(Dated: July 30, 2021)

The classical physics is approached from quantum mechanics in the macroscopic limit. The technical device to achieve this goal is the quantum version of the central limit theorem, derived for an observable at a given time and for the time-dependent expectation value of the coordinate. The emergence of the classical trajectory can be followed and the deterministic classical laws can be recovered in all practical purposes owing to the largeness of Avogadro’s number. The emergence of a classical trajectory is followed qualitatively in Wilson’s cloud chamber.

I. INTRODUCTION

The problem of recovering the laws of classical physics from the quantum level is beset by the conceptual problems. The exploration of the difference in the logical structure of the classical and quantum level has already been started long time ago by pointing out that the logic of quantum states is non-distributive as opposed to the Boolean logic of classical physics [1, 2]. This structure was generalized later [3, 4] but it remains to be seen how such an approach can help us to understand better the problem. The solution may even lie beyond quantum theory and be related to the usual separation of physical laws and initial conditions [5, 6]. A slightly different trial starts with the construction of hidden parameter theories [7] and seems to end at contextuality [8–10] without a reconciliation of the two regimes in sight.

Maybe the most disturbing qualitative difference of the quantum and classical descriptions is the apparent non-deterministic nature of the choice of the spectrum element of an observable which is realized in a measurement. One is advised to rely on a new dynamical mechanism, such as spontaneous localization [11, 12] or quantum stochastic processes [13] as a quick fix up of this selection process. The solution of this problem lies beyond the realm of quantum mechanics and will not be pursued here.
The challenge hiding in these problems is the by now well established and understood feature of physical laws that they depend on the scales and this dependence is smooth for observations of finite resolution. How can the logic and determinism change continuously between the quantum to the classical regimes? A hint to the answer might be found in more recent developments. The need of an increased accuracy of monitoring the motion of macroscopic bodies during the detection of gravitational waves has led to non-demolition measurements [14], to weak measurements [15], to a more careful treatment of quantum noise [16] and to optomechanical devices [17]. These examples show that classical concepts can be brought in agreement with quantum effects in a consistent and systematic manner. The idea of continuous measurement [18] is another possibility to fit the quantum and the classical domains. The common elements of these ideas is the introduction of a flexible length or time scale which suppresses the uncertainties in the measurements and thereby approaching classical physics from the quantum level. Another development which narrows the qualitative differences of the quantum and the classical level is the possibility that the quantum jump, assumed to make the choice of the measured value, is actually a dynamical process enfolding in finite time [19, 20].

A proposition is put forward in the present work, namely the generalization of the central limit theorem to quantum mechanics provides a simple and generic framework to approach classical physics in the macroscopic limit. The relation between the renormalization group and the central limit theorem has already been discussed in the context of the generalized central limit theorem and the UV fixed points [21–25]. The central limit theorem is considered here from the point of view of quantum mechanics without the systematic methodology of the renormalization group. The traditional classical laws are approached but never reached exactly according to this scenario in a manner similar to the way thermodynamics emerges from statistical physics. The surprising large large value of Avogadro’s number renders the uncertainty of the average over a macroscopic sample negligible for all practical purposes without getting bogged down into the intricacy of contradicting logical structures. Such an approach of the classical physics is not a new idea, it is the backbone of almost all attempt to arrive at the well known classical domain from a microscopic level. The modest steps, presented below, simply to draw the attention to analogies with the way the central limit theorem functions in classical probability theory.

