Strong light-matter interaction effects on molecular ensembles

Raphael F. Ribeiro

(Dated: July 16, 2021)

Despite the potential paradigm breaking capability of microcavities to control chemical processes, the extent to which photonic devices change properties of molecular materials is still unclear, in part due to challenges in modeling hybrid light-matter excitations delocalized over many length scales. We overcome these challenges for a photonic wire under strong coupling with a molecular ensemble. Our simulations provide a detailed picture of the effect of photonic wires on spectral and transport properties of a disordered molecular material. We find stronger changes to the probed molecular observables when the cavity is redshifted relative to the molecules and energetic disorder is weak. These trends are expected to hold also in higher-dimensional cavities, but are not captured with theories that only include a single cavity-mode. Therefore, our results raise important issues for future experiments and model building focused on unraveling new ways to manipulate chemistry with optical cavities.

Strong light-matter interactions hosted by nanostructures and optical microcavities can induce significant and qualitative changes to chemical processes [13–15] including photoconductivity [4, 5], energy transport [6–8], and optical nonlinearities [9–11]. Much of the observed phenomenology stems from the hybridization of the collective material polarization and the resonances of an optical cavity, which leads to the formation of delocalized polariton modes when the energy exchange between the collective molecular excitations and the photonic structure is faster than the dissipative processes acting on each subsystem [12–14]. Polaritonic states are always accompanied by molecular states weakly coupled to light [15]. The latter are also sometimes called “dark states”, since the optical response of strongly coupled molecular ensembles is dominated by polaritonic excitations. The weakly coupled states form a reservoir containing the vast majority of the states of the system with significant molecular character [15–17], and therefore, they play an essential role in equilibrium and non-equilibrium phenomena in optical cavities [13–15, 24].

Polaritons dominate the optical response of a strongly coupled device, but the reservoir states are much more numerous [15–17]. Therefore, it is puzzling that significant changes in thermal reaction rates and branching ratios of some organic systems [22–27] were observed under conditions of infrared collective strong coupling. The dominance of molecular reservoir modes over polaritonic [17] suggests there is no simple explanation of the cavity effect on thermal reactions based on transition-state theory [30–32]. This notion motivates the hypothesis that cavity-induced changes to chemical reactions originate from dynamical effects of the electromagnetic environment on intramolecular vibrational relaxation [33–34] (see also [35–37], for theoretical treatments of strong light-matter interaction effects on chemical reaction dynamics when a single molecule is strongly coupled to a cavity photon mode and dark states are absent).

Given the complexity of polaritonic systems with states delocalized over length scales of the order of the optical wavelength, much of what is known about collective strong coupling relies on quantum mechanical simulations of effective models [38, 39] where the cavity is modeled as a single bosonic mode and the molecular system has permutational symmetry, i.e., it consists of an ensemble of identical $N_M$ two-level systems with equal transition energies, dipole moments and center of mass positions [13, 14, 17]. In these models, hybrid light-matter excitations (lower and upper polaritons, LP and UP, respectively) extending over the entire system emerge from the interaction of the homogeneous cavity field with the molecular bright mode corresponding to the totally symmetric combination of molecular states where a single molecule is excited. The other $N_M - 1$ molecular modes are degenerate and correspond to the dark reservoir discussed above. Permutationally invariant models deviating from this Tavis-Cummings (TC) picture due to exciton-phonon coupling [40–42], and addition of local molecular baths attached [17] have also been investigated.

The effects of material imperfections on polaritonic and dark states were probed in early work by Houdre et al. [16] who showed that the presence of energetic and structural disorder leads to weak photonic intensity borrowing by the reservoir states, but only minor changes to the TC picture arise when the collective light-matter interaction $\Omega_R/2$ (Rabi splitting) is much greater than the mean fluctuation $\sigma$ of the material transition energies. More recently, Scholes revisited the polariton coherence protection in single-mode 0D cavities [43], whereas Botzung et al. [44] provided quantitative localization properties of the weakly coupled states of an energetically disordered emitter ensemble under strong coupling to the electric field of a single spatially homogeneous cavity mode. Both studies agree with Ref. [16] that polariton coherence is largely unaffected by energetic disorder weaker than the collective light-matter coupling, but also
noted that dark modes inherit spatial delocalization (see also Refs. 18 [45]).

