernzerhof generalized gradient approximation was used to calculate the exchange-correlation energy. Electron core interaction was described by the projector augmented wave pseudo-potentials supplied with VASP. The self-consistent-field process was stopped once the energy difference between two consecutive steps was smaller than 10^{-5}eV; the k-points were converged within 10^{-5}meV/atom. To achieve this convergence 6\times6\times6 k-point mesh was employed in the optimization of the atomic positions and lattice parameters. A gaussian smearing with standard deviation of 0.2 and an energy cutoff of 520eV were also used for the optimization.

Electron Density of States (DOS) calculations were performed using a 16\times16\times16 K-point grid. An en-
ergy cutoff of 400eV was employed and the tetrahedron method with Bloch corrections was used for electron smearing. For the electron band structure calculation, the same energy cutoff was used with the calculation being made using 20 K-points between the high symmetric K-points of the Brillouin zone associated to the primitive cubic cell.

We also performed an elastic tensor calculation employing a $6 \times 6 \times 6$ K-point grid, an energy cutoff of 800eV and a step size of 0.015 Å for the central differences. The strain-stress method as implemented on VASP was applied to the primitive unit cell \[31\]. Elastic properties were afterwards extracted using MechElastic script \[32\].

The phonon dispersion and the phonon density of states were also calculated using density functional perturbation theory as implemented in VASP to compute the Hessian matrix, thus, obtaining the interatomic force constants. A supercell of $2 \times 2 \times 2$ (regarding the primitive cubic cell) and $3 \times 3 \times 3$ K-point grid were used the phonon dispersion was then obtained using the Phonopy code \[33\].

In addition, atomic orbital computations at the HSE06-6-31G(d,p) level \[34\] were performed with Gaussian09 \[35\].

The new C$_{60}$-based carbon clathrate structure was found in DFT investigations of possible intermolecular bonds formed between C$_{60}$ molecules in the fcc lattice. A new intermolecular bonding was considered, in which bonds are formed between pentagons of neighboring molecules. The new bonding has four intermolecular covalent bonds and is denoted “double 5/5 2+3 cycloaddition” joining two pentagonal rings in an antiparallel fashion, Figures 1a) and S1. Strout and coworkers reported a similar bonding, although it involves hexagons instead of pentagons \[21\]. A new polymeric structure is then constructed with each molecule adopting a standard molecular orientation and bonded, through the double 5/5 2+3 cycloadditions, to its twelve near neighbors (NN) in the fcc lattice, as illustrated in Figure 1b).

An important consequence of having each molecule bonded to its neighbors via the double 5/5 2+3 cycloadditions, is that the resulting fcc polymeric structure has its octahedral interstitial sites enclosed by truncated icosahedron cages (identical to the original C$_{60}$ molecular cages) and its tetrahedral interstitial sites enclosed by distorted truncated octahedron cages. These truncated octahedron cages, with 24 atoms arranged in 8 hexagons and 6 rhombi, are a distorted version of the sodalite-type cages displayed by numerous clathrates \[11,13\]. The original C$_{60}$ molecular cages are strongly deformed and their double hexagonal rings, lying perpendicular to the cubic axes, are now perfectly planar. The C$_{60}$ cages formed on the octahedral sites are exactly equal to the original C$_{60}$ molecular cages. Hence, as it is illustrated in Figure 2a), the resulting Fm$ar{3}$m fcc structure can be described by a reduced Pm$ar{3}$m simple cubic structure, with half of the lattice constant. The C$_{60}$ cages share with each other the planar double hexagonal rings, while they share hexagons with the C$_{24}$ sodalite-like cages, thus, forming a carbon clathrate structure. Figure 2, b) and c), illustrates the cages exhibited by this clathrate structure, emphasizing the different origins of the two C$_{60}$ cages, one corresponding to the original molecules and the other, centered at the octahedral sites, resulting from the polymeric bonding.

The structural optimization carried out on the fcc lattice, at zero pressure and without symmetry constraints, gives a lattice constant of 12.42 Å, the standard molecular orientation remains unaltered during the optimization. A structural optimization conducted in the simple cubic cell gives exactly the same relaxed structure with a lattice constant of 6.21 Å, half of the relaxed fcc cell. The optimized atomic coordinates of the asymmetric cell, together with their Wyckoff positions, are given in table S1 for the simple cubic structure. The C2 atoms are sp$^2$-hybridized, whereas both C1 and C3 atoms are sp$^3$-hybridized, and they are depicted in Figure 2 b). Similar values were obtained from HSE06-6-31G(d,p) level calculations, table S1.

The total energy calculated for the equilibrium clathrate structure is -7.93eV/atom, significantly larger than the -8.85eV/atom calculated for the C$_{60}$ molecule. This new structure is also less stable than other 3D C$_{60}$ polymer structures [20].

