Error mitigation is an essential component of achieving practical quantum advantage in the near term, and a number of different approaches have been proposed. In this work, we recognize that many state-of-the-art error mitigation methods share a common feature: they are data-driven, employing classical data obtained from runs of different quantum circuits. For example, Zero-noise extrapolation (ZNE) uses variable noise data and Clifford-data regression (CDR) uses data from near-Clifford circuits. We show that Virtual Distillation (VD) can be viewed in a similar manner by considering classical data produced from different numbers of state preparations. Observing this fact allows us to unify these three methods under a general data-driven error mitigation framework that we call UNITed Technique for Error mitigation with Data (UNITED). In certain situations, we find that our UNITED method can outperform the individual methods (i.e., the whole is better than the individual parts). Specifically, we employ a realistic noise model obtained from a trapped ion quantum computer to benchmark UNITED, as well as state-of-the-art methods, for problems with various numbers of qubits, circuit depths and total numbers of shots. We find that different techniques are optimal for different shot budgets. Namely, ZNE is the best performer for small shot budgets (10^5), while Clifford-based approaches are optimal for larger shot budgets (10^6 – 10^8), and for our largest considered shot budget (10^10), UNITED gives the most accurate correction. Hence, our work represents a benchmarking of current error mitigation methods, and provides a guide for the regimes when certain methods are most useful.

I. INTRODUCTION

As new generations of quantum computers become larger and less noisy, the practical application of quantum algorithms is just around the corner. It is likely that any quantum algorithm that can achieve an advantage over its classical counterpart will have to contend with substantial hardware error. While quantum error correction may eventually allow one to eliminate hardware noise, doing so will require many more qubits and significantly less noise. Although full error correction will not be practical in the near term, it is possible to partially mitigate errors with far lower resource requirements. A number of such error mitigation techniques have been proposed [1, 2], each with their own benefits and trade-offs.

One of the most popular approaches to error mitigation is zero noise extrapolation (ZNE) [3]. ZNE involves collecting data at different noise levels and fitting an extrapolation to the noiseless case. A variety of methods have been introduced to amplify the noise as well as to perform the extrapolation [3, 4]. ZNE has been shown to work well for small problem sizes [5], but has faced challenges for large problem sizes [6]. Due to the uncertainty of the extrapolation ZNE does not have performance guarantees for regimes of high noise. Explicitly, for circuits involving many gates, the lowest error points available are often too noisy for such fits to be helpful.

Alternatively, classically simulable circuits can be used to inform the experimenter about noise in a quantum device [6–10]. The Clifford data regression (CDR) method makes use of the Gottesman-Knill theorem [11] which guarantees that quantum circuits containing only Clifford gates can be classically simulated. CDR constructs a training set using data obtained from classically simulable near-Clifford circuits similar to the generic quantum circuit of interest. This set of data is then used to perform a regressive fit on an ansatz mapping noisy to exact expectation values. The fitted ansatz is used to estimate the value of the noiseless result. Furthermore, the combination of CDR and ZNE, which can outperform either method separately, has been considered and is called variable-noise CDR (vnCDR) [12]. vnCDR uses training data involving near-Clifford training circuits evaluated at multiple noise levels and can be thought of as using Clifford data to inform the extrapolation to the zero noise limit.

More recently, error mitigation via virtual distillation (VD) has been introduced [13, 14]. VD mitigates noise by simultaneously preparing multiple copies of a noisy state, entangling them, and making measurements to virtually prepare a state which is more pure than the original noisy states. Further improvements have been made and analyses have been performed [15–18]. While VD could achieve exponential error suppression in some regime [13–15], it has been noted that VD requires a number of shots that

* The first two authors contributed equally to this work.
scales exponentially in the number of qubits used for sufficiently large noise rates [15].

Given the success of merging ZNE and CDR into vnCDR, in this paper we consider whether or not it is beneficial to unify these other error mitigation methods with VD. By considering the number of copies used in VD to be a noise-control parameter, we use Clifford data to guide an extrapolation to the noiseless case (corresponding to the many copy limit), much like vnCDR. While also adding ZNE-like noise amplification we arrive at a framework unifying CDR, ZNE, and VD, which we call UNIfied Technique for Error mitigation with Data (UNITED).

In order to get a realistic idea of how ZNE, vnCDR, VD, and UNITED compare we carry out a numerical study benchmarking the performance of each technique when mitigating a local observable produced by a random quantum circuit. We explore their performance on a simulator based on the current error rates of an ion-trap quantum computer. We compare performance across various system sizes and circuit depths, involving systems of up to 10 qubits and depths of up to 128 Molmer-Sørensen entangling gates layers. Furthermore, we systematically compare the necessary shot cost for each method in its mitigation task, providing a fair comparison to guide experimenters in this field.

Overall, we show an advantage of vnCDR over VD and ZNE for all considered regimes apart from the regime of shallow circuits with $10^5$ shots for which ZNE performs best. For the largest considered shot budget ($10^{10}$) our new unified method UNITED gives an advantage over all other methods considered. ZNE and VD can give good corrections, but their corrections do not significantly improve with a reasonable increase in the total shot budget. The unified approaches of vnCDR and UNITED display significant improvement over both ZNE and VD, but a higher total shot cost is necessary to unlock that improvement. This suggests that the unified methods (vnCDR and UNITED) are the more powerful techniques, and the advantage they offer becomes clear when investing sufficient resources. Hence, we believe such unified methods are crucial to explore.

II. STATE-OF-THE-ART ERROR MITIGATION METHODS

A. Zero Noise Extrapolation

ZNE [3] uses noisy expectation values of an observable of interest $X$ obtained from the quantum circuit of interest $U$ run at increased noise to extrapolate to the noise free limit. Originally, Richardson extrapolation [19] was proposed to estimate the noise-free observable [3]. The method was applied successfully to mitigate variational ground state quantum simulations with IBM quantum computers [5, 20].