However, the majority of optical cavities employed in polariton chemistry research are multimode Fabry-Perot or plasmonic cavities with a continuous spectrum corresponding to the photon in-plane momentum. In these systems, disorder is known to severely restrict polariton space-time coherence 15 [46] and may lead to weak or strong Anderson localization as well as diffusive and ballistic transport depending on the initial wave-packet, disorder strength, cavity geometric parameters, and the magnitude of light-matter interactions 47. Numerical simulations have shown that polariton wave functions can be localized over different length scales depending on their mean wave-vector 18 [50] (see 51 for a recent study of multimode cavity effects on polariton relaxation).

Despite their prominence, much less attention has been paid to multimode strong coupling effects on the reservoir states of structurally and energetically disordered molecular ensembles. These states form the majority of the excitations with significant molecular character, and therefore, they largely determine the equilibrium and transport properties of the molecular subsystem in an optical cavity.

Here, we employ numerical simulations of the microscopic states of a multimode photonic wire under strong coupling with a disordered molecular ensemble to investigate the influence of the cavity on the local molecular density of states and mean exciton return probability at infinite time. These quantities essentially reflect properties of the reservoir modes (since they are much more numerous than the polaritonic) and allow us to quantitatively probe the effects of optical cavities on the molecular ensemble.

Our results have significant implications for future model-building in polariton chemistry since they provide illustrations of qualitative shortcomings of the single-mode representation of multimode optical cavities. We also suggest practical principles to enhance cavity effects on molecular properties likely holding for generic systems, e.g., we find that when the molecules are resonant only with the lowest-energy cavity band, strong coupling effects on the probed molecular properties are not maximized at zero detuning. Wave function localization theory 46-47,52 and simple spectral overlap arguments explain this fact which adds another piece to the puzzle 53 of the optical cavity effect on chemical reactions, since some experimental observations suggest that cavity effects on chemical reactions are greater when the detuning vanishes. Second, while cavity-assisted transport may be generally favored in single-mode cavities interacting with an ideal sample in a 0D geometry 44,54, we show that in higher-dimensional geometries, in general, coherent transport across is more efficient in systems with weaker disorder.

Results and Discussion

Microscopic model. We model an optical microcavity with $O(\mu m)$ longitudinal and lateral confinement lengths $L_x$ and $L_y$ along the $z$ and $y$ axes, respectively 54. The length of the long axis is $L \gg L_x, L_y$. The molecules are distributed homogeneously along $x$ and $y$ and equal $y, z$ coordinates (see Fig. 1). Ideal reflective surfaces confine the EM field along $z$ and $y$, whereas periodic boundary conditions are assumed along $x$. We include a single polarization of the EM field parallel to the direction of each molecule’s transition dipole moment. The bare cavity modes have frequency $\omega = (c/\sqrt{\varepsilon})k$, where $c$ is the speed of light, $\varepsilon$ is the static dielectric constant of the intracavity medium and $k$ is the magnitude of the three-dimensional wave-vector $k = (2\pi m_x/L, n_y\pi/L_y, n_z\pi/L_z)$, where $m_x \in \mathbb{Z}$, and $n_y$ and $n_z$ are positive integers. The parameters $L, L_y, L_z$ and $\epsilon$ are chosen such that the molecules are only resonant with cavity modes in its lowest energy band ($n_z = n_y = 1$). Therefore, we ignore all other bands, and only include photons with $k = (2\pi m/L, \pi/L_y, \pi/L_z)$, $m \in \mathbb{Z}$. From now on, we label the cavity modes by $q \equiv k_x$ and omit any reference to $k_y$ and $k_z$ since they will remain constant throughout this paper, and denote $q$ as the wave-vector.

FIG. 1. (a) Photonic wire model employed in this work where molecules (ovals) extend along a single long cavity axis ($x$) and have equal $z$ and $y$ coordinates. (b) Example of a single realization of uncorrelated energetic (top) and dipolar fluctuations (bottom) for a system containing 1001 molecules. (c) Dispersion for a photonic cavity with $(L_x, L_y) = (200, 400)$ nm, and $L \equiv L_x = 0.025$ mm under strong interaction with a molecular system including 1001 molecules with mean transition energies $E_M = 2.1$ eV (top) and $2.0$ eV (bottom), respectively, $\Omega_R = 0.3$ eV, and root mean squared energetic and dipolar fluctuations $\sigma = 0.2\Omega$, and $\sigma_\mu = 0.05\mu_0$. To obtain this figure, we sort in ascending order the eigenvalues of the bare and interacting light-matter Hamiltonians and assigned a corresponding eigenstate index to each eigenvalue. The $x$-axis corresponds to this eigenstate index.
degree of freedom of the cavity. The empty cavity Hamiltonian is thus given by:

\[ H_L = \sum_q \hbar \omega_q a_q^\dagger a_q, \quad \omega_q = \frac{c}{\epsilon} \sqrt{q_0^2 + q^2}, \]  

(1)

where \( q_0 = \sqrt{(\pi/L_z)^2 + (\pi/L_y)^2} \).

