We uncover a remarkably regular array of singularity-like structures within the deep strong-coupling limit of qubit-oscillator (e.g. light-matter) systems described by the quantum Rabi model, as a function of time and coupling strength. These non-analytic anomalies in the Loschmidt amplitude (echoes) suggest the existence of new forms of dynamical phase transition within this deep strong-coupling regime. The key feature whereby the initial state collapses into orthogonal states at select values of the interaction strength and select times, may be used to enhance – or attack – quantum information processing or computation schemes that rely on removing – or retaining – a given quantum state.

Qubit-oscillator systems (e.g. confined light-matter interactions or spin-nanomechanical resonators) play a key role in physics and its applications, including the burgeoning field of quantum computing [1] as well as quantum optics [2], molecular physics [3] and hybrid quantum devices [4]. This motivates the search for a deeper theoretical understanding of their quantum dynamics. The quantum Rabi model (QRM) [5] describes the fundamental building block for such systems – a single two-level qubit (e.g. atom, quantum dot or NV center) coupled to an oscillator (e.g. photon or phonon) mode – while the Dicke model [6] generalizes this to multiple qubits. Although there is an exact solution for the spectrum of the QRM [7, 8], the resulting expression is difficult to manipulate for practical dynamical applications.

Perturbative methods have been developed for different values of the qubit-oscillator (e.g. light-matter) coupling strength $g$, leading to a classification of the system into regimes depending on the value of $g$ [9]. When $g$ is considerably smaller than the natural frequencies of the qubit and the bosonic mode, i.e. the weak coupling regime, the QRM is well described by the exactly solvable Jaynes-Cummings model [10]. When $g$ is a significant fraction of these frequencies, the system lies in the strong coupling (SC) or ultrastrong coupling (USC) regimes. When the coupling strength becomes larger than the natural frequencies of the system, the system lies in the deep strong-coupling regime. While experiments have been performed in the SC regime for decades via cavity quantum electrodynamics (QED) [11], recent advances in achieving the USC [12, 13] and DSC [15] experimentally have brought these regimes to the forefront of attention.

The current capability to experimentally vary the strength of the coupling $g$ over a wide range of values, raises the possibility of exploring non-analytic behaviors that point toward new phase transitions [16]. Such behaviors could also arise as a function of time in a driven system, i.e. a dynamical quantum phase transition (DQPT) [17]. One of the key quantities in the study of DQPTs is the Loschmidt Amplitude (LA) which is the overlap between the initial quantum state of the system and the time-evolved one. Its zeroes play the same role in the complex time plane as the Yang-Lee zeroes of the partition function do in the complex temperature plane [18]. Sharp, non-analytic features in its time-evolution suggest dynamical phase transitions [17]. Recent theoretical work on the single qubit QRM has shown several quantum phase transition behaviors in the off-resonant limiting case where the ratio between the qubit splitting energy and the mode goes to infinity at the same time as $g$ goes to infinity [19]. In this limit, the ground-state of the QRM undergoes a second-order phase transition while excited states show signatures of an excited state quantum phase transition [20]. Experimental realizations with a single trapped ion have already been reported [21], and a DQPT has been proposed in the off-resonant limit [22]. More generally, studies across different types of qubit-oscillator systems have suggested that the ultra-strong coupling regime is relevant to a wide range of fundamental physics phenomena such as virtual photon accessibility in the Casimir effect [23, 24], and novel applications including optomechanical nanosystems [25-27].

This paper shows that deep strong coupling generates a new regime of non-analytic features suggestive of dynamical phase transitions, even for the simplest of systems (QRM). Our full numerical calculations show that approximate zeroes of the LA (echoes) emerge in a staircase structure as a function of the coupling strength $g$ and time $t$ after the onset of this coupling. In addition to being relevant to the fundamental quantum speed limit for information processing, i.e. minimal time for the evolution to an orthogonal state [25, 29], these orthogonality-points in $(g,t)$ space can provide well-defined stages in a quantum computation or information processing scheme. For situations where they are undesirable, our findings
provide the combinations of $g$ and $t$ to avoid.

