Email: liuqh@sustech.edu.cn
Dirac semimetal (DSM) is a phase of matter, whose elementary excitation is described by the relativistic Dirac equation. Its parity-time symmetry enforces the linear-dispersed Dirac cone in the momentum space to be non-chiral, leading to surface states connected adiabatically to a topologically trivial surface state. Inspired by the flavor symmetry in particle physics, we theoretically propose a massless chiral Dirac equation linking two Weyl fields with the identical chirality by assuming $SU(2)$ isospin symmetry, independent of the space-time rotation exchanging the two fields. Dramatically, such symmetry is hidden in certain solid-state spin-1/2 systems with negligible spin-orbit coupling, where the spin degree of freedom is decoupled with the lattice. Therefore, it cannot be explained by the conventional (magnetic) space group framework. The corresponding system is called chiral DSM. The four-fold degenerate Dirac fermion manifests linear dispersion and a Chern number of $\pm 2$, leading to a robust network of topologically protected Fermi arcs throughout the Brillouin zone. For material realization, we show that the transition-metal chalcogenide CoNb$_3$S$_6$ with experimentally confirmed collinear antiferromagnetic order is ideal for chiral DSM. Our work unprecedentedly reveals a condensed-matter counterpart of the flavor symmetry in particle physics, leading to further possibilities of emergent phenomena in quantum materials.
The Dirac equation combines the two cornerstones of modern physics—quantum mechanics and relativity. It is the first step towards the quantum field theory that gives birth to the standard model of particle physics. It complies with the Dirac quantum fields of spin-$\frac{1}{2}$ particles, furnishing particular irreducible representations (irreps) of the Lorentz group. There are several manifestations of the Dirac equation in condensed matter systems, such as graphene\textsuperscript{1}, topological insulators\textsuperscript{2,3}, Dirac semimetals (DSMs)\textsuperscript{4-6}, Weyl semimetals\textsuperscript{7,8}, and $d$-wave high-temperature superconductors. The low-energy electronic structure of the Dirac points in a three-dimensional (3D) DSM, i.e., four-fold degenerate crossing points formed by doubly degenerate linear bands, is well described by the massless Dirac equation in the $(3+1)$D space-time. Investigations on 3D DSMs have been confined to the field of nonmagnetic materials where inversion symmetry $P$ and time-reversal symmetry $T$ coexist. Recently, candidates for DSM have been extended to include magnetic materials, which preserve the combination of $P$ and $T$ to ensure the doubly degenerate energy bands\textsuperscript{9-11}.

A four-component Dirac field can be decomposed into two two-component Weyl fields with opposite chirality in the limit of zero mass, implying that the chirality of a massless Dirac fermion must be zero because the antiunitary $PT$-symmetry forces the two branches of each doubly degenerate band to have opposite Berry curvatures (Fig. 1a). Hence, the Fermi arc surface states connecting two Dirac points in a DSM are generally not topologically protected, unlike Weyl points (Fig. 1b). These effects establish the current textbook Gestalt underlying our understanding of Dirac physics.

This study proposes the theory and material realization of novel DSM having Dirac points with nonzero chirality, called chiral Dirac semimetal (chiral DSM, Fig. 1c,d). We
considered a massless Dirac field in vacuum furnishing chiral and four-dimensional (4D) irreps, connecting two Weyl fields via a type of $SU(2)$ flavor symmetry—analogous to the isospin symmetry relating a proton and a neutron. Remarkably, such $SU(2)$ isospin symmetry can be perfectly obtained by the spin space group—an expanded symmetry group compared with the traditional magnetic space group—existing in magnetic materials with negligible spin-orbit coupling (SOC). The symmetry description involves decoupled spin and lattice operations. We show that the transition-metal chalcogenide CoNb$_3$S$_6$ with a chiral crystal structure and collinear antiferromagnetic (AFM) order is an ideal candidate for such chiral DSM. The resulting Dirac points have Chern numbers $C = \pm 2$, manifesting a robust network of topologically protected Fermi arcs throughout the surface Brillouin zone.