The macroscopic limit of quantum systems can be realized in different manners. The
typical rearrangement corresponds to the measurement of a microscopic property by a macroscopic measuring apparatus. To comply with the probabilistic predictions of quantum mechanics one considers a large set of equivalent and independent microscopic systems. Another possibility is to look for macroscopic quantum effects where a single observed systems of macroscopic size is used [29]. Such macroscopic quantum phenomena form a wide and colorful set. The simplest is the indistinguishably of identical elementary particles, leading to the solution of Gibbs mixing paradox. It is perhaps the most universal macroscopic quantum effect owing to its scale independence. Superconductivity or superfluidity are related to spontaneous symmetry breaking and are clear realizations of macroscopic phenomenons, treated by an approximation valid only in the thermodynamical limit. In general, the semiclassical approximation can be used to discover a wide class of macroscopic quantum phenomena as saddle point effects [30]. The non-unique definition of the actual number of degrees of freedom [31–35] and the non-triviality of their distribution over the possible states [36] indicate the richness of macroscopic quantum phenomena. A common feature of the macroscopic limit in different systems is the decoherence of the macroscopic (collective) variables [26–28]. It is important to realize that the macroscopic variable may have intrinsic environment within the system without a tensor product structure of the Hilbert space [37]. We restrict our attention in this work to the first case where the measured phenomenon is microscopic and only the measuring apparatus amplifies it to macroscopic size.

As the first step the central limit theorem is extended over expectation values in section II by calculating the second cumulant of the distribution of the average of an observable over of a set of $N_s$ independent microscopic systems. The decrease of the width of the fluctuations is compatible with a reduction of the Planck constant $\hbar \rightarrow \hbar/N_s$. The dynamical generalization of the central limit theorem for the average of the expectation value of a continuous coordinate is given in section III. The role of the cumulants is taken over by the connected Green functions and they are shown to become suppressed as $N_s \rightarrow \infty$. The results of the continuous observation is spoiled by the mass-shell singularities and to avoid this problem the observations over a discrete set of time is considered. Furthermore the condition of the applicability of the central limit theorem is given for an interactive set of microscopic systems. The clarification of the role of a macroscopic measuring apparatus in the measuring process is taken up in section IV. It is shown that a harmonic measuring apparatus realizes a linear amplification and Wilson’s cloud chamber is briefly discussed.
where the collapse of the wave function takes place as a dynamical process in a strongly coupled environment. Finally the summary is presented in section V. Two appendices are included with some technical details. The basic idea and equations of the Closed Time Path (CTP) formalism are summarized in appendix A. A harmonic measuring apparatus is discussed in appendix B.

II. CENTRAL LIMIT THEOREM FOR AN OBSERVABLE

We consider the measurement of an observable $A$ on a closed microscopic system whose pure states belong to the Hilbert space $\mathcal{H}$. The measurement is repeated on the ensemble of $N_s$ copies of the system, the pure states of the ensemble form the direct product $\otimes \mathcal{H}^{N_s}$. The operator representing our observable of the $n$-th system, $A_n$, acts on the $n$-th factor of the direct product space and $\bar{A} = \frac{1}{N_s} \sum_{n=1}^{N_s} A_n$ stands for the average observable. If the systems are indistinguishable then one has to (anti)symmetrize their state in $\otimes \mathcal{H}^{N_s}$ but this does not change the expectation value of $\bar{A}$ where the elements of the ensemble are not distinguished. We allow some variation of the state within the ensemble and assume that $N_k = p_k N_s$ systems are placed into the state defined by the reduced density matrix $\rho_k$ and $\sum_k p_k = 1$.

The limit $N_s \to \infty$ can be realized by two different scenarios. (i) The textbook example consists of an ensemble of identically prepared, independent microscopical systems, accessed one-by-one, and the expectation value of $\bar{A}$ is identified with the average of the measurements. (ii) Another, more realistic alternative is to consider a set of $N_s$ microscopic systems where we measure directly $\bar{A}$, e.g. the center of mass of a mirror in a gravitation radiation detector or a total electric dipole moment of a solid in a linear response study.