More formally, ZNE usually assumes that the noise can be characterized by a single parameter $\lambda$ which is the noise strength. We consider a task of estimating the expectation value $\mu = \langle 0 | U^T X U | 0 \rangle$ from measurements on a noisy quantum device. Here $| 0 \rangle$ is the initial state. To perform the extrapolation we measure the observable for $n + 1$ noise strengths $\lambda_j = c_j \lambda_0$, where $1 = c_0 < c_1 < \cdots < c_n$. Here $\lambda_0$ is the smallest noise strength which can be obtained for the quantum device. We call $c_j$ coefficients noise levels. For each noise level we obtain the expectation value $\hat{\mu}_j$. The Richardson extrapolation estimates the noise free value $\mu$ as

$$\hat{\mu}' = \sum_{j=0}^{n} \gamma_j \hat{\mu}_j,$$

where

$$\sum_{j=0}^{n} \gamma_j = 1, \sum_{j=0}^{n} \gamma_j c_j^k = 0 \text{ for } k = 1, \ldots, n. \quad (2)$$

Richardson extrapolation approximates $\mu$ with an error scaling as $O(\lambda_0^{n+1})$ [3]. Nevertheless, the Richardson extrapolation in the presence of shot noise leads to exponential growth of $\hat{\mu}'$ uncertainty with increasing $n$ [21]. Richardson extrapolation is equivalent to fitting a polynomial of order $n$ on the various noisy expectations, treating the noise levels $c_j$ as independent variables [22].

To address problems with reliability of Richardson extrapolation for large $n$ lower order polynomial fits and exponential fits have been proposed [20, 21, 23]. Furthermore, approaches for noise characterized by multiple parameters have been postulated [24].

The original proposal stretches pulses used to implement gates to increase the hardware noise [3]. Nevertheless, it is often more convenient to increase noise performing so called identity insertions [20–22]. These methods insert groups of gates that evaluate to the identity into the circuit of interest. This does not change a state encoded by the circuit $U | 0 \rangle$ but increases the number of gates in the circuit, scaling the noise.

ZNE provides a very simple framework to mitigate errors introduced by noise on some observable of interest. However, there are several technical challenges which limit its power. Firstly, ZNE assumes that low enough noise levels are experimentally accessible to enable successful extrapolation to the zero noise limit. Furthermore, the best choice of the ansatz used to perform the extrapolation is not known a priori [21]. Also, controlled increase of the noise strength is hardware dependent and may be challenging to implement in practice [5].

B. Clifford Data Regression

We first introduce the CDR framework which provides background for the more general vnCDR and UNITED methods. CDR [6] uses classically simulable training circuits consisting mainly of Clifford gates to learn effects
of the noise on an observable of interest. For the training circuits the expectation value $X$ is evaluated classically and on noisy quantum hardware. This data is used to train a function mapping the noisy to the exact expectation values, which is then used to mitigate the expectation value $X$ for some circuit of interest. The method was successfully applied to quantum simulations of condensed matter systems with IBM quantum computers [6, 25].

The training circuits $S = \{V_i\}_{i=1}^{N_t}$ are chosen to be similar to $U$. The simplest strategy to construct the training set is to replace most of non-Clifford gates in the circuit of interest by a Clifford gate which is similar [6]. Alternatively, the usage of Markov Chain Monte Carlo was proposed to construct training sets where the training circuits have a low cost function value in the case of variational quantum algorithms [6]. To ensure classical simulability of the training circuits, they contain at most $N$ non-Clifford gates, with the cost of their classical simulation growing exponentially with $N$. The training set is constructed as $T_{\text{CDR}} = \{(x_{i}, y_{i})\}$, where $x_{i}$ and $y_{i}$ are the noisy and exact expectation values of $X$ for the near-Clifford training circuits. This data is used to fit a linear function, \[ f_{\text{CDR}}(x) = a_1 x + a_2, \] (3)

which approximates a relation between the noisy and exact expectation values. Values of parameters $a_1, a_2$ are found by least-squares linear regression on $T_{\text{CDR}}$. The trained ansatz is then applied to estimate the noise-free result for the circuit of interest $\hat{\mu}_{\text{CDR}} = f_{\text{CDR}}(\hat{\mu}_0)$.

The primary challenge in CDR is the construction of the near-Clifford training circuits as the optimal procedure to construct the training set is not known in general. Furthermore, the method requires evaluation of the observable of interest for the training circuits which may result in a large shot cost of the mitigation for large training sets.

C. Variable noise Clifford Data Regression

vnCDR conceptually unifies ZNE with CDR by using a training set involving near-Clifford circuits evaluated at several noise levels to mitigate $X$ for $U$ which in general can not be simulated classically [12]. This data is used to learn the parameters that lead to the best extrapolation to the zero noise limit. The method was successfully implemented for quantum dynamics simulations with IBM quantum computers [25].

The training set is defined as $T_{\text{vnCDR}} = \{(x_{i,j}, y_{i,j})\}_{i=1}^{N_t}$, where $x_{i,j} = (x_{i,0}, \ldots, x_{i,n})$ is the vector of noisy estimates of the expectation value $X$, with length $n + 1$. $x_{i,j}$ is evaluated for the circuit $V_i$ with noise scaled by a factor $c_j$. For $n = 0$ the vnCDR training set becomes equivalent to the CDR training set. This data is then used to fit a linear function $f_{\text{vnCDR}}$, \[ f_{\text{vnCDR}}(x) = \sum_{j=0}^{n} a_j x_j. \] (4)

where $f_{\text{vnCDR}}$ approximates relation between the noisy and the exact expectation values and is fitted using least-squares regression on the data from vectors given by training circuits $V_i$ for all $i$, who’s index has been dropped in the equation above. This leads to the best fit parameters $a_j^*$.