**Constructing massless chiral Dirac fields with additional flavor symmetry**

First, we briefly review the conventional Dirac field. Its field operators furnish a 4D irreducible representation of the Lorentz group. After that, we considered the symmetry condition supporting the chiral Dirac field. The Lorentz group is the group of Minkowski space-time symmetries obeying the principle of relativity. Such a group can be written as a combination of two disconnected pieces—$O(3,1) = SO(3,1) + P SO(3,1)$, where $SO(3,1)$ $^{12}$ is a connected subgroup of $O(3,1)$. Any irreps of $SO(3,1)$ can be labeled by the irreps of two $su(2)$ algebras, denoted as $(j^+, j^-)$, with $j^\pm = 0, 1/2, 1, 3/2, \ldots$, because the Lie algebra of $SO(3,1)$ consists of six generators forming two individual $su(2)$ algebras commuting with each other. Weyl fields—the simplest fields for spin-$\frac{1}{2}$ fermions—furnish the irrep $(0,1/2)$ or $(1/2,0)$ for right or left-handedness, satisfying
two-component massless Weyl equations when \( P \) is broken. The reducible representation of \( SO(3,1) \), i.e., \((0,1/2) \oplus (1/2,0)\), in the presence of \( P \), becomes irreducible for the Lorentz group \( O(3,1) \), giving rise to the Dirac fields.

The Dirac fields obey the famous Dirac equation, 

\[
(-i \alpha^i \partial_i + m \beta) \psi(x) = i \partial_0 \psi(x),
\]

where \( \alpha^i = \tau_x \otimes \sigma_i \) and \( \beta = \tau_z \otimes \sigma_0 \). It explains several new phases and phenomena such as antimatter, SOC, and Zeeman effect. However, seldom considered is the possibility of elementary spin-1/2 particles described by four-component fields having \((1/2,0) \oplus (1/2,0)\) (or equivalently, \((0,1/2) \oplus (0,1/2)\)), endowing chirality to Dirac fermions. \( P \) should be broken first to obtain such chiral Dirac fields, reducing the corresponding symmetry group to \( SO(3,1) \). Therefore, \((1/2,0) \oplus (1/2,0)\) would become a reducible representation, corresponding to a field that naturally decomposes into two Weyl fields. Second, additional internal symmetries need to be assumed to elevate the symmetry hierarchy of the system, rendering \((1/2,0) \oplus (1/2,0)\) representation irreducible. Internal symmetry operations are required to decouple the space-time operations according to the Coleman–Mandula theorem\(^{13}\). Furthermore, we selected them to form an \( SU(2) \) group connecting two Weyl fields with the same chirality, analogous to the \( SU(2) \) flavor symmetry in high-energy physics. Specifically, it is analogous to the isospin symmetry proposed by Heisenberg, pairing a proton and a neutron forming an \( SU(2) \) doublet\(^{14}\).

This isospin symmetry can stabilize free and causal quantum fields that follow the representation \((1/2,0) \oplus (1/2,0)\) (and \((0,1/2) \oplus (0,1/2)\), see Supplementary Note A). Such fields are known as chiral Dirac fields, described by the following chiral Dirac equation:
\[ i\alpha^i \partial_i \psi(x) = \pm i \partial_0 \psi(x), \quad (1) \]

where \( \psi(x) \) denotes a four-component free field operator and \( \alpha^i = \tau_i \otimes \sigma_0 \). In addition, such a field must be massless in the (3+1)D space-time because one cannot find a mass term to gap a chiral field without breaking the space-time rotational symmetry. Furthermore, the energy spectrum of equation (1) is doubly degenerate owing to the protection of the additional SU(2) group, resembling the role of \( P \) in the conventional Dirac equation.

**Theory of chiral Dirac semimetal**

A massless Dirac fermion can have chirality if there is a SU(2) isospin symmetry originating from an internal degree of freedom (DOF), independent of the space-time symmetry. In condensed matter solids with elementary excitations (quasiparticles), although spin is an internal DOF of an electron, its rotational operations are completely locked to the rotations of the lattice owing to the relativistic SOC effect. However, the corresponding symmetry description of compounds composed of light elements with negligible SOC requires decoupled spin and lattice DOF operations, forming symmetry groups called spin groups\(^\text{15–17}\). In analogy with the fact that isospin symmetry is good enough in prediction of the possibility and rates of nuclear reaction when the masses of the two particles\(^\text{18}\), e.g., proton and neutron or up and down quarks, are similar, spin group symmetry protects degeneracies, topological charges, and surface states of certain topological materials when SOC is weak. We next show that the combination of translation and spin rotation in certain magnetic compounds with long-range magnetic
order leads to a hidden $SU(2)$ symmetry group, supporting the emergence of novel quasiparticles described by the massless chiral Dirac equation (see equation (1)).