The molecular ensemble is represented by a set of \( N_M = L/a \) two-level systems with transition frequencies sampled from a Gaussian distribution (representing low-frequency fluctuations of the solvent environment around each molecule) with mean \( E_M \) and variance \( \sigma^2 \), so the transition energy for the \( i \)th molecule is \( E_i = E_M + \sigma_i \), where \( \langle \sigma_i \rangle_d = 0 \) and \( \langle \sigma_i \sigma_j \rangle_d = \sigma^2 \delta_{ij} \). We also include structural disorder to our model by introducing random deviations of the molecular center of mass positions relative to a perfect crystal arrangement with lattice spacing \( a \), and by allowing the single-molecule transition dipole moment to deviate weakly from the mean value \( \mu_0 > 0 \). The \( i \)th molecule position is \( x_i = (i-1)a + \Delta x_i \) (mod \( M/N_M \)), where \( \Delta x_i = f_i a \), and \( f_i \) is sampled from a uniform distribution over \( [-f \pi / L, f \pi / L] \). The parameter \( f \) controls the maximal \( (1 + 2f)a \) and minimal \( (1 - 2f)a \) intermolecular distances, respectively. The magnitude of the transition dipole moment of the \( i \)th molecule is given by the random variable \( \mu_i \), sampled from a normal distribution with mean \( \mu_0 > 0 \) and variance \( \sigma^2 \). Structural disorder is typically neglected in numerical treatments of disorder effects on polaritons, but is included here since when \( \Omega_R \gg \sigma \), polariton localization at low energies is primarily driven by fluctuations in the molecular position and dipole moments (relative to a perfectly ordered system) 46–47.

Assuming \( a \) is sufficiently large, the Hamiltonian for the bare molecules is:

\[ H_M = \sum_{i=1}^{N_M} (E_M + \sigma_i) b_i^\dagger b_i, \]  

(2)

where \( E_M = \hbar \omega_M \), \( b_i^\dagger \) (\( b_i \)) create (annihilate) an excitation at the \( i \)th molecule. These operators can be written as \( b_i^\dagger = |i\rangle \langle 0| \) and \( b_i = |0\rangle \langle i| \), where \( |0\rangle \) is the state where all molecules and cavity is in the ground-state and in \( |i\rangle \) only the \( i \)th molecule is excited. The total Hamiltonian is given by:

\[ H = H_L + H_M + H_{LM}, \]  

(3)

where \( H_{LM} \) contains the light-matter interaction. We employ the Coulomb gauge \([56]\) in the rotating-wave-approximation since we take \( \Omega_R < 0.1 E_M \) \([57]\). It follows that,

\[ H_{LM} = \sum_{j=1}^{N_M} \sum_q \frac{-i\Omega_R}{2 \sqrt{\omega_M \omega_q \mu_j}} \left( e^{i q x_j} a_q - e^{-i q x_j} a_q^\dagger b_j \right) \]  

(4)

where \( \Omega_R = \mu_0 \sqrt{\hbar \omega_0 / 2 \epsilon}, \rho = N_M / L, \) and \( S = L_y L_z \). We ignored the diamagnetic contribution (\( A^2 \) term) to \( H_{LM} \) since its effects are negligible under strong coupling 55.

For given \( \Omega_R \) and \( a = 1 / \rho \), the number of molecules \( N_M \) photon modes \( N_C \) are free parameters. A choice of \( N_M \) and \( N_C \) is equivalent to imposing low and high-energy cutoffs to the EM field. \( L = N_M a \) defines the resolution of the cavity in reciprocal space \( \Delta q = 2 \pi / L \), and \( N_C \) defines the maximal cavity mode energy \( E_{max} \). Simulation results are independent of these cutoffs as long as \( L \) is larger than the longest coherence length of the system and \( E_{max} \) is greater than any relevant energy scale. Alternatively, independence of molecular observables to the number of considered degrees of freedom in the thermodynamic limit (\( N_M, L \to \infty \) with fixed \( \rho \)) can be imposed to obtain a minimal number of molecular and cavity modes. Such computationally optimal minimal number of modes varies depending on the relevant observable as well as on the disorder strength and light-matter coupling.