The fitted parameters $a_j^*$ are then used to obtain vnCDR estimate of $X$ for $U$, $\hat{\mu}_{\text{vnCDR}} = f_{\text{vnCDR}}(\hat{\mu})$, where $\mu = (\mu_0, \ldots, \mu_n)$ is comprised of the $n + 1$ noisy expectations for the circuit of interest.

vnCDR shares several common features with CDR and ZNE. The functional form of the ansatz is a linear combination of noisy estimates which resembles Richardson extrapolation. Therefore, vnCDR can be understood as performing an extrapolation guided by near-Clifford circuits with a similar structure to the circuit of interest. Nevertheless, the fitted ansatz do not require explicit knowledge of the noise levels unlike ZNE ansatze, potentially easing ZNE requirements for precise control of the noise strength. Both CDR and vnCDR use training on data produced by near-Clifford quantum circuits. Consequently, vnCDR can be also treated as adding additional relevant data features to the CDR training set.

As in the case of CDR the construction of an informative training set is the primary technical challenge. Furthermore, adding additional noise levels to the vnCDR training set increases shot cost of the mitigation. Therefore, the best choice of noise levels is not known a priori.

D. Virtual Distillation

Virtual distillation (VD) [13, 14] uses $M > 1$ copies of a noisy state $\rho$ corresponding to a quantum circuit $U$ to obtain expectation values of an observables $X$ for a purer, “distilled” state. VD mitigates its expectation value by computing

$$\hat{\mu}_{\text{VD}} = \frac{\text{Tr}[\rho^M X]}{\text{Tr}[\rho^M]}, \quad (5)$$

We consider the eigenvalue decomposition of $\rho$

$$\rho = \sum_{i=0}^{2^Q-1} \lambda_i |\psi_i\rangle \langle \psi_i|, \quad (6)$$

with $\lambda_i$ decreasing with increasing $i$, and $Q$ being the number of the qubits. Then,

$$\hat{\mu}_{\text{VD}} = \frac{\langle \psi_0|X|\psi_0\rangle}{1 + \sum_{i=0}^{2^Q-1} (\lambda_i/\lambda_0)^M} + \sum_{i=0}^{2^Q-1} (\lambda_i/\lambda_0)^M \langle \psi_i|X|\psi_i\rangle. \quad (7)$$
Therefore, with increasing $M$, {VD} exponentially suppresses contributions to $\hat{\mu}_{VD}$ from eigenvectors of $\rho$ other than the dominant one $|\psi_0\rangle$. While increasing $M$ suppresses the errors it also increases the shot cost of the estimation of $\hat{\mu}_{VD}$ exponentially with a given accuracy for large error rates [15].

VD implicitly assumes that the dominant eigenvector $|\psi_0\rangle$ is close to the noise-less state $|\psi_{\text{exact}}\rangle$. Therefore, the quality of the VD correction is limited by a noise floor

$$\epsilon = \langle \psi_0 | X | \psi_0 \rangle - \langle \psi_{\text{exact}} | X | \psi_{\text{exact}} \rangle.$$  

(8)

The noise floor can be bounded from above using a quantity called the coherent mismatch

$$c = 1 - |\langle \psi_{\text{exact}} | \psi_0 \rangle|^2,$$  

(9)

i.e.,

$$|\epsilon| \leq 2c||X||_{\infty},$$  

(10)

where $||X||_{\infty}$ is the largest eigenvalue of $X$ [16]. For realistic noise, $\epsilon$ usually does not equal 0 [13]. Nevertheless, it was shown that for sufficiently small error rates the noise floor does not prevent VD from significantly reducing the impact of noise [16].

$\text{Tr}[\rho^M X]$ can be computed using $M$ copies of the noisy state $\rho$ and an ancillary qubit with a controlled permutation of the copies which changes position of each copy (so-called controlled derangement). Consequently, $QM+1$ qubits are required to mitigate a $Q$-qubit state. This number can be reduced to $2Q+1$ by employing qubit resets and increasing the depth of the circuit performing the controlled derangement [15]. The controlled derangement can be implemented as a circuit of $QM$ controlled swaps. Therefore, the derangement introduces errors to the estimates of $\text{Tr}[\rho^M X]$ and $\text{Tr}[\rho^M]$ which may require correction with other error mitigation methods [13].

Recently, VD-inspired methods were proposed which further reduce required qubit counts [17, 18] and conceptually unify VD with both ZNE and subspace expansion techniques enabling error mitigation beyond the noise floor [26–28].

III. UNIFYING VARIABLE NOISE CLIFFORD DATA REGRESSION METHODS WITH VIRTUAL DISTILLATION

In this section we unify VD into the framework provided by mitigation strategies based on training on Clifford circuit data. These learning based error mitigation methods like CDR and vnCDR assume that effect of the noise can be learned from near-Clifford circuits evaluated on both a noisy quantum device and a classical simulator. Results obtained with vnCDR show that it is often beneficial to supplement the CDR training data with data from the training circuits run under increased noise. Similarly, one can consider supplementing the vnCDR training set with results obtained by VD to improve its performance. This can be understood as using Clifford data to first extrapolate VD results to the limit of large $M$, and then to perform an extrapolation to the zero noise limit. This conceptually unifies VD, ZNE and CDR into one mitigation method which we call UNified Technique for Error mitigation with Data (UNITED).

To motivate the form of the UNITED ansatz we use Richardson extrapolation to perform the aforementioned double extrapolation to the zero noise limit. In the following we neglect the errors introduced by imperfect derangement and using a finite number of shots. The error of mitigating an observable $X$ using VD with $M$ copies, can be expressed as

$$|\mu - \hat{\mu}_M| = O(\xi^M + \epsilon),$$  

(11)

where $\mu$ is the exact value, $\hat{\mu}_M$ is the VD mitigated expectation value obtained using $M$ copies, $|\xi| < 1$ corresponds to the error introduced by a part of the noisy state orthogonal to its dominant eigenvector $|\psi_0\rangle$ and $\epsilon$ is the noise floor.

We use Richardson extrapolation in the number of copies up to copy $M_{\text{max}}$. Taking results obtained for each value of $M$ as corresponding to an noise level $c_M$ we obtain a mitigated expectation value

$$\hat{\mu}' = \sum_{M=1}^{M_{\text{max}}} \gamma_M \hat{\mu}_M,$$  

(12)

where

$$\sum_{M=1}^{M_{\text{max}}} \gamma_M = 1, \quad \sum_{M=1}^{M_{\text{max}}} \gamma_M c_M^k = 0,$$  

(13)

for $k = 1, \ldots, M_{\text{max}}$. The mitigated estimate $\hat{\mu}'$ has an error of order $O(\xi^{M_{\text{max}}+1} + \epsilon)$. Therefore, extrapolation on the copy data improves on VD suppression of the incoherent error for $M = M_{\text{max}}$ without requiring $M > M_{\text{max}}$.