We considered a collinear AFM system belonging to the type-IV Shubnikov space group, as schematically shown in Fig. 2a. We used a four-band model with two orbitals separately located at sublattices A and B and the Neel vector along the z-axis to describe such a system. Three elements in the spin space group were considered, including a two-fold spin rotation perpendicular to the magnetic moment followed by a fractional translation symmetry, $u_x^{1/2} = \{U_x(\pi)||E|\tau_{1/2}\}$, and a spin rotation operation along magnetic moments with an infinitesimal rotation angle, $\{U_z(\theta)||E|0\}$, where $U_n(\theta)$, represents pure spin rotation $\theta$ along n axis and $\tau_{1/2}$ denotes the half translation along the z-axis (see Methods). We can write the general form of the Hamiltonian as $H(k) = \Sigma_{i,j=0,x,y,z} f_{ij}(k) \tau_j \otimes \sigma_i$, where $\sigma$ and $\tau$ operate on spin and site DOF, respectively, and $f_{ij}(k)$ represents real functions of $k$. After that, the the elements can be represented as

$$u_x^{1/2} = -ie^{-i k \tau_{1/2} \tau_x} \otimes \sigma_x, \quad u_y^{1/2} = -ie^{-i k \tau_{1/2} \tau_x} \otimes \sigma_y \quad \text{and} \quad \{U_x(\theta)||E|0\} = \tau_0 \otimes e^{-i \theta \sigma_z}.$$  

We applied these symmetry constraints to the Hamiltonian $H(k)$ and obtained the following equation:

$$H(k) = d_0(k) \sigma^0 + \sum_{i=1,2,3} d_i(k) \sigma^i,$$  (2)

where $d_0(k)$ and $d_i(k)$ represent real functions of $k$, $\sigma^0 = \tau_0 \otimes \sigma_0$ and $\sigma^i = (\tau_x \otimes \sigma_0, \tau_y \otimes \sigma_z, \tau_z \otimes \sigma_x)$. Moreover, $\sigma^i$ satisfies the anticommutation relation, $\{\sigma^i, \sigma^j\} = 2 \delta_{ij}$, which guarantees a two-fold degeneracy. It permits the possible Dirac points occurring at generic momenta when $d_i(k) = 0$ for all $i$. Around a Dirac point, this Hamiltonian can be expanded as follows:
where the second terms can be unitarily transformed into equation (1) by considering an isotropic Dirac cone. The first term, \( b_{j,0} k_j \alpha^0 \), can contribute to the kinetic energy. It will break the Lorentz symmetry if \( b_{j,0} \) is nonzero like the terms leading to type-II Weyl semimetal\(^{19}\).

Analogous to the chiral Dirac equation protected by the \( SU(2) \) isospin symmetry in quantum field theory, the chiral DSM is protected by a hidden \( SU(2) \) symmetry independent of the spatial rotations. To elucidate this, we show the existence of a hidden symmetry group with the group elements written as \( \exp(-i \theta \cdot \rho) \), where \( \theta = (\theta_1, \theta_2, \theta_3) \) represents real three-vector, and \( \rho \) denotes a three-vector of the three generators. The latter can be constructed proportional to the representations of \( u_1^{1/2}, u_2^{1/2}, \) and \( \{U_z(\pi)|E|0\} \), i.e., \( \rho = \left( \frac{1}{2} \tau_x \otimes \sigma_x, \frac{1}{2} \tau_x \otimes \sigma_y, \frac{1}{2} \tau_0 \otimes \sigma_z \right) \). Since \( \rho_i \) satisfies Pauli algebra, the group \( \{\exp(-i \theta \cdot \rho)\} \) is isomorphic to an \( SU(2) \) symmetry group. Such a \( SU(2) \) symmetry transforms the two Weyl quasiparticles, on the basis of \( \{|A, \uparrow\rangle, |B, \uparrow\rangle\} \) and \( \{|B, \downarrow\rangle, |A, \downarrow\rangle\} \), respectively, to their arbitrary linear combinations around a Dirac point up to a phase factor (the transformation of basis is shown in Fig. 2b).