We employ \( N_C = N_M \) in our simulations below, since in this case, the thermodynamic limit is reached with a small number of disorder realizations for the observables and range of parameters probed in our studies. Most cavity modes are highly off-resonant with the molecular system in every case, and we checked that a smaller number of cavity modes \( N_C^0 \) would suffice to obtain thermodynamic limit predictions. However, as mentioned above, \( N_C^0 \) depends on various parameters and we leave for future work a detailed analysis of optimal multimode cavity representations 59 for studying the effects of photonic devices on molecules.

**Observables.** Let the eigenstates and eigenvalues of \( H \) be denoted by \( \psi \) and \( E_\psi \), respectively. The ensemble averaged molecular local density of states (LDOS) gives the conditional probability that an excited molecule will be detected with energy \( E \):

\[ \rho_M(E) = \frac{1}{N_M} \sum_{n=1}^{N_M} \langle 1_n | \delta(H - E)| 1_n \rangle = \sum_\psi \langle P_{n\psi} \rangle \delta(E_\psi - E), \]  

(5)

where \( P_{n\psi} = | \langle 1_n | \psi \rangle |^2 \) and \( \langle P_{n\psi} \rangle = \sum_{n=1}^{N_M} | \langle 1_n | \psi \rangle |^2 / N_M \) is the average probability to find a molecule excited when the system is in the eigenstate \( | \psi \rangle \). In the absence of light-matter interactions, \( \rho_M^0(E) \) is a Gaussian distribution centered at \( E_M \) and width \( \sigma \). We quantify photonic effects on the molecular LDOS by comparing the Shannon entropy

\[ S[\rho_M] = - \int_0^\infty dE \rho_M(E) \ln[\rho_M(E)], \]  

(6)

of the molecules inside and outside of an optical cavity. The mean probability that an initially excited molecule at time \( t = 0 \) will be detected in the same state at \( t > 0 \) is the time-dependent exciton return probability \( P_M(t) = \ldots \)
\[ \sum_{j=1}^{N_M} P_j(t)/N_M, \] where
\[ P_j(t) = |\langle 1_n|e^{-iHt/\hbar}|1_n \rangle|^2. \] (7)
The exciton return probability \( \Pi_M \) is the \( t \to \infty \) limit of \( P_M(t) \):
\[ \Pi_M \equiv \lim_{t \to \infty} P_M(t) = \frac{1}{N_M} \sum_{n=1}^{N_M} \sum_{\psi} P_{n\psi}^2 \]
\[ = \sum_{\psi} (|P_{n\psi}|^2). \] (8)
The exciton escape probability \( \chi_M \) is simply related to \( \Pi_M \) via:
\[ \chi_M = 1 - \Pi_M. \] (9)
This quantity provides the ensemble-averaged probability that energy initially stored as a localized molecular exciton migrates to a distinct molecule or is converted into a cavity photon after an infinite amount of time.

\( \Pi_M \) gives a measure of energy diffusion, whereas \( \rho_M(E) \) is directly related to thermodynamic and kinetic quantities. These quantities will be employed below as proxies to assess cavity effects on the properties of molecules under collective strong coupling with a photonic wire.

**Thermodynamic limit convergence.** First, we show that with a small number of molecules and modes we obtain robust predictions for cavity-induced changes in molecular properties. We take \( L_y = 400 \) nm, \( L_z = 200 \) nm, and dielectric constant \( \epsilon = 3 \). This gives a lowest energy cavity mode with \( E_C(0) = \hbar \omega_0 = 2.0 \) eV, whereas \( q_{\text{max}} = \pi/a \) with \( a = 10, 25, \) and \( 50 \) nm. To probe the thermodynamic limit of \( \rho_M(E) \) and \( \Pi_M \), we take \( \Omega_R = 0.3 \) eV, \( E_M = 2.0 \) eV, \( \sigma = 0.2 \), \( \omega_R = 0.1 \), and \( \sigma_M/\mu_0 = 0.05 \). To compute the molecular LDOS entropy we employed 400 bins of width 5 meV spanning the interval \([1.5 \text{ eV}, 3.5 \text{ eV}]\).