We consider arguably the simplest example of a driven qubit-oscillator system: a two-level system with level splitting $\omega_0$ described by Pauli operators $\hat{\sigma}_z$, $\hat{\sigma}^+$ and $\hat{\sigma}^-$, coupled with strength $g(t)$ to a single boson mode (QRM) at resonance:

$$\hat{H}(t) = \omega_c \hat{a}^\dagger \hat{a} + \frac{\omega_0}{2} \hat{\sigma}_z + g(t)(\hat{a}^\dagger + \hat{a})(\hat{\sigma}^+ + \hat{\sigma}^-), \quad (1)$$

where $\hbar = 1$. The operators $\hat{a}^\dagger \hat{a}$ denote boson ladder operators, which for simplicity we call photon operators. This Hamiltonian commutes with the parity operator $\hat{P} = e^{i \pi (\hat{a}^\dagger \hat{a}^\dagger + \frac{1}{2}(1 + \hat{\sigma}_z))}$. Given an initial state with zero excitations in both qubit and oscillator sub-systems $|\psi(0)\rangle = |0,0\rangle$ (i.e., even parity) the time-evolution remains confined to the even Hilbert subspace. Hence a basis can be chosen as $\{|n,m\rangle\} \equiv \{|n,m|\}$, noting that $m = 0$ when $n$ is even while $m = 1$ otherwise. Hence Eq. (1) becomes:

$$\hat{H}(t) = \omega_c \hat{a}^\dagger \hat{a} - \frac{\omega_0}{2} e^{i \pi \hat{a}^\dagger \hat{a}} + g(t)(\hat{a}^\dagger + \hat{a}). \quad (2)$$

This form explicitly shows the strong anharmonicity, mediated by the qubit, of the oscillator sub-system. The Loschmidt amplitude (LA)

$$\mathcal{L}(t) = \langle \psi(0) | \hat{U}(t,0) | \psi(0) \rangle,$$  

(3)

calculates the fidelity of the time-evolved state $|\psi(t)\rangle = \hat{U}(t,0)|\psi(0)\rangle$ with respect to the initial state $|\psi(0)\rangle$. We calculate the final state $|\psi(t)\rangle$ under Eq. (1) given the initial ground state $|\psi(0)\rangle \equiv |0,0\rangle$. Though the Rabi model is integrable \cite{7}, no analytical results are available for the case of interest here, i.e. the non-equilibrium resonant Rabi model.

We benchmark tested our full numerical calculations using the $\omega_0 \to 0$ limit for which the exact analytic solution is known \cite{23,31}, noting that our calculations can be generalized to other time-dependent quenchings \cite{24}. While this simple limiting case does not show any signature of a dynamical phase transition, the situation changes drastically with a finite qubit splitting $\omega_0 = \omega_c$. For convenience, we use a logarithmic scale by defining a Loschmidt echo rate (LER) exponent as \cite{17}:

$$\gamma(g,t) = -\log_{10}\left|\mathcal{L}(g,t)\right|$$

and corresponding exponents can be defined for derivatives with respect to $t$ and $g$:

$$\beta(g,t) = -\log_{10}\left|\frac{\partial \mathcal{L}(g,t)}{\partial t}\right| \text{ and } \chi(g,t) = -\log_{10}\left|\frac{\partial \mathcal{L}(g,t)}{\partial g}\right|.$$  