Therefore, the hidden \( SU(2) \) symmetry acts as isospin symmetry. Hence, it supports the chiral Dirac fermion in condensed matter physics. The DSM protected by hidden \( SU(2) \) symmetry under the regime of spin group has two distinct features compared with conventional DSMs. i) Nonzero even Chern number (e.g., \( C = \pm 2n \)). Recall that the antiunitary \( PT \) symmetry in conventional DSMs guarantees two degenerate bands with opposite chirality for massless quasiparticles, leading to a zero Chern number for the
Dirac point. On the contrary, \( \{ \exp(-i \theta \cdot \rho) \} \) is a unitary symmetry group, ensuring that the degenerate states have the same Berry curvature. ii) The chiral Dirac point exists even without the protection of any additional symmetry except the translational and the \( SU(2) \) isospin symmetries. A perturbation to \( H(\mathbf{k}) \) — that does not break \( U_{\chi}^{1/2} \) or \( U_{z}(\theta) \) — typically shifts the position of the Dirac point without opening a gap, resembling the case of Weyl semimetals. It could be proved that except \( \alpha^{i} = (\tau_{x} \otimes \sigma_{x}, \tau_{x} \otimes \sigma_{y}, \tau_{x} \otimes \sigma_{z}) \) (for the conventional DSM), \( \alpha^{i} = (\tau_{x} \otimes \sigma_{0}, \tau_{y} \otimes \sigma_{z}, \tau_{x} \otimes \sigma_{z}) \) for the massless chiral DSM is the only solution of \( \alpha^{i} \) that fulfills the anticommutation relation (up to a unitary transformation, see Supplementary Note B). This solution has never been discussed in the literature. Fig. 2c summarizes the distinction between the conventional and chiral DSMs.

**Material Realization: CoNb\(_{3}\)S\(_{6}\)**

To realize chiral DSM in realistic materials, we first summarize the required conditions as following design principles: (i) collinear AFM order, (ii) broken \( P \) and \( PT \) symmetry, and (iii) presence of \( \{ T | \tau_{1/2} \} \) symmetry. We note that i) and iii) ensure the presence of spin group symmetry \( U_{\chi}^{1/2} \) and \( U_{z}(\theta) \) without SOC. Based on these principles, we propose that the chiral transition-metal chalcogenide CoNb\(_{3}\)S\(_{6}\) is a representative chiral DSM that hosts Dirac points around the Fermi level. Fig. 3a shows that CoNb\(_{3}\)S\(_{6}\) crystallizes in the chiral space group \( P6_{3}22 \). It has an AFM order with magnetic moments directed along a crystal axis within the a-b plane below the Neel temperature, \( T_{N} \), of \( \sim 26 \) K. This structure corresponds to the type-IV magnetic space group \( P_{b}2_{1}2_{1}2 \) (No. 18.22). It has one two-fold rotation along the \( x \)-axis \( \{ U_{x}(\pi) || C_{x}(\pi) || 0 \} \), two screw rotations \( \{ U_{y}(\pi) || C_{y}(\pi) || \tau_{(b+c)/2} \} \) and \( \{ U_{z}(\pi) || C_{z}(\pi) || \tau_{(b+c)/2} \} \), and nonsymmorphic
time-reversal \( \{ T | \tau_{(a+b)/2} \} \), as per the notation of spin space groups. Some symmetry operations beyond the conventional magnetic space group, including \( \{ E || C_x(\pi) | 0 \} \) and \( \{ T U_n(\pi) || E | 0 \} \), are permitted without SOC, forming the spin space group \( P_B \uparrow \downarrow 2_1 \downarrow 2_1 \downarrow 2_{\text{cmm}} \) (see Supplementary Note C).