In Fig. 2 we give \( \rho_M(E) \) obtained with five realizations of a system with \( N_M = N_C = 1001 \) and \( 5001 \) and \( a = 10 \) nm. Despite the small number of realizations, Fig. 2 shows that the model with \( N_M = 1001 \) leads to \( \rho_M(E) \) nearly indistinguishable from that with \( N_M = 5001 \).

We confirm these observations quantitatively in Fig. 3, where we show the insensitivity of both \( S[\rho_M] \) and the \( \Pi_M \) to \( N_M \) for all \( a \). Fig. 3 shows that upon strong coupling, \( \Delta S = S[\rho_M] - S[\rho_M^{(0)}] > 0 \). This variation depends on \( \rho = N_M/a \), but is always finite. Similarly, the cavity induces a density-dependent change in the exciton localization (\( \Pi_M = 1 \) for the bare molecules). We discuss the physical origin of these observations in detail in the next Section.

Figures 2 and 3 show that self-averaging of the molecular ensemble allows the thermodynamic limit for \( \rho_M(E) \) and \( \Pi_M \) to be reached already with \( N_M = N_C = 1001 \) (the minimal number required is likely smaller especially for \( N_C \)). Thus, in what follows, we restrict our attention to systems with \( N_C = N_M = 1001 \).

**Microscopic states.** Before presenting our analysis of the cavity effect on molecular properties, we mention briefly that our computations reveal quasi-extended and localized low energy polariton states in qualitative agreement with earlier work focused on disorder effects on 1D polaritonic states \[ \text{[8, 50]} \] (although, we note that the Hamiltonians used in these studies break time-reversal symmetry and therefore lead to quantitatively distinct properties relative to our work since coherent localization is generally weakened when time-reversal symmetry is absent). These qualitative features of polariton localization in photonic wires have been thoroughly investigated so we provide no detailed discussion, except to mention that there is a clear analogy between the polaritonic state and the thermodynamic limit of the molecular properties. We discuss this analogy in detail in the next Section.

In Fig. 4 we show the energy spectrum obtained with five realizations of a system with \( N_M = N_C = 1001 \) and \( 5001 \) and \( a = 10 \) nm. Despite the small number of realizations, Fig. 4 shows that the model with \( N_M = 1001 \) leads to \( \rho_M(E) \) nearly indistinguishable from that with \( N_M = 5001 \).

We confirm these observations quantitatively in Fig. 5, where we show the insensitivity of both \( S[\rho_M] \) and the \( \Pi_M \) to \( N_M \) for all \( a \). Fig. 5 shows that upon strong coupling, \( \Delta S = S[\rho_M] - S[\rho_M^{(0)}] > 0 \). This variation depends on \( \rho = N_M/a \), but is always finite. Similarly, the cavity induces a density-dependent change in the exciton localization (\( \Pi_M = 1 \) for the bare molecules). We discuss the physical origin of these observations in detail in the next Section.

Figures 4 and 5 show that self-averaging of the molecular ensemble allows the thermodynamic limit for \( \rho_M(E) \) and \( \Pi_M \) to be reached already with \( N_M = N_C = 1001 \) (the minimal number required is likely smaller especially for \( N_C \)). Thus, in what follows, we restrict our attention to systems with \( N_C = N_M = 1001 \).

**Microscopic states.** Before presenting our analysis of the cavity effect on molecular properties, we mention briefly that our computations reveal quasi-extended and localized low energy polariton states in qualitative agreement with earlier work focused on disorder effects on 1D polaritonic states \[ \text{[8, 50]} \] (although, we note that the Hamiltonians used in these studies break time-reversal symmetry and therefore lead to quantitatively distinct properties relative to our work since coherent localization is generally weakened when time-reversal symmetry is absent). These qualitative features of polariton localization in photonic wires have been thoroughly investigated so we provide no detailed discussion, except to mention that there is a clear analogy between the polaritonic state and the thermodynamic limit of the molecular properties. We discuss this analogy in detail in the next Section.