The central limit theorem can easily be recovered for transition amplitudes or expectation values. We discuss the later, the former can be recovered in similar manner. Let us start with the cumulant generator function of the observable $A$, defined by

$$e^{iw_{(j)}} = \text{Tr}[\rho_k e^{ijA}]$$

We assume a continuous, unbound spectrum, the extension of our procedure for bounded or discrete spectrum is straightforward. The probability distribution of $A$ is given by the
Fourier transform

\[ p_k(a) = \int \frac{dj}{2\pi} e^{-ija} \text{Tr}[\rho_k e^{ijA}] \]  

(2)

since

\[ \text{Tr}[\rho_k A^n] = \int dap(a) a^n. \]  

(3)

It is easy to see that the generator function of $\bar{A}$, $e^{i\bar{w}(j)} = \langle e^{ijA} \rangle$, assumes the form

\[ \bar{w}(j) = N_s w_q \left( \frac{j}{N_s} \right), \]  

(4)

where $w_q(j) = \sum_k p_k w_k(j)$ is the average of the generator functions $w_k(j)$. One uses quenched averaging because the choice of the initial state influences the system for arbitrarily long time in a closed dynamics. It is a matter of a trivial expansion in $1/N_s$ to find the normal distribution around $\langle A \rangle$ of $O(1/\sqrt{N_s})$ width,

\[ p(\bar{a}) = \sqrt{\frac{(A - \langle A \rangle)^2}{2\pi N_s}} e^{-\frac{(A - \langle A \rangle)^2}{2(A - \langle A \rangle)^2}} (A - \langle A \rangle)^2. \]  

(5)

The decisive dynamical difference between the scenarios (i) and (ii) is that while several measurements are performed in (i) only a single measurement is carried out in (ii). The central limit theorem corresponds to scenario (i) and the dynamical aspect of the narrowing of the peak of $p(\bar{a})$ in scenario (ii) is that the disturbance of a single measurement is distributed over a large number of systems. Such a point of view is consistent with the effective reduction of Plank’s constant, $\hbar \rightarrow \hbar/N_s$, for canonically conjugate pairs, $\bar{p}$ and $\bar{q}$. The suppression of the incompatibility of canonically conjugate pairs opens the possibility of recovering a unique trajectory for the average observable $\bar{A}$. Hence the single measurement of scenario (ii) is non-demolishing when $N_s \rightarrow \infty$. The mathematical equivalence of the two scenarios indicates that classical physics is reached by the averages in both cases.

The non-demolishing nature of the measurement of $\bar{A}$ can simply be established in the Heisenberg representation. Let us assume that the ensemble of systems of scenario (i) and the measuring apparatus follow a closed dynamics with Hamiltonian $H = \sum_n (H_{s,n} + A_n B) + H_a$ where $H_a$ denotes the Hamiltonian of the apparatus, $H_{s,n}$ stands for the Hamiltonian of the independent systems and the term $A_n B$ describes the interaction Hamiltonian between a microscopic system and the apparatus, $B$ being a apparatus operator. The Hamiltonian of scenario (ii) is the same except $B = B'/N_s$. The commutator $[\bar{A}, H] = [A, H_s]/N_s$ in the
Schrödinger representation implies $[\bar{A}_H(t), H] = \mathcal{O}(N_s^{-1})$ in the Heisenberg representation and the integration of the Heisenberg equation yields
\begin{equation}
[\bar{A}_H(t), \bar{A}_H(t')] = \mathcal{O}(N_s^{-1}),
\end{equation}
the measurement is non-demolishing [14] as $N_s \to \infty$. This result is formal as it stands since possible singularities in time or frequency are ignored, a more careful discussion of this point follows below.

The difference between the two scenarios is shown clearly by the dynamics of the measuring apparatus, namely an apparatus observable, $A_a$, has the commutator $[A_a, H] = \mathcal{O}(N_s^j)$ with $j = 1$ and 0 in the case (i) and (ii), respectively. The disturbance of the apparatus by the measurement increases with the number of measurements and both the the measured system and the measuring apparatus should be renewed after each measurement.