Similarly to vnCDR one can use near-Clifford circuits to fit the Richardson extrapolation coefficients (12). Therefore, we use a training set constructed analogously to the vnCDR training set replacing $c > 1$ noisy expectation values with VD mitigated multi-copy expectation values. Furthermore, we use the linear ansatz used by vnCDR to learn large $M$ VD-mitigated expectation values. We call this approach Clifford Guided Virtual Distillation (CGVD). This motivation comes with the caveat that we do not have classical access to the noise floor for near-Clifford circuits so we propose to use their exact expectation values instead implicitly assuming that the noise floor is negligible.

The CGVD training set for an observable $X$ and a circuit of interest $U$ is defined as $T_{CGVD} = \{ (x_i, y_i) \}$, where $x_i = (x_{i,1}, \ldots, x_{i,M_{\text{max}}})$ is the vector of the noisy
the best fit parameters produced by training circuits $V$. We note that the ansatz can be generalized to apply to other choices of noisy and VD-mitigated training data. The training set is fitted with a linear ansatz to approximate the relation between the vector of noisy values, the VD-mitigated expectation values and the exact expectation value

$$ f_{\text{CGVD}}(x) = \sum_{m=1}^{M_{\text{max}}} b_m x_m, \quad (14) $$

where the parameters $b_m$ are fitted using least-squares regression on the training data consisting of vectors $x_i$ produced by training circuits $V_i$ for all $i$, who’s index has been dropped in the above equation. This leads to the best fit parameters $b^*_m$ that are then used to correct the noisy and VD-mitigated estimates of $X$ expectation value for the circuit of interest. In Appendix A we show that CGVD perfectly mitigates global depolarizing noise. The perfect correction is possible as for this noise model the noise floor is zero.

As previously mentioned, the CGVD method can be further generalized to mitigate effects of the noise floor by unifying it with vnCDR. Evaluating observables mitigated by VD for different levels of state preparation noise and different numbers of copies.

We supplement the CGVD training set with the noisy and VD-mitigated expectation values for $c_j > 1$ and fit the training set using a linear ansatz motivated by the form of (19).

More explicitly, we use the most general training set $T_{\text{UNITED}} = \{(\tilde{x}_i, y_i)\}$, where $\tilde{x}_i = (\tilde{x}_{i,0,1}, \ldots, \tilde{x}_{i,n,M})$ is the vector of noisy and VD mitigated estimates with copies $1$ to $M_{\text{max}}$, and state preparation levels $c_0$ to $c_n$, evaluated from the circuit $V_i$. The ansatz we train is,

$$ f_{\text{UNITED}}(x) = \sum_{j=0}^{n} \sum_{M=1}^{M_{\text{max}}} d_{j,m} x_{j,m}, \quad (20) $$

using least-squares regression on the vectors denoted $\tilde{x}_i$ produced by training circuits $V_i$, who’s index has been dropped in the above equation. This outputs the fitted parameters $d_{j,m}^*$ that define the best possible mapping from the noisy to exact values in the training set on average.

The trained ansatz, with parameters $d_{j,m}^*$, is then used to correct data obtained by similarly applying VD for different numbers of copies and changing state preparation noise levels for the circuit of interest. In this way we use near-Clifford circuits mitigated with VD to guide VD applied to the circuit of interest while also using noise data to extrapolate from the VD mitigated observables to the zero-noise limit. We note that under this framework, vnCDR is a special case of UNITED. This special case is recovered by taking $M_{\text{max}} = 1$.

It is important to note that although Richardson extrapolation motivates the form of the fitted ansatz, it does not guarantee good performance of the new method for several reasons. Firstly, all methods to scale physical noise are only approximate so the noise levels will be imperfectly controlled, leading to imperfect extrapolated zero noise estimates. Nevertheless, successful applications of ZNE and vnCDR show that imperfect noise scaling control does not preclude successful error mitigation. Furthermore, training a model based on near-Clifford circuit data is not equivalent to performing a Richardson extrapolation, so performance of UNITED depends on the ability to construct informative training sets. On the other hand, analogous to the case of vnCDR, we expect that fitting ansatz coefficients (20) instead of performing an extrapolation is beneficial as it does not require knowledge of noise levels, reducing impact of imperfect noise control. Additionally, adding copy data to the training set further increases the shot cost of the mitigation. Therefore, the best choice of noise levels and the
We consider random quantum circuits built of the native circuits will converge with increasing weaknesses of each method.

We study several total shot budgets per benchmark the method for various system sizes and circuit depths. We consider several noise levels. UNITED additionally requires per-terest are required for many training circuits evaluated at several noise levels. UNITED additionally requires per-

It is worth noting that deep circuits implemented for trapped-ion quantum computing architecture are a favorable setting for VD as this architecture enables all-to-all connectivity which decreases the depth of the controlled derangement circuit compiled to native gates [30]. Furthermore, it is expected that for sufficiently deep circuits and sufficiently small gate error rates, the coherent mismatch does not prevent good quality VD-mitigation [16].

B. The noise model

We use a noise model of a trapped-ion quantum computer developed in [31, 32]. The model uses local depolarizing and dephasing channels as well as imprecision in the rotation angles of the gates. The parameters used are derived from trapped-ion experiments to simulate errors of current trapped-ion devices. For a detailed description of the noise model including gates error rates see Ref. [32]. We neglect measurement error in our simulations as it can be mitigated by specialized techniques [33, 34].