In Fig. 4 we show the energy spectrum obtained with five realizations of a system with \( N_M = N_C = 1001 \) and \( 5001 \) and \( a = 10 \) nm. Despite the small number of realizations, Fig. 4 shows that the model with \( N_M = 1001 \) leads to \( \rho_M(E) \) nearly indistinguishable from that with \( N_M = 5001 \).

We confirm these observations quantitatively in Fig. 5, where we show the insensitivity of both \( S[\rho_M] \) and the \( \Pi_M \) to \( N_M \) for all \( a \). Fig. 5 shows that upon strong coupling, \( \Delta S = S[\rho_M] - S[\rho_M^{(0)}] > 0 \). This variation depends on \( \rho = N_M/a \), but is always finite. Similarly, the cavity induces a density-dependent change in the exciton localization (\( \Pi_M = 1 \) for the bare molecules). We discuss the physical origin of these observations in detail in the next Section.

Figures 4 and 5 show that self-averaging of the molecular ensemble allows the thermodynamic limit for \( \rho_M(E) \) and \( \Pi_M \) to be reached already with \( N_M = N_C = 1001 \) (the minimal number required is likely smaller especially for \( N_C \)). Thus, in what follows, we restrict our attention to systems with \( N_C = N_M = 1001 \).
ton states obtained in photonic wires and the local exciton ground-states and the quasi-extended exciton states of polymers \[60\] \[61\]. This analogy is a consequence of Anderson localization universality according to which, in general, there are no extended states over a 1D system in the thermodynamic limit. Instead, any small amount of disorder leads to a breakdown of long-range order.

In photonic wires strongly coupled to a material, wave function localization and more generally, the expected distance-dependent decay of intermolecular correlations (mediated by the optical cavity) emerge only when both disorder and multiple electromagnetic field modes are included in the light-matter Hamiltonian. This framework forms the basis of our examination below of polaritonic effects on macroscopic molecular ensembles described with a multimode cavity model. As we will see, single-mode models fail qualitatively in capturing essential trends describing the properties of a molecular ensemble in an optical cavity. Every quantity reported corresponds to the mean value obtained from 10 realizations of a system with a given set of disorder parameters. Standard deviations were computed for every observable reported and checked to be small enough not to qualitatively change any presented trends.

Density and energetic disorder dependence.
The entropy of the molecular LDOS \( S[\rho] \) measures the spread of the molecular exciton energy distribution. When the photonic subsystem is represented by a single-mode, \( \Delta S[\rho_M] = S[\rho_M] - S[\rho_M^{(0)}] \) is essentially zero, for all particle numbers, densities and disorder parameters studied. Our simulations suggest otherwise for photonic wires (assuming any broadening induced by the free space electromagnetic field vacuum is much smaller than the inhomogeneous broadening caused by the low-frequency environmental modes coupled to the relevant molecular transition): the strong interaction of multiple near-resonant photonic modes with the molecular ensemble leads to finite and positive \( \Delta S[\rho_M] \) (Fig. 3). Indeed, for various values of energetic disorder variance, \( \chi_M \) shows a consistent gain in \( S[\rho_M] \) by the molecular system upon interacting with the optical cavity. We see two other important trends: for a fixed \( \Omega_R \), (i) \( \Delta S[\rho_M] \) increases with the mean intermolecular distance (or alternatively, \( \Delta S[\rho_M] \) decreases with \( \rho \)), and (ii) \( \Delta S[\rho_M] \) is in general a decreasing function of the energetic disorder strength.

The decay of \( \Delta S[\rho_M] \) with increasing disorder is not surprising: in the limit where the molecular system is perfectly ordered (\( \sigma/\Omega_R = 0 \) and the molecules live on a perfect lattice sharing equal transition dipole moment), the exciton-polaritons become maximally delocalized, and \( \Delta S[\rho_M] \) is maximized (Fig. 4). For any finite value of \( \sigma \), Anderson localization operates \[62\], and in the thermodynamic limit both exciton-polaritons and weakly coupled reservoir states localize over distances smaller than the size of the system. When \( \sigma/\Omega_R \) is close to 1, the majority of the excitations with significant molecular character become very similar to the localized bare molecule excitations, and therefore, \( \Delta S[\rho_M] \to 0 \).