III. MACROSCOPIC LIMIT OF THE COORDINATE

The average over a large number of independent microscopical systems becomes classical. What kind of effective dynamics do the average obey? The response to this question is sought by constructing the effective dynamics of the center of mass coordinate of a large set of non-interacting one-dimensional particles. The key quantity is the generator functional of the connected Green functions of the coordinate.

A. Generator functional

The dynamics of the coordinate $x$ of a particle is assumed to be defined by a CTP action $S_s[\tilde{x}]$, cf. appendix A. The role of the cumulants is taken over by the connected Green functions whose generator functional is defined by the path integral expression
\begin{equation}
e^{i\hbar W_\rho[\tilde{\bar{j}}]} = \int D[\tilde{x}]e^{\frac{i\hbar}{\hbar}S_\rho[\tilde{x}] + \frac{i\hbar}{2}\int dt\tilde{\bar{j}}(t)\tilde{x}(t)},
\end{equation}
where the action $S_\rho[\tilde{x}] = S_s[\tilde{x}] - i\hbar \ln \rho(x_+(x(t_i), x_-(x(t_i)))$ contains the initial condition in terms of the initial density matrix $\rho$. The parameterization $x_\pm = x \pm x_d/2$, $j_\pm = j/2 \pm j_d$, $\tilde{x}\tilde{j} = x_+ j_+ + j_- x_- = x j + x_d j_d$ will be used below. The knowledge of the generator functional $W_\rho[\tilde{j}]$ allows us to reconstruct $S_\rho[\tilde{x}]$ by functional Fourier transformation. We use the
coordinate as our single observable however the extension of the subsequent arguments can easily be generalized over other observable by the use of appropriately generalized generator functional.

We now take \( N_s \) independent copies of our system with initial density matrices belonging to the set \( \{ \rho_k \} \) where the state \( \rho_k \) occurs \( N_k = p_k N_s \) times. The generator functional for the connected Green functions of the average coordinate, \( \bar{x} = \sum_{n=1}^{N_s} x_n / N_s \), is given by

\[
\mathcal{W}[\tilde{j}] = N_s W_q \left[ \frac{\tilde{j}}{N_s} \right].
\]

(8)

where \( W_q[\tilde{j}] = \sum_k p_k W_{\rho_k}[\tilde{j}] \) is the quenched average of the generator functionals over different preparations. The quantum central limit theorem, spelled out below, consists of the suppression of the higher than first order connected Green functions.

**B. Continuous observations**

The effective quantum action for \( \bar{x} \) can be obtained by the functional Fourier transformation,

\[
e^{i\Sigma_q[\bar{x}]} = \int D[\tilde{j}] e^{i\mathcal{W}[\tilde{j}] - \frac{i}{\hbar} \int dt \tilde{j}(t) \bar{x}(t)},
\]

(9)

the case \( N_s = 1 \) being trivial, \( \Sigma_q[\bar{x}] = S_q[\bar{x}] \). When \( N_s \gg 1 \) one finds

\[
\Sigma_q[\bar{x}] = N_s \left[ \frac{1}{2} \int dt \, d t' [\bar{x}(t) - \bar{x}_{cl}(t)][\tilde{D}^{-1}(t, t')][\bar{x}(t') - \bar{x}_{cl}(t')] + \mathcal{O}(N_s^{-1}) \right]
\]

(10)

where \( \bar{x}_{cl, \sigma}(t) = \delta W_q[0] / \delta j_\sigma(t) = \bar{x}_{cl}(t) \) denotes the first moment of the averaged preparation and \( D_{\sigma, \sigma'}(t, t') = -\delta^2 W_q[0] / \delta j_\sigma(t) \delta j_{\sigma'}(t') \) stands for the propagator. The factor \( N_s \) can be interpreted as a simple rescaling of the Planck constant, \( \hbar \to \hbar / N_s \). The dynamics is seriously truncated in the macroscopic limit, the first moment is kept untouched but the connected Green functions, representing the quantum fluctuations, are suppressed. The difference between the classical physics of the non-fluctuating first moment as trajectory and the quantum physics of a large but finite set of microscopic systems stems from the \( \mathcal{O}(N_s^{-1}) \) corrections.