C. The results

First we analyze the case of \( L = Q \ (q = 1) \). For this choice we consider \( Q = 4, 6, 8, 10 \). For each pair of \( L \) and \( Q \) values we consider 30 instances of random quantum circuits. For each random quantum circuit we mitigate the expectation value of \( \sigma_Z \) acting on the first qubit of the circuit \( \langle \sigma_1^{(2)} \rangle \). We perform the mitigation with data obtained using a finite number of shots. For each mitigated expectation value and each error mitigation method we assign total number of shots used by the method to mitigate the expectation value. We call this number the total shot budget \( N_{\text{tot}} \). We consider \( N_{\text{tot}} = 10^5 - 10^{10} \).

Different error mitigation methods require estimates of observables from a different total number of circuits. In the case of ZNE the circuit of interest needs to be evaluated for several different state preparation noise levels. In the case of vnCDR, estimates for the observable of interest are required for many training circuits evaluated at several noise levels. UNITED additionally requires performing VD mitigation for both the training circuits and the circuit of interest. Therefore, for the same shot budget, different mitigation methods have different numbers of shots per observable estimation. Consequently, for a given total number of shots, the accuracy of individual observable estimates decreases as the required total number of circuits increases. We note that for fixed \( N_{\text{tot}} \) we can distribute shots between different observable evaluations in many ways. Here for the sake of simplicity for a given method we assign the same shot numbers for all observable estimates required to mitigate the observable of interest.

In Figure 2 we plot mean and maximal absolute errors of \( \langle \sigma_2^{(1)} \rangle \). We find that performance of the error mitigation methods depends primarily on the shot budget. We ob-

IV. NUMERICAL RESULTS

In this section we present the performance of ZNE, vnCDR, VD and UNITED applied to noisy outputs obtained from simulations of an trapped-ion quantum computer with a realistic noise model. We consider the task of mitigating the output of random quantum circuits to benchmark the method for various system sizes and circuit depths. We study several total shot budgets per mitigated expectation value, highlighting strengths and weaknesses of each method.

A. Random quantum circuits

We investigate random quantum circuits for various numbers of qubits \( Q = 4, 6, 8, 10 \) and several depths. We consider random quantum circuits built of the native gates of the trapped-ion quantum computer, namely of \( L \) layers of alternating nearest-neighbor Molmer-Sørensen entangling gates decorated with general single qubit unitaries, see Fig. 1 for details. Both the entangling gates and the single qubit unitaries are parametrized by randomly chosen angles. Here we simulate random quantum circuits with \( L = gQ \), taking \( g = 1 \) and \( g = 16 \).

We expect that for such a setup, random quantum circuits will converge with increasing \( L \) to random quantum states sampled according to Haar measure [29]. Therefore, the setup is general and challenging, making it relevant for testing error mitigation methods. Furthermore,
FIG. 2. Comparing error mitigation methods for \( L = Q \). Mean and maximal absolute errors of the expectation value of \( \sigma_Z \) measured at the first qubit of 30 instances of random quantum circuits for noisy estimates and estimates obtained with error mitigation methods. In (a), the results for total number of shots per mitigated (noisy) expectation value \( N_{\text{tot}} = 10^5 \). In (b), \( N_{\text{tot}} = 10^6 \). In (c), \( N_{\text{tot}} = 10^8 \). In (d), \( N_{\text{tot}} = 10^{10} \). For \( N_{\text{tot}} = 10^5 \), we find that ZNE gives the best results. For \( N_{\text{tot}} = 10^6 \), \( 10^8 \) vnCDR gives the best results while for \( N_{\text{tot}} = 10^{10} \) UNITED gives the best results.

We see that the expectation values mitigated by ZNE and VD converge with increasing \( N_{\text{tot}} \) fastest. ZNE is the best for the smallest total shot budget \( N_{\text{tot}} = 10^5 \). The convergence of vnCDR is slower but it outperforms ZNE and the other methods for \( N_{\text{tot}} = 10^6 \) and \( N_{\text{tot}} = 10^8 \). We find that UNITED convergence with increasing \( N_{\text{tot}} \) is the slowest but it gives the best results for \( N_{\text{tot}} = 10^{10} \). We see that quality of the mitigated results decreases with increasing \( Q \) as the number of noisy gates increases. Nevertheless even for the largest considered \( Q = 10 \), a factor of 5–10 improvement over the noisy results can be obtained with vnCDR and UNITED. \( Q = 4 \) results with various \( N_{\text{tot}} \) are shown in Figure 3(a).

Next we analyze the case of \( L = 16Q \) (\( g = 16 \)). For this choice we simulate \( Q = 4, 6, 8 \). Again, for each pair of \( L \) and \( Q \) values we consider 30 instances of random quantum circuits and mitigate \( \langle \sigma_Z^L \rangle \) for each of them. As in the case of \( g = 1 \) we perform the mitigation for \( N_{\text{tot}} = 10^5 - 10^{10} \). For \( Q = 6, L = 96 \) and \( Q = 8, L = 128 \) we are unable to obtain improvement over the noisy results with any error mitigation method as the number of the noisy gates is too large. For smaller systems of \( Q = 4, L = 64 \) we find that learning-based error mitigation methods outperform VD and ZNE even for \( N_{\text{tot}} = 10^5 \). For \( N_{\text{tot}} = 10^5 - 10^{10} \) we find that both vnCDR and UNITED give a factor of 5–10 improvement over the noisy results. For \( N_{\text{tot}} = 10^5 - 10^{10} \) we see an improvement of vnCDR over UNITED. Again we find that ZNE and VD estimates converge fastest with increasing \( N_{\text{tot}} \). Again UNITED convergence is the slowest but it also provides the best mitigation quality for large shot budget. We show \( Q = 4 \) results in detail in Fig. 3(b).

V. IMPLEMENTATION DETAILS

A. Zero Noise Extrapolation

In the simulations described above, we use two noise levels \( c \in \{1, 2\} \) and linear extrapolation. We compared this approach to linear extrapolation for \( c \in \{1, 2, 3\} \) and exponential extrapolation for both \( c \in \{1, 2\} \) and \( c \in \{1, 2, 3\} \) and found that it is the best one in general.