The consistent increase of \( \Delta S[\rho_M] \) with the intermolecular distance is more intriguing. It can be understood by noting that if the cavity modes are integrated out in a path integral representation of the partition function of the system, \[63\] \[64\], the effective action for the molecular system acquires retarded two-body intermolecular interactions mediated by the cavity with coupling constant proportional to the the magnitudes of the single-molecule transition dipole moments \[61\] \[50\] \[65\]. For systems with fixed \( N_M \) and \( \Omega_R \), the mean transition dipole moment is proportional to \( 1/\sqrt{\rho} \propto \sqrt{\rho} \) (since \( \Omega_R \propto \sqrt{\rho} \mu^2 \) and \( \rho \propto 1/a \)). Therefore, when \( \Omega_R \) and \( N_M \) are fixed, the cavity effects on single molecules become stronger with decreasing density.

![FIG. 4. Left: Entropy gained by the molecular LDOS upon strong coupling with a photonic wire as a function of the intermolecular distance (molecular density) for varying energetic disorder variance, \( \sigma/\Omega_R \). Right: Molecular return probabilities for the same systems. Each point corresponds to an average obtained over 10 disorder realizations.](image)

In Fig. 4 (right), we also examined the mean exciton escape probability \( \chi_M = 1 - \Pi_M \) as a function of the mean intermolecular distance \( a \) for varying values of energetic disorder. \( \chi_M \) increases with \( a \) further corroborating the argument above that stronger cavity effects on single-molecule properties are expected on more dilute systems with fixed \( \Omega_R \) and \( N_M \). Similarly, \( \chi_M \) is maximized for a perfectly ordered system and exciton localization becomes stronger, in general, with increasing energetic disorder. These results are in contrast to recent work showing that in 0D photonic devices, disorder typically enhances light-assisted energy transport by a strongly coupled emitter ensemble \[44\] \[54\]. Fig. 4 (right) shows that when the local excitations of a material are separated by finite distances within a multimode photonic device, exciton localization becomes more prominent as \( \sigma \) increases (except for small values of \( \sigma/\Omega_R \)). As expected from wave function localization theory \[66\], the mean exciton escape probability is, in general, a decreasing function
of the energetic disorder strength. Nevertheless, it is notable that $\chi_M$ retains a significant value even when $\sigma/\Omega_R = 1$, indicating potentially substantial coherent polariton-mediated transport of molecular excitons even for a highly disordered system.

**Cavity detuning effects.** In several chemical reactions where strong influence by optical cavities has been reported, the obtained data suggests that the photonic material maximizes its effect on the reactive system when a specific transition of the reactant is on-resonance with the $q = 0$ mode of the optical cavity [22–24, 27]. This feature motivates our study of $S[\rho_M]$ and $\chi_M$ as a function of cavity detuning. In Fig. 5, we present our results and compare to the predictions of a single-mode cavity model.

Under strong coupling with the photonic wire, Fig. 5 shows that the local molecular DOS entropy and the exciton escape probability are maximally affected by the optical cavity when the lowest-energy photon mode is red-shifted relative to the molecular system. In our multimode disordered model, the photonic material is least effective at modifying low-energy properties of the molecular ensemble when the photons are all blue-shifted relative to the excitons. This trend is robust with respect to changes in the molecular density, and the density dependence follows the pattern discussed in the previous subsection.

The observed maximization of the effects of multimode photonic devices on low-energy observable properties (i.e., depending only on the ground and first excited-states of the excitonic subsystem) of the molecular system when $E_M < E_C$ can be understood as follows. First, when $E_M - E_C \leq 0$, a significant fraction of the molecular excitons will be significantly off-resonant with all cavity modes (especially if $\sigma/\Omega_R$ is not too small) and the spectral overlap of photonic and molecular modes will be weaker. In addition, polaritons formed from strongly interacting cavity modes with $q \approx 0$ tend to localize over smaller distances than polaritons dominated by wavevectors with larger magnitude, since in states with maximal long-distance coherence the wave-vector uncertainty $\delta q$ is much smaller than $q$ [15, 48–47]. Therefore, in devices where the molecules are only resonant with $q \approx 0$ transitions (zero detuning), any small amount of disorder will lead to polariton modes with finite $\delta q > q$. The latter are localized over distances smaller than the wavelength, and any delocalization effects on the molecular system induced by the formation of polaritons will be weaker relative to the case where the molecules are resonant with cavity modes with larger $q$ [15, 47–50]. Note that, although our numerical results are strictly valid for one-dimensional systems, both arguments employed to explain the observed trends are independent of the dimensionality of the photonic and molecular system. Therefore, the detuning dependence reported in Fig. 5 is expected to hold generically for more realistic treatments of the molecules and the photonic device.