For a pulsed coupling of constant height $g$, the dynamics are contained within the complete set of even parity eigenstates $|E_m\rangle$ with energy $E_m$ for the QRM Hamiltonian (Eq. (1)) where $\mathcal{L}(g,t) = \sum_m e^{-iE_m t}|\langle E_m | \psi(0)\rangle|^2$. Figure 1 shows our results
to $\gamma(g,t)$ at $\omega_0 = \omega_c$ and $|\psi(0)\rangle = |0,0\rangle$, across a wide region of the DSC $(g,t)$ plane. We find that using a basis set of up to 750 photon states guarantees convergence. While a smooth continuum occupies the left half of the one-period evolution, a ladder of localized singularities arises for $\gamma(g,t)$ in the right half. We emphasize that this ladder of LER sin-
singularities has nothing to do with quenching through an equilibrium quantum phase transition, since the QRM at resonance doesn’t show the emergence of any kind of equilibrium phase transition. Therefore, we conclude that this non-analytic dynamical behavior of the LER at select points in the \((g, t)\) plane, can be understood as a DQPT when quenching from the uncoupled qubit-oscillator ground state to a final DSC coupled system – regardless of the finite size of the matter sub-system.

So far we have pointed out the existence of a ladder of LA echoes. Deeper insight is gained by inspecting the trajectories of the full LA in the complex plane (see Fig. 2). The ladder of LA echoes is intimately connected with DQPTs which are well known to have no local order parameter. Instead, DQPTs have been associated with dynamical topological order parameters which can be extracted from the Pancharatnam phase of the LA itself Eq. (3). For critical translational invariant systems, the dynamical topological order parameter is quantized as an integer number that jumps at critical times. We do not know of any previous reports of such signatures in a system such as the QRM that does not have an associated length scale.

The LA exhibits highly nontrivial behavior in terms of its rotation in the complex plane. A clockwise rotation corresponds to a positive curvature and a counterclockwise rotation corresponds to a negative curvature. Figure 3 shows the rotation directions in different regimes, and the location of the maxima of \(\gamma\), \(\beta\) and \(\chi\). The maxima of \(\beta\) must always correspond to zero curvature, since a zero complex velocity implies zero curvature. In the DSC regime, we find alternating regions of clockwise and anti-clockwise rotations. Figure 3 reveals a rich dynamical phase diagram with additional topological phase transitions which are a different class from those previously reported for the off-resonant QRM. The phases separated by these topological transitions are distinguished from each other by this topological feature, and each can in principle be assigned a topological number. Interestingly, the wavy boundary between these regions seems to follow the location of the discrete ladder of LA zeros for higher values of \(g\) (Fig. 3 right panel) indicating a hidden relationship between changes in this rotational behavior and the emergence of singularities. Moreover, zeros in the LA derivatives with respect to time \((\beta(g, t))\) and coupling \((\chi(g, t))\) fall on this same undulating border that separates different LA-chirality regions. This is a key signature of the emergence of a topological dynamical phase transition.

For the LA and LER exponents, we find a near perfect collapse of numerical values of \(\gamma(g, t)/g^2\) for the QRM, with the corresponding analytical result for the zero qubit splitting (QZS) limit result, given by

\[
\mathcal{L}_0(g, t) = e^{i\theta(g, t)}e^{-2\left(\frac{\omega}{\omega_c}\right)^2}\sin^2\left(\frac{\omega t}{2}\right),
\]

with \(\theta(g, t)\) being defined as

\[
\theta(g, t) = \left(\frac{g}{\omega_c}\right)^2 [\omega_c t - \sin(\omega_c t)].
\]

This yields

\[
\gamma_0(g, t)/g^2 \sim \sin^2\left(\frac{\omega_c t}{2}\right)
\]
as a universal value which is independent of the specific coupling strength \(g\). In the trailing edge of the coupling pulse, there is good agreement between the exact numerical results and the expression calculated from the Loschmidt echo rate for a ZQS system \([|\mathcal{L}_0(g, t)|]\) in Eq. (4), especially after the kink in \(\gamma(g, t)/g^2\) (see Fig. 4). This collapse suggests that the anharmonicity induced by the qubit in the effective oscillator in Eq. (2), fades away for long pulse durations that place the system to the right of the wavy chirality border in Fig. 3. This raises the possibility of designing tailored pulses for which the LA and the corresponding exponent become identical in the long time pulse limit for the highly anharmonic resonant qubit-boson case and for the simple harmonic ZQS system.