When scaling the noise in our simulations we use factors \( c = 2, 3 \). To implement \( c = 2 \) we replace \( XX(\theta)XX(\theta-\alpha) \) with \( \alpha \) chosen randomly. We treat \( R_Z \) and \( R_Y \) in the same way. To implement \( c = 3 \) we replace \( XX(\theta)XX(\theta)XX(\alpha)XX(\theta-\alpha) \) performing an identity insertion. Again, we treat \( R_Z \) and \( R_Y \) in the same way. Both procedures scale the number of all types of
gates in our random quantum circuits by the noise level.

B. variable noise Clifford Data Regression

To construct the near-Clifford training circuits we use an algorithm from [15]. We replace $XX$ and $RY$ by closest to them Clifford gates of the same type. We also replace a fraction of $RZ$ gates by closest to them $RZ$ Clifford gates, leaving $N = 10$ $RZ$ gates intact. See details of the algorithm in [15].

When constructing the noise-scaled circuits necessary for vnCDR we use the same method of noise scaling as used in the ZNE implementation. In our simulations above we use $c \in \{1, 2, 3\}$. We found that this choice of noise levels results in better results than using $c \in \{1, 2\}$.

In order to maximize the information contained within the training set while minimizing the number of shots used to evaluate their outputs on noisy hardware we inspect the distribution of the exact values produced by these circuits. We initially construct 100 near-Clifford circuits using the method introduced above. We find that with increasing number of qubits an increased fraction of their exact expectation values is becoming close to 0. Additionally, we find that removing most of such circuits from the training set is not decreasing the quality of the correction while at the same time decreasing the shot cost of the mitigation. Therefore, to construct the training set, we select $N_t$ of them with the largest absolute values of the exact expectation values. We choose $N_t = 50$. We note that this post-selection method can be further improved. For example, one can use use Markov Chain Monte Carlo to construct a training set with desired distribution of exact or noisy expectation values [6].

C. Virtual Distillation

We implement VD by computing $Tr[\rho^{M}X]$ for the noisy state $\rho$ and neglecting errors which occur during the derangement circuit execution. This assumption enables classical simulation of VD for a $Q$-qubit system while simulating $Q$ noisy qubits instead of the $2Q + 1$ that would otherwise be required to simulate the derangement. We present results of VD using 2 copies as we observed that this typically gave the best results. We explore the performance of VD for various numbers of copies in Appendix B.

D. Unified Data-driven Error Mitigation

To implement UNITED we choose the same near-Clifford circuits as for vnCDR. We choose $M_{\text{max}} = 3$ and state preparation noise levels $c \in \{1, 2, 3\}$. We found that these parameters performed best across the regimes investigated.

E. Shot budgeting

Each technique described above requires a certain total number of circuits in order to mitigate the observable of interest. This, therefore, corresponds to a different number of observable evaluations. For VD, it is necessary to perform a measurement for 2 different circuits obtained with the controlled derangement [13]. In the case of ZNE, one needs to measure the expectation value of $n+1$ circuits built from one circuit of interest at $n+1$ noise levels. For vnCDR, we additionally need to evaluate each training circuit for $n+1$ noise levels. This means that in total vnCDR requires $(n+1)(N_t+1)$ circuit evaluations. Finally, for UNITED we need to mitigate the observable estimates using VD with $M_{\text{max}} - 1$ instances of random quantum circuits plotted versus the shot budget.

In (a) for $Q = 4, L = 4$. In (b) results for $Q = 4, L = 64$. For $Q = 4, L = 4$ we find that ZNE and VD estimates converge first. vnCDR estimates converge slower but outperform VD and ZNE for $10^7 - 10^{10}$ shot budgets. UNITED convergence is the slowest but it gives the best results for $N_{\text{tot}} = 10^9, 10^{10}$. For $Q = 4, L = 64$ again ZNE and VD estimates convergence is the fastest but it is outperformed by vnCDR and UNITED for all considered shot budgets. vnCDR and UNITED converge slowest but they outperform the other methods for all considered budgets. We see an improvement of UNITED over vnCDR for $N_{\text{tot}} = 10^9, 10^{10}$. Further discussion of VD performance for different shot budgets is explored in Appendix B.

FIG. 3. Convergence of error mitigation methods with increasing $N_{\text{tot}}$. Mean and maximal absolute errors of the expectation value of $\langle \sigma_x \rangle$ for random quantum circuits plotted versus the shot budget. We use 30 instances of random quantum circuits. In (a) results for $Q = 4, L = 4$. In (b) results for $Q = 4, L = 64$. For $Q = 4, L = 4$ we find that ZNE and VD estimates converge first. vnCDR estimates converge slower but outperform VD and ZNE for $10^7 - 10^{10}$ shot budgets. UNITED convergence is the slowest but it gives the best results for $N_{\text{tot}} = 10^9, 10^{10}$. For $Q = 4, L = 64$ again ZNE and VD estimates convergence is the fastest but it is outperformed by vnCDR and UNITED for all considered shot budgets. vnCDR and UNITED converge slowest but they outperform the other methods for all considered budgets. We see an improvement of UNITED over vnCDR for $N_{\text{tot}} = 10^9, 10^{10}$. Further discussion of VD performance for different shot budgets is explored in Appendix B.
different copies for the training circuits, the circuit of interest and for each of $n + 1$ noise levels. Therefore, the number of circuit evaluations required by UNITED is $(n + 1)(N_t + 1)(2M_{\text{max}} - 1)$.

In this work we consider several total shot budgets $N_{\text{tot}}$. For each method we distribute the shots across measurements dividing $N_{\text{tot}}$ by the number of measurements. We note that this strategy may not be optimal as it may be beneficial to distribute the shots unequally between noise levels or copy numbers. Furthermore, one can fine-tune the values of $n$, $N_t$, $M_{\text{max}}$ for given $N_{\text{tot}}$. We leave systematic investigation of more advanced budgeting strategies for a future work.