Given these notions, it is unsurprising that single-mode 0D cavities display qualitative distinct effects on molecules when compared with a multimode device. When the photonic material has a single mode, the spectral overlap between the cavity and the molecular subsystem is maximized when they are resonant. This leads to a maximal cavity-mediated exciton escape probability at zero detuning (Fig. 5), since if the retained mode were off-resonant with the molecular system, the spectral overlap of the material and the cavity would be weaker. This behavior is exclusive to 0D systems with isolated modes and does not apply to cavities with a continuous spectrum, such as those employed in almost all polariton chemistry experiments. In Fabry-Perot cavities or photonic wires, negative cavity detuning gives enhanced light-matter spectral overlap, and a larger number of propagating (delocalized) polariton modes relative to a cavity with zero detuning. Hence, low-energy properties of molecular ensembles are expected to be more affected by a photonic material when it is redshifted relative to the molecules. A similar conclusion was reached in Ref. [29] upon analysis of the viability of a hypothetical mechanism for cavity effects on charge transfer rates [67].

Our observations do not contradict experimental results on polariton effects on chemical reactions, since we only investigated the influence of strong light-matter interaction effects on low-energy properties of the molecular system involving only the ground and first excited-states of the material, while the energy scales and relevant microscopic states governing thermal chemical reaction rates can be much higher (especially for some of the reactive systems studied experimentally where the relevant timescales range from minutes to hours).

In addition, we assumed that only the lowest energy cavity-photon band interacts with the molecular system whereas in infrared optical cavities it is typical for the
molecular transitions to have $N > 1$ resonances. The zero-detuning condition is then satisfied only by one of the resonant cavity bands, whereas the remaining $N - 1$ have resonances at $q \neq 0$. Further work is required to establish whether the inclusion of multiple polariton bands allows recovery by low-energy effective models of the approximate experimental trend that zero-detuning cavities exert stronger influence on the local properties of a molecular system.

Conclusions
We investigated spectral and transport properties of disordered molecular excitons under collective strong coupling with a photonic wire. Our results suggest that low-energy effects of polaritons on bulk properties of the molecular ensemble are largest when the single-molecule transition dipole moment is large, inhomogeneous disorder is small, and when the cavity is redshifted (negatively detuned) relative to the molecular system. In negatively detuned devices, there exists enhanced spectral overlap between the cavity and the molecular system. In addition, polariton modes with significant molecular content have mean wave-vector far from zero, and delocalization is protected from the small fluctuations induced by structural and energetic disorder.

The detuning dependence of cavity effects on molecular properties is particularly relevant when viewed in the context of recent research on polariton effects on thermal chemical reactions. Several of the reported experiments imply that photonic materials are more effective at changing reaction rates when the molecular system is resonant with the lowest energy mode of a cavity band (zero detuning). Our results suggest otherwise, but do not contradict experiments, since we only assess low-energy properties of the molecular system, whereas the studied slow chemical reactions are complex events involving much higher excited states than those included in our model.

The increasing number of molecules, cavity photon modes, dimensionality, and introducing dynamical disorder and cavity leakage are unlikely to qualitatively change any of the trends reported in this work. We expect the behavior with cavity detuning, energetic disorder, and density (for a fixed $\Omega_R$), of molecular properties under strong coupling to photonic devices to be generic for low-energy polariton models. For example, while wave function delocalization is significantly more favored in 2D and 3D relative to the case studied in this paper, it remains true that the spectral overlap between excitons and the optical cavity will be weaker at zero or positive detuning when compared to negative. Dynamical disorder (time-dependent fluctuations of the exciton frequency, position and dipole magnitude/orientation) induces further exciton localization and ultrafast coherence decay reducing the efficiency of intermolecular exciton transport reported here, but is unlikely to affect any of the qualitative trends reported.

To conclude, we reiterate that although 0D single-mode cavity theories are insightful and predictive of many features of polaritonic optical response, these models give incorrect qualitative predictions for the cavity effects on molecular ensembles analyzed in this work. Specifically, single-mode models fail to capture the detuning, density, and disorder strength dependence of the exciton escape probability and molecular LDOS entropy gain upon collective strong coupling with a photonic device. These shortcomings must be recognized in future model building aimed at establishing novel practical ways to control chemistry with optical microcavities.