The probability distribution of \( \bar{x} = (\bar{x}_+ + \bar{x}_-)/2 \) can be obtained by setting \( j_d = 0 \) and performing the Fourier transformation only in \( j \),

\[
p[\bar{x}] = e^{\frac{N_s}{2\pi} \int dt dt' [\bar{x}(t) - \bar{x}_{cl}(t)][(\tilde{D}^{-1})^{-1}(t, t')][\bar{x}(t') - \bar{x}_{cl}(t')] + \mathcal{O}(N_s^0)},
\]

(11)
to a normalization factor. The positivity of the spectral density \( A_{20} \), makes \( D_i(t, t') \) a negative definite operator and the probability distribution is Gaussian with an \( O(N_s^{-1/2}) \) width around the expectation value. The decoherence in the coordinate space, the suppression of the contribution to the generator functional with increasing \( \bar{x}_d = \bar{x}_+ - \bar{x}_- \), can be read off from

\[
p_d(\bar{x}_d) = e^{-\frac{1}{2} \text{Im} \mathcal{S}_q[\bar{x}]}
\]

with

\[
\text{Im} \mathcal{S}_q[\bar{x}] = \frac{N_s}{2} \int dt dt' \bar{x}_d(t)(D^{-1})^i(t, t')\bar{x}_d(t') + O(N_s^0).
\]

Note that the kernel of the quadratic forms (11) and (13) differ.

Let us consider the time translation invariant limit \( t_i \to -\infty, t_f \to \infty \) when the spectral function \( \rho(\omega) = -D^i(\omega)/\pi \) for \( \omega > 0 \) peaks at the quasi-particle frequencies. The effective dynamics of \( \bar{x} \) is markedly different for discrete and continuous spectrum. In the case of discrete spectrum \( D^i \) displays Dirac-delta singularities at the stable particle modes, cf. the last equation in (A11). However their contributions, the on-shell stable particle modes, drop out from the harmonic action and their amplitudes acquire a uniform probability distribution according to (11). The dynamics remain coherent since \( (D^{-1})^i(\omega) = -D^f(\omega)/D^r(\omega)D^a(\omega) = O(\epsilon) \) at the quasi-particle peaks, cf. the last equation in (A15). Such a state of affairs follows naturally from noting that the finite time observations can resolve the discrete spectral lines. The spectrum of a macroscopic system is usually continuous and we can not resolve the individual energy levels. Hence the quasi-particles usually have finite life-time and their decay indicates an underlying interaction with the environment implying decoherence, eg. eqs. (A23).

While the effective quantum dynamics for the average \( \bar{x} \) is given by the Fourier transformation (9) the corresponding classical effective action is defined by the Legendre transformation,

\[
\mathcal{S}_{cl}[\bar{x}] = \mathcal{W}[\bar{j}] - \int_t \bar{x}(t)\bar{j}(t), \quad \bar{x}(t) = \frac{\delta \mathcal{W}[\bar{j}]}{\delta \bar{j}(t)}.
\]

In fact, the inverse transformation,

\[
\mathcal{W}[\bar{j}] = \mathcal{S}_{cl}[\bar{x}] + \int_t \bar{x}(t)\bar{j}(t), \quad -\bar{j}(t) = \frac{\delta \mathcal{S}_{cl}[\bar{x}]}{\delta \bar{x}(t)},
\]

shows that the peak of the probability distribution (11) satisfies the Euler-Lagrange equation of \( \mathcal{S}_x[\bar{x}] \). The quantum and the classical actions are usually different however the Fourier and
the Legendre transformations agree for quadratic functions leading to $S_{cl}[\bar{x}] = S_q[\bar{x}] + \mathcal{O}(N_s^0)$, in other words Ehrenfest’s theorem becomes valid since the width of a wave packet of $\bar{x}$ is $\mathcal{O}(N_s^{-1/2})$.