VI. DISCUSSION

The ability to efficiently and accurately mitigate hardware errors will be essential to achieving practical application of near-term quantum computers. A number of approaches have been proposed to fill this need, each bringing useful new ideas. In this work, we have discussed some state-of-the-art methods and examined how the approaches might best be combined. Specifically, we have considered zero noise extrapolation (ZNE), variable noise Clifford data regression (vnCDR), and virtual distillation (VD) and proposed two new methods that represent unifications of the ideas behind these approaches. We applied these methods to the mitigation of errors in local observables measured from states prepared with random circuits. As these methods have different strengths and resource requirements, we have considered their performance with $10^5-10^{10}$ total shots to mitigate the expectation value of an observable of interest with up to $Q = 10$ qubits with depth $L = Q$ as well as up to $Q = 8$ for depth $L = 16Q$. We used a realistic simulation of a noisy trapped-ion device, which was chosen as the trapped-ion architecture enables all-to-all connectivity.

Combining the ideas of near-Clifford circuit data and the multi-copy data from VD, we formulated Clifford guided VD (CGVD) which uses Clifford data to guide a Richardson-like extrapolation to the many copy limit. We generalize this method to perform Clifford guided double Richardson-like extrapolation. We first extrapolate to the limit of many copies and then we extrapolate to the limit of zero noise floor. The new method, UNIfied Technique for Error mitigation with Data (UNITED), can be viewed as unification of CDR, ZNE and VD methods. Furthermore, vnCDR is a special case of the new general method.

We find that when at $N_{\text{tot}} = 10^{10}$, UNITED is the optimal technique for $L = Q$ depth circuits of up to 8 qubits by a factor of 1.5 compared to vnCDR on average. We also find that vnCDR is preferable at budgets $N_{\text{tot}} = 10^5, 10^8$. For $N_{\text{tot}} = 10^5$, ZNE is optimal for circuits with depths $L = Q$ while vnCDR is optimal for more noisy $L = 16Q$. We observe that increasing the shot budget improves the error mitigated expectation value only until a performance ceiling is reached. As we see, different techniques have different performance ceilings, and we find that unified methods are able to draw from more data than VD and ZNE to reach better corrections when more resources are available.

As the available quantum devices continue to grow in qubit number and reduce the rate of hardware errors, practical applications of quantum computing grow ever closer. Due to the high number of qubits that are required for full error correction, it seems likely that error mitigation will play a pivotal part in those early applications. This work provides a useful reference for those who are seeking such applications to determine which combination of strategies is best for their use case.

A natural question one might ask is if there are other forms of data that would be useful to include in an error mitigation approach. Error mitigation for deep quantum circuits is challenging, but perhaps some other source of data (other than those we considered) would extend the depth for which error mitigation is practical. Further unification with other error mitigation techniques such as noise-resilient quantum compiling [35–39], verified phase estimation [40] and specific approaches leveraging symmetries and/or post-selection [28, 41–43] is likely to be a promising research direction.

Another interesting direction for future work is to consider how best to determine when to measure new expectation values (i.e. more near-Clifford circuits, more noise levels, more copies of the state, etc.) versus expending more shots per expectation value in order to get the best mitigation possible with fixed resources. Finally, we note that investigation of effects of noisy controlled derangement on VD and UNITED performance will be necessary for full understanding of these methods’ potential.

Appendix A: Correcting for global depolarizing noise with CGVD or UNITED

Here we motivate the UNITED ansatz by considering its performance on mitigating the action of a global depolarizing noise channel on some observable of interest. The ansatzes used in CDR and vnCDR have been shown to perfectly correct global depolarizing noise and this fact is used to motivate the form of the CGVD ansatz. We note in this setting there is no limit set by coherent mismatch when using VD, so one expects a combination of VD and CDR to perform well. First, we consider CGVD since the treatment is the same as in the UNITED case and can be generalized very simply.

Consider a global depolarizing noise channel that acts on all Q qubits. For some state \( \rho = |\psi\rangle \langle \psi| \) produced by quantum circuit \( U \), this channel takes the form:

\[
\rho \rightarrow (1-p)\rho + p\frac{I}{d}. \tag{A1}
\]

Consider the effect of the above channel on some observables of interest \( X \)

\[
\tilde{X} = (1-p)X^{\text{exact}} + p\frac{\text{Tr}(X)}{d}, \tag{A2}
\]

where \( X^{\text{exact}} = \text{Tr}(\rho X) \). We consider the CGVD ansatz that combines observables evaluated at several numbers of copies in the VD circuit structure. For simplicity we omit the small changes in the rate of errors for different numbers of copies due to the swap noise. We can rewrite (14) as follows

\[
\tilde{X}_{\text{CGVD}} = \sum_{m=1}^{M} a_m \tilde{X}_m, \tag{A3}
\]

where \( \tilde{X}_{\text{CGVD}} \) is the estimate of the observable of interest, \( a_m \) are the parameters fitted using least squares regression on the data generated by the near-Clifford training circuits mitigated using VD with up to \( M \) copies.

We can express an observable mitigated with VD using \( m \) copies as

\[
\tilde{X}_m = \frac{\text{Tr}(\rho^m X)}{\text{Tr}(\rho^m)}. \tag{A4}
\]

We can evaluate \( \tilde{X}_m \), assuming \( \rho \) has been acted upon by a global depolarizing channel as defined in (A1). First focusing on the denominator,

\[
\text{Tr}(\rho^m) = \text{Tr}\left( \sum_{k=0}^{m} \binom{m}{k} (1-p)^k \rho^{(m-k)} \left( \frac{p}{d} \right)^{k} \right) \tag{A5}
\]

\[
= \sum_{k=0}^{m} \binom{m}{k} (1-p)^k \text{Tr}(\rho^{m-k}) \left( \frac{p}{d} \right)^{k}. \tag{A6}
\]

Noting that when \( m = k \) we are tracing over the identity, we obtain:

\[
\text{Tr}(\rho^m) = \left( \frac{1 + (d-1)(1-p)}{d} \right)^m + (d-1) \left( \frac{p}{d} \right)^m. \tag{A7}
\]

where \( d = 2^Q \) is the dimension of the Hilbert space. Now evaluating the numerator of (A4) we obtain

\[
\text{Tr}(\rho^m X) = \text{Tr}(\rho X) \left( \frac{1 + (d-1)(1-p)}{d} \right)^m + \left( \frac{p}{d} \right)^m \left( \text{Tr}(X) - \text{Tr}(\rho X) \right). \tag{A8}
\]