The electronic band structure and the density of states (DOS) are shown in Figure 3. The carbon clathrate is a narrow-gap semiconductor with an indirect band gap of 0.68eV between the bottom of the conduction band at the M point and the top of the valence band at the X point. This value was also computed at the HSE06-6-31G(d,p) level yielding 1.33eV.

The mechanical stability of the C$_{60}$-based clathrate structure was evaluated by computing the elastic tensor and checking the elastic stability criteria, which are the following for the cubic symmetry: $C_{11} - C_{12} > 0$, $C_{11} + 2C_{12} > 0$, $C_{44} > 0$. The computed values for these elastic constants are $C_{11}$=446GPa, $C_{12}$=179GPa and $C_{44}$=207GPa and therefore all the conditions of stability are satisfied. We used these values to compute the elastic properties, in the framework of Voigt- Reuss-Hill...
approximation, obtaining $B_0 = 268\text{GPa}$, $G=174\text{GPa}$, $E=429\text{GPa}$, and $\nu = 0.23$, for the bulk, shear and Young moduli, and the Poisson ratio, respectively [37].

We have also estimated the clathrate hardness using the macroscopic hardness model developed by Chen and coworkers, as implemented in MechElastic code [32, 38]. A value of 21.6GPa was found, in agreement with the observed moderate elastic constants [13, 20]. The C$_{60}$-based carbon clathrate with bigger cages and 20% of sp$^2$ carbons has a lower mechanical performance than the reported theoretical carbon clathrates, having smaller cages and being fully sp$^3$-bonded.

High-pressure and high-temperature (HPHT) are known to induce ordered polymerization of C$_{60}$ molecules. Indeed, with increasing pressure synthesis, one-dimensional and two-dimensional C$_{60}$ polymers have been prepared; inducing 3D polymerization require higher pressures, above 10GPa. The clathrate structure reported here is, therefore, likely to be prepared by subjecting fullerite C$_{60}$ to HPHT conditions above 10GPa. Its density, 2.5g/cm$^3$, is close to densities reported for the 3D C$_{60}$ polymers already synthesized. However, in the new C$_{60}$-based carbon clathrate eighty percent of its atoms are sp$^3$-hybridized, a proportion higher than it was experimentally reported for 3D polymers. Yamanaka and coworkers found two 3D polymerized phases, with Immm and R¯3m symmetries, both obtained at 15GPa and 823 K. coworkers found two 3D polymerized phases, with Immm experimentally reported for 3D polymers. Yamanaka and coworkers subjected fullerite C$_{60}$ to HPHT conditions above 10GPa. Its density, 2.5g/cm$^3$, is close to densities reported for the 3D C$_{60}$ polymers already synthesized. However, in the new C$_{60}$-based carbon clathrate eighty percent of its atoms are sp$^3$-hybridized, a proportion higher than it was experimentally reported for 3D polymers. Yamanaka and coworkers found two 3D polymerized phases, with Immm and R¯3m symmetries, both obtained at 15GPa and 823 K, containing 49% and 45% of sp$^3$ carbons, respectively [24]. On the other hand Lyapin and coworkers reported a cubic 3D C$_{60}$ polymer obtained at 12.5GPa with 60% of its atoms in sp$^3$ hybridization state [25]. Recently, Zhang and coworkers subjected fullerite C$_{60}$ to 25GPa to synthesize three amorphous phases with an estimated ratio of sp$^3$ carbons between 43% and 72% [26].

The elastic properties of the new clathrate structure, in particular the calculated bulk modulus of 268GPa, are close to those reported for 3D C$_{60}$ polymers. Lyapin and coworkers [24] reported a bulk modulus of 280GPa, although the published data has a significant uncertainty. Mezouar and coworkers [24] also reported a 3D polymer with a bulk modulus of 288GPa.

It is then plausible that C$_{60}$ 3D unresolved polymer phases might consist or include carbon clathrates related to the one reported here. This possibility, if confirmed, would highlight the relevance of high-pressure in inducing or stabilizing carbon clathrate structures.

In summary, a novel C$_{60}$-based carbon clathrate was predicted through DFT investigations of C$_{60}$ polymerization in the solid state. To the best of our knowledge, this is the first proposed carbon clathrate structure with C$_{60}$ molecular building blocks and, since it results from C$_{60}$ polymerization, it is quite likely to be prepared through high pressure high temperature treatment of fullerite C$_{60}$.

The high number of sp$^3$ carbons in this phase leads to a semiconducting material with moderate elastic properties. Yet, appropriate doping, for instance, using endohedral metallofullerenes, may render this phase metallic and superconducting with properties potentially similar to other carbon clathrates and the new metal hydrides, which display room-temperature superconductivity at megabar pressures.