The action $S_q$ conveys a non-trivial massage, the suppression of the fluctuations. However the simplicity of $S_{cl}$ is deceptive because the initial state is anchored in the action $S_\rho$ in the path integral (7). An equation of motion of classical physics is universal because the auxiliary conditions, needed to specify a given solution, are independent from them. The variational equation of $S_{cl}$ is satisfied by the expectation value of the coordinate is not universal since it already contains the initial conditions. We may nevertheless explore the physics of different average trajectories, $\bar{x}_{cl}(t)$, by using a suitable chosen $N_s$-independent physical external source $j_{ph,\sigma}(t) = \sigma j_{ph}(t)$. The procedure based on the external source $\sigma j_{ph} + j_\sigma/N_s$, $j_\sigma$ being the book-keeping auxiliary variable used up to now leads to a dynamics which is dominated by the trajectories in the $\mathcal{O}(N_s^{-1/2})$ vicinity of $\bar{x}_{cl}(t)$.

C. Discrete observation times

The formal result (6) indicating the non-demolishing nature of the measurement for large $N_s$ seems to be supported by the $\mathcal{O}(N_s^{-1/2})$ width of the probability distribution (11). However in a closed dynamics (11) is actually flat for the normal modes defined by the discrete Dirac-delta peaks of the spectral function.

A less formal and more reliable argument for the emergence of a classical trajectory can be constructed by the help of a discrete set of measurements, carried out at discrete times, $t_\ell$, $\ell = 1, \ldots, N_m$. The external source is now written in the form $\tilde{j}(t) = \sum_\ell \tilde{j}_\ell \delta(t - t_\ell)$ and the generator functional $\mathcal{W}[\tilde{j}]$ is reduced to a function of the coefficients $\tilde{j}_\ell$,

$$\mathcal{W}_s(\tilde{j}) = \tilde{j} \bar{x} - \frac{1}{2N_s} \tilde{j} \tilde{D} \tilde{j}$$

where the quantities without time arguments is either an $N_m$ dimensional vectors or $N_m \times N_m$ matrix, written in component form as $\bar{x}_{\sigma,\ell} = \delta W_q[0] / \delta j_\sigma(t_\ell) = \bar{x}_\ell$ and $\tilde{D}_{\ell,\ell'} = -\delta^2 W_q[0] / \delta \tilde{j}(t_\ell) \delta \tilde{j}(t_{\ell'}) = \tilde{D}(t_\ell - t_{\ell'})$. The corresponding action function,

$$S_q(\bar{x}) = S_{cl}(\bar{x}) = -\frac{N_s}{2} (\bar{x} - \bar{x}_{cl}) \tilde{D}^{-1}(\bar{x} - \bar{x}_{cl}),$$

differs from (10) that here the inverse is that of a $2N_m \times 2N_m$ matrix $\tilde{D}(t_\ell, t_{\ell'})$ as opposed to an operator $\tilde{D}(t, t')$ acting on time-dependent functions. The physical origin of the difference
is that while (10) contains the full information about the harmonic dynamics the (17) encodes a “stroboscope physics”, the dynamics at the time scales $t_j - t_{j-1}$ [42].

Let us consider first a single observation whose result is summarized by the distribution function

$$\chi(\tilde{z}_1) = \int d\tilde{x} e^{i\tilde{z}q(\tilde{x})} \delta(\tilde{x}_1 - \tilde{z}_1).$$

(18)

The UV finiteness of the dynamics assures that the response to an external source builds up continuously in time and the retarded and the advanced propagators are vanishing when the external source is turned on or off, respectively, $D^r(0) = D^a(0) = 0$. The dependence on $j_{1d}$ is suppressed according to the block structure (A8) and we find

$$\chi(\tilde{z}_1) = \delta(z_{1d}) \sqrt{\frac{N_s\hbar}{-2\pi D^2(0)}} e^{\frac{N_s}{2D^2(0)}(z_1 - \bar{z}_1)^2}$$

(19)

with $D^l(0) < 0$. The observation leads to a collapse of the two members of the CTP doublet, a complete decoherence, owing to the unitarity of the time evolution and the common value follows a narrow Gaussian distribution, peaked at the expectation value.