The band structure calculation (Fig. 3b) shows that CoNb\textsubscript{3}S\textsubscript{6} is a metal with multiple hole pockets near the \( \Gamma \) point, consistent with the experiments showing holes as major system carriers. The symmetry properties guarantee the following topological features that appear in the band structure. First, the spin space group does not have \( P \). However, it has \( u_{x}^{1/2} = \{ U_{z}(\pi) || E | \tau_{(a+b)/2} \} \) and \( \{ U_{z}(\theta) || E | 0 \} \), ensuring doubly degenerate bands for chiral DSM. Second, the two-fold spatial rotations decoupled to spin rotations—\( \{ E || C_x(\pi) | 0 \} \), \( \{ E || C_y(\pi) | \tau_{(a+c)/2} \} \) and \( \{ E || C_z(\pi) | \tau_{(a+c)/2} \} \)—commute with \( u_{x}^{1/2} \) along the \( \Gamma - X \), \( \Gamma - Y \), and \( \Gamma - Z \) lines, ensuring that the two degenerate energy bands have identical rotation eigenvalues on the high-symmetry lines. Therefore, the three two-fold rotation operations can provide additional protection for Dirac points.

Remarkably, there are multiple Dirac points around the Fermi level and four Dirac points at \( \sim 0.7 \) eV above the Fermi level. We focused on the four Dirac points highlighted in Fig. 3b for clarity because the Dirac points near the Fermi level are crowded with the hole pockets. The four Dirac points are located along \( \Gamma - X \) and \( \Gamma - Y \) lines. We found that the crossing bands along these high-symmetry lines have opposite eigenvalues of \( \{ E || C_x(\pi) | 0 \} \) or \( \{ E || C_y(\pi) | \tau_{(a+c)/2} \} \), indicating that the Dirac points are protected by \( C_2 \) rotation. The Berry curvature calculation (see Fig. 3d) shows that the two Dirac points along \( (-X) - \Gamma - X \) act as the source of the Berry curvature, and the other two act as the
drain manifesting the chiral nature of the Dirac point. Further calculation of the Wilson loop showed that the Chern number over a spherical surface around a Dirac point along $\Gamma - X(Y)$ was $-2$ ($+2$) (see Supplementary Fig. S1). Therefore, we name the Dirac points along $\Gamma - X(Y)$ as $N_1, N_2$ ($P_1, P_2$). We obtained the Dirac-type $k \cdot p$ Hamiltonian in the following by applying the symmetry operations, $u_x^{1/2}$, $U_x(\theta)$ and $\{T|C_2(\pi)|\sigma_{(b+c)/2}\}$, to the low-energy Hamiltonian near $N_1$:

$$H(k) = (a_0 + a_1 k_x) \tau_0 \otimes \sigma_0 + (a_2 k_y) \tau_x \otimes \sigma_0 + (a_3 k_z) \tau_y \otimes \sigma_x + (a_4 k_x) \tau_z \otimes \sigma_x. \quad (4)$$

The results of our DFT calculation can be used to obtain the parameters of equation (3), giving rise to an anisotropic Dirac cone. By implementing the spin rotation $e^{-i/2(\pi/2)\sigma_y}$ to equation (3) (transforming $\sigma_x$ terms into $\sigma_z$ terms), the Hamiltonian is block-diagonalized into two Weyl Hamiltonians of the same chirality, indicating the nature of chiral DSM.