Further insight into the emergence of this LA ladder comes from the following exact relationship for an arbitrary quantum system

\[
\mathcal{L}(t) = \mathcal{L}(t - \tau)\mathcal{L}(\tau) + M(t, \tau)
\]

where the memory term is

\[
M(t, \tau) = \langle \psi_0 | \tilde{U}(t, \tau) \tilde{Q} \hat{U}(\tau, 0) | \psi_0 \rangle
\]

and \(\tilde{Q} = 1 - |\psi_0\rangle\langle\psi_0|\). Using Eqs. (3) and (7), we obtain an equation of motion for the LA

\[
\frac{\partial \mathcal{L}}{\partial g} + i \frac{\partial \mathcal{L}^*}{\partial \tau} = -\frac{i t}{2} \mathcal{L}(g, t) + \mathcal{G}(g, t)
\]

where \(\mathcal{G}(g, t) = it \sum_{n=1}^{\infty} \left[ \frac{(-1)^{n+1} - 1}{2} + n \right] \int_0^1 dx \langle \psi_0 | e^{-ix\hat{H}(g, t)} | n \rangle \langle n | e^{-i(1-x)\hat{H}(g, t)} | \psi_0 \rangle \) and \(|n\rangle \equiv \langle n | e^{-i(1-x)\hat{H}(g, t)}}
\[ \gamma(g, t)/(g/\omega_c)^2 \]

FIG. 4. Numerical and ZQS results for \( \gamma(g, t)/(g/\omega_c)^2 \), for coupling strength \( g \) values corresponding to the first four LA zeros. In the trailing edge of the coupling pulse, there is a collapse of the exact numerical results onto the curve for the ZQS, Eq. (6).

The staircase nature of the anomalies (i.e. LA zeros) as a function of \( g \) and \( t \), reflects the fact that the LA equation of motion resembles a generalized Burgers’ shock-wave equation in which \( \partial \mathcal{L} / \partial t - (g/t) \partial \mathcal{L} / \partial g \) contains a convolution of \( \mathcal{L}(g, t) \) over time plus correction terms. This suggests the propagation of short-lived, modified shock waves in \( \mathcal{L}(g, t) \) as a function of \( g \) and \( t \), as observed.

Our findings have further implications. First, this discrete staircase of LA-zeros not only appears for the QRM, but it also shows signs of existing for multi-qubit systems (Dicke model) and with more complicated time varying couplings \[35\]. Although a comprehensive treatment of the scaling of such complex systems remains to be explored, our results open up a path to tailoring zeros of the LA using a time-dependent interaction and by increasing the number of qubits.

Second, photon states lacking the vacuum component are predicted to present highly non-classical features, such as negative values of the Wigner function and Schrödinger-cat state generation \[36\]. Our findings demonstrate that a simple QRM (e.g. single qubit-photon) system is an ideal platform for realizing such non-classical light states, simply by varying the coupling \( g \) and time since onset \( t \).

Third, the key feature whereby the initial state collapses into orthogonal states in a punctuated way as a function of \( g \) and \( t \), may be used to enhance – or attack – future quantum information processing or computation implementations that rely on removing – or retaining – a given quantum state. This finding could motivate new schemes that exploit this fact for erasing memory of an initial state. However, it also flags a potential vulnerability to external attack in quantum information processing schemes that require maintaining some memory (i.e. non-zero vacuum component) of the initial state.

Finally, we note that decoherence should have a negligible effect on the ladder of LA anomalies reported here, since they occur within a single cavity cycle scale of time and in the DSC regime, placing the system in an ultra-fast regime where the unitary treatment above discussed should be appropriate.