Combining the above we arrive at the following expression,

\[
X_m = f_m \text{Tr}(\rho X) + \frac{1-f_m}{d} \text{Tr}(X), \tag{A9}
\]

where

\[
f_m = 1 - \frac{dp^m}{(d-1)p^m + (d-p(d-1))^m}. \tag{A10}
\]
Taking $m = 1$ leads to $f_1 = 1 - p$ which gives the expected result. Using (A3) we can determine the criteria for this ansatz to give a perfect mitigation,

$$\hat{X}_{\text{CGVD}} = \sum_{m=1}^{M} a_m \left( f_m \text{Tr}(\rho X) + \frac{1-f_m}{d} \text{Tr}(X) \right). \quad (A11)$$

Therefore, we require

$$\sum_{m}^{M} a_m f_m = 1, \quad \text{Tr}(X) = 0. \quad (A12)$$

A global depolarizing noise channel will have the same effect on the training circuits as it will on the circuit of interest. As we have access to the exact observable for these circuits, the coefficients required to lead to a perfect mitigation can be learned. As such, the ansatz used in CGVD can be used to perfectly mitigate global depolarizing noise using a near-Clifford training set.

It is straightforward to extend this analysis to involve the ansatz including multiple noise levels. Notice that under the action of global depolarizing noise defined in (A1), if this channel acts $j$ times throughout the dynamics we can write

$$\rho_j \rightarrow (1 - p^j)\rho + p^j \frac{I}{d}. \quad (A13)$$

Now let’s consider UNITED ansatz that combines observables mitigated with VD using various numbers of copies at various noise levels. This ansatz can be written as follows

$$\hat{X}_{\text{UNITED}} = \sum_{m=1}^{M} a_{m,j} \hat{X}_{m,j}, \quad (A14)$$

where $\hat{X}_{\text{UNITED}}$ is the mitigates observable, $a_{m,j}$ are the parameters fitted using least squares regression on the data generated by the near-Clifford VD training circuits with up to $M$ copies, evaluated with $n$ different noise levels.

Working through the same analysis with this ansatz we find that for the effects of global depolarizing noise the be perfectly mitigated we require

$$\sum_{m}^{M} a_{m,j} f_{m,j} = 1, \quad \text{Tr}(X) = 0. \quad (A15)$$

where

$$f_{m,j} = 1 - \frac{dp^{mj}}{(d-1)p^{mj} + (d-p^j(d-1))^m}. \quad (A16)$$

Therefore, we can conclude that both CGVD and UNITED can perfectly mitigate the effect of global depolarizing noise on some observable of interest.

The assumption $\text{Tr}(X) = 0$ is not restrictive due to the common decomposition of operators into Pauli terms (which have zero trace) and the identity. However, we can consider an ansatz which includes an additional constant term to be fitted. In which case (A3) becomes

$$\hat{X}_{\text{CGVD}} = \sum_{m=1}^{M} a_m \hat{X}_m + b, \quad (A17)$$

Thus, (A11) becomes

$$\hat{X}_{\text{CGVD}} = \sum_{m=1}^{M} a_m \left( f_m \text{Tr}(\rho X) + \frac{1-f_m}{d} \text{Tr}(X) \right) + b. \quad (A18)$$

Therefore, including a constant term in the ansatz, to perfectly mitigate the effect of depolarizing noise we require

$$\sum_{m}^{M} a_m f_m = 1, \quad \sum_{m}^{M} \frac{1-a_m}{d} \text{Tr}(X) = b. \quad (A19)$$

Including a constant term in the UNITED ansatz leads to a similar conclusion. Therefore, one can see global depolarizing noise can be perfectly mitigated using near-Clifford circuit to train the parameters of the CGVD and UNITED ansatze.

**Appendix B: Optimal parameters for virtual distillation**

Here we systematically explore convergence of VD estimates with increasing number of copies $M$. In Figure 4 we plot the mean and maximal errors of VD $\langle \sigma_{Z}^{Q} \rangle$ estimate for 30 random quantum circuits and $M = 2 - 6$. In this figure we show results for smallest $N_{\text{tot}} = 10^5$ and the largest $N_{\text{tot}} = 10^{10}$ considered here. We find that for $Q = 4 - 10$ and $g = 1$ $M = 2$ gives typically optimal results for both shot budgets. We note that for $Q = 4 - 10$, $g = 1$ and $N_{\text{tot}} = 10^{10}$ $M = 2 - 5$ VD give very similar results indicating that $M = 2$ is large enough to reach the noise floor. Our findings agree with [16], which argues that with an exception of highly noisy circuits $M \leq 3$ is sufficient to reach the noise floor. For more noisy $Q = 4, g = 16$ circuits we find that the optimal $M$ depends strongly on $N_{\text{tot}}$. For $N_{\text{tot}} = 10^{10}$ $M = 2$ is optimal but it gives on average a small factor 1.2 improvement over the noisy results. For $N_{\text{tot}} = 10^{10}$ $M = 4$ is optimal giving a factor of 2.5 improvement. Based on the obtained results we use $M = 2$ in the main text as it is optimal for most circuits. We note that although with $M = 4$ VD performance can be improved for $Q = 4, g = 16$ and large $N_{\text{tot}}$ this improvement is not large enough to outperform vnCDR and UNITED.
FIG. 4. Convergence of VD estimates with increasing $M$. In (a) results for $N_{\text{tot}} = 10^5$ and in (b) results for $N_{\text{tot}} = 10^{10}$ plotted versus number of VD copies $M$. For reference purposes we include single copy noisy results as $M = 1$. The plots show that for $g = 1 M = 2$ is optimal while for $Q = 4, g = 16$ the optimal $M$ increases with increasing $N_{\text{tot}}$. The left plots show the mean values while the right plots show the maximal value.