The topological charges of the chiral DSM imply the existence of Fermi arc surface states connecting two Dirac points with opposite chirality. However, Dirac points with opposite chirality are not connected by any symmetry owing to the lack of inversion symmetry and mirror symmetry in the system. Therefore, we found an energy offset of 87 meV. Moreover, Dirac points, $P_1$ and $P_2$ ($N_1$ and $N_2$), are connected by a two-fold spatial rotation. Hence, they are located at the same energy. There are two disconnected electron Fermi pockets, separately enclosing $P_1$ and $P_2$, and two disconnected hole pockets, separately enclosing $N_1$ and $N_2$, for the (001) surface when Fermi energy exists between the two. Every electron pocket is connected to a hole pocket by a branch of Fermi arc surface states due to the enclosure of the different topological charges in
electron and hole pockets, forming a network across the Brillouin zone (see Fig. 4a). Interestingly, the surface states are also doubly degenerate because \( \{U_x(\pi)|E|\tau_{(a+b)/2}\} \) is preserved on this surface, in sharp contrast to the conventional topological insulators or DSMs where the surface bands are spin-polarized and nondegenerate. The degenerate Fermi arc surface states are split into two branches for the (100) surface with broken symmetry of \( \{U_x(\pi)|E|\tau_{(a+b)/2}\} \), as shown in Fig. 4b. The various Fermi arc surface states are robust against perturbations, maintaining the collinear A-type AFM order in the absence of SOC. On the contrary, topological protection for the surface states on the conventional DSM does not exist\(^{23}\).

The Chern number of a 2D slice in the Brillouin zone changed in the multiples of 2 because the Dirac points have chiralities of \( \pm 2 \). Fig. 4c shows that the Chern number of the slice perpendicular to the x-axis changes as a function of \( k_y \). The Chern number calculated on slice near \( \Gamma \)—between Dirac points with opposite chirality—is \( \pm 2 \). The result is consistent with the Berry curvature calculation (Fig. 3c), where the Berry curvature flow from \( N_1 \) and \( N_2 \) to \( P_1 \) and \( P_2 \). Fig. 4d shows the corresponding edge states with two branches of chiral surface states connecting the conduction and valence bands that are doubly degenerate at \( SU(2) \)-preserved edge and nondegenerate at \( SU(2) \)-broken edge, further validating the chiral nature of the Dirac points.

**Discussion**

Robust surface states of conventional DSMs are rare except for specific nonsymmorphic symmetries to protect the surface states\(^{24,23}\). The chiral DSM provides robust fermi-arc surface states, potentially leading to unexplored emergent transport and
optical properties. For example, the Dirac points of opposite chirality in CoNb$_3$S$_6$ do not lie at the same energy, possibly leading to a large and quantized response to circularly polarized light$^{25}$. Furthermore, the net anomalous Hall conductivity and spin Hall conductivity in CoNb$_3$S$_6$ should be zero owing to the presence of $\{T||E|\tau_{1/2}\}$ symmetry and $\{T||U_n(\pi)|0\}$ symmetry. However, breaking $\{T||E|\tau_{1/2}\}$ symmetry and $\{T||U_n(\pi)|0\}$ symmetry through the small SOC effect and small tilting of magnetic moments may lead to a large anomalous Hall conductance because of the uncompensated Berry curvature and multiple Fermi arcs emerging from the Dirac points. It has been observed in CoNb$_3$S$_6$, accompanied by small out-of-plane components of the magnetic moments$^{26}$.

Finally, we note that our chiral DSM is significantly different from the semimetal with four-fold degenerate points having a Chern number of ±2 or ±4$^{4,27-31}$. First, these quasiparticles are stabilized by the little groups with high-order rotation operations or the little groups with nonsymmorphic symmetry operations. Therefore, these elementary excitations can only appear at specific high-symmetry momenta of the Brillouin zone. However, our chiral Dirac points can appear at generic momenta. This property implies the emergence of dense Dirac points within a small energy range, possibly leading to stronger topological effects. Second, previously studied models with four-fold degenerate points with nonzero Chern number inevitably have nondegenerate energy bands away from the high-symmetry points. Therefore, they do not strictly fulfill the Dirac equation in quantum field theory. However, our chiral DSM was derived from the quantum field theory perspective with doubly degenerate dispersions around the Dirac points, stabilized by the hidden $SU(2)$ isospin symmetry.
Methods

Notations of spin space groups

Because spin and orbit degrees of freedom are partially decoupled in magnetic systems when SOC effect is weak, we have to consider spin and spatial rotations separately. We separate denote spin rotations and spatial rotations as $U_n(\theta)$ and $C_n(\theta)$ where $n$ denotes the rotation axis and $\theta$ is the rotation angle. By considering time reversal $T$, spatial inversion symmetry $P$ and translation symmetry $t$, all elements of a spin space group can be written as the following form:

$$\{T^{n_1} U_n(\theta)|P^{n_2} C_m(\varphi) |t\},$$

with $n_1 = 0,1$ and $n_2 = 0,1$. Although time reversal $T$ could reverse momentum in the reciprocal space, both $T$ and $U_n(\theta)$ can be seen as the symmetries of spin in real space when analyzing symmetry of materials. $P$, $C_m(\varphi)$ and $t$ are spatial symmetries. Thus, we separate the 5 types of symmetry into spin symmetries, $T$ and $U_n(\theta)$, and spatial symmetries, $P$, $C_m(\varphi)$ and $t$, by a double line.

First-principles calculations

The first-principles calculations were carried out using projector-augmented-wave (PAW) method \textsuperscript{32}, implemented in Vienna ab initio simulation package (VASP) \textsuperscript{33} within the framework of density-functional theory \textsuperscript{34, 35}. Contributions of exchange and correlation effects were accounted by the generalized gradient approximation (GGA) with the Perdew-Burke-Ernzerhof (PBE) formalism \textsuperscript{36, 37}. An energy cut off of 520 eV is used in our calculations. The whole Brillouin-zone was sampled by $5 \times 8 \times 4$. 
Monkhorst-Pack grid \(^{38}\) for all cells. Due to the local magnetic moments contributed from 3d electrons in Co atoms, GGA+U approach \(^{39}\) within the Dudarev scheme \(^{40}\) is applied and we set the U on Co to be 3 eV, which produces local magnetic moments of \(2.2 \mu_B\) consisting well with the experiments \(^{22}\). A tight-binding Hamiltonian is obtained base on maximally localized Wannier functions \(^{41,42}\) of Co-3d, Nb-4d, S-3p orbitals, from which the topological surface states, Berry curvature and Chern number are calculated. The iterative Green’s function implemented in WannierTools package is used for surface states calculations \(^{43}\).

\[ e^{-i\theta(\cos(\omega)\frac{1}{2}\sigma_x + \sin(\omega)\frac{1}{2}\sigma_y)}(\psi_u \phi_d). \]

The comparison between the conventional DSM and chiral DSM.

**Fig. 3 Crystal and bulk electronic properties of CoNb$_3$S$_6$.**

**a**, The crystal structure of CoNb$_3$S$_6$. **b**, The Brillouin zones of bulk (001) and (100) surfaces of CoNb$_3$S$_6$. **c**, The band structure of CoNb$_3$S$_6$ without spin-orbit coupling. There are two chiral Dirac points at \(~0.7\) eV above the fermi level, \(N_1\) and \(P_1\), and another two Dirac points, \(N_2\) and \(P_2\) (not shown), that are connected to \(N_1\) and \(P_1\) through two-fold rotation. **d**, Distribution of in-plane components of the Berry curvature on \(k_z = 0\) plane, where \(N_1/N_2\) and \(P_1/P_2\) denote the source and sink, respectively.
**Fig. 4** Protected topological surface states of chiral DSM CoNb$_3$S$_6$.  

---

**a,b**, Iso-energy surface states connect electron pockets and hole pockets, separately enclosing Dirac points with opposite chirality on (001) and (100) surfaces of CoNb$_3$S$_6$. **c**, The transition of Chern number defined on 2D slices in the Brillouin zone perpendicular to the y-axis as a function of momentum $k_y$. **d**, Chiral edge states of the 2D slice ($k_y = 0.1$ (2$\pi$/b)) with Chern number of 2. Doubly degenerate edge bands are found in SU(2)-preserved edge, while spin-polarized nondegenerate edge bands are found in SU(2)-broken edge. The notations are defined as $\Gamma_1 = \Gamma + \bar{P}$, $\bar{X}_1 = \bar{X} + \bar{P}$, $\Gamma_2 = \Gamma + \bar{P}$, and $\bar{Z}_2 = \bar{Z} + \bar{P}$, where $\bar{P} = \frac{1}{5}(\bar{Y} - \bar{\Gamma})$. 

---

*Notation:* $\Gamma, \bar{X}, \Gamma_1, \bar{X}_1, \Gamma_2, \bar{Z}_2, \bar{P}$.