In the case of two observations, separated by the time $\tau = t_2 - t_1 > 0$ the relevant distribution function,

$$\chi(\tilde{z}_1, \tilde{z}_2) = \int d\tilde{x}_1 d\tilde{x}_2 e^{i\tilde{z}q(\tilde{x}_1, \tilde{x}_2)} \delta(\tilde{x}_1 - \tilde{z}_1) \delta(\tilde{x}_2 - \tilde{z}_2),$$

(20)

can be obtained by a straightforward integration,

$$\chi(\bar{z}_1, \bar{z}_2) = \delta_{z_{2d}, 0} \sqrt{\frac{(2\pi N_s \hbar)^3}{-D^3(0)D^2(\tau)}} e^{\frac{N_s}{2D^2(0)}} \frac{N_s}{D^2(0)D^2(\tau)} \frac{D^3(0)(\bar{z}_1 - \bar{x}_1)^2 + 2i \bar{z}_d (D^1(0)(\bar{z}_2 - \bar{x}_2) - D^1(\tau)(\bar{z}_1 - \bar{x}_1)) + D^2(0)D^2(\tau) - D^2(\tau) - D^2(0)}{D^3(0)D^2(\tau) + D^2(0)D^2(\tau) - D^2(\tau)} \bar{z}_1^2.$$  

(21)

The distribution of the result of the first measurement is identical to the case of a single measure and the second, last measure is completely decohered. But the rest is difficult to understand, there seems to be a non-trivial $z_{1d}$-dependence which influences the distribution of the result of the second measurement. Since the off-diagonality is not observable it is better to integrate it out or equivalently, to perform the Fourier transform of $W(\bar{j})$ for $j_d = 0$,

$$\chi(\tilde{z}_1, \tilde{z}_2) = \frac{2\pi \hbar N_s}{\sqrt{D^2(0) - D^2(\tau)}} e^{\frac{N_s}{2D^2(0)}} \frac{D^4(0)(\tilde{z}_1 - \tilde{x}_1)^2 + 2i \tilde{z}_d (D^1(0)(\tilde{z}_2 - \tilde{x}_2) - D^1(\tau)(\tilde{z}_1 - \tilde{x}_1)) + D^2(0)D^2(\tau) - D^2(\tau) - D^2(0)}{D^3(0)D^2(\tau) + D^2(0)D^2(\tau) - D^2(\tau)} \tilde{z}_1^2.$$  

(22)

where $\tilde{z}(\pm) = \tilde{z}_2 \pm \tilde{z}_1$ and $\tilde{x}(\pm) = \tilde{x}_{2, +} \pm \tilde{x}_{1, +}$. This is a more reasonable result, namely the unitarity of the time evolution, the non-observability of $x_d$, decouples the observations in the limit $N_s \to \infty$. 
It is instructive to carry out the limit of two close observations, \( \tau \to 0 \). The distribution of the velocity \( V = (\bar{x}_2 - \bar{x}_1)/\tau \) and the coordinate \( X = (\bar{x}_1 + \bar{x}_2)/2 \) for small \( \tau \to 0 \) is

\[
\chi(X, V) = \frac{2\pi \hbar N_s}{\sqrt{-2D^i(0)\dot{D}^i(0)\tau}} e^{N_s \left[ \frac{(X - x_{cl})^2}{2D^i(0)} - \tau \frac{(V - \dot{x}_{cl})^2}{2D^i(0)} \right]}
\]

with \( \dot{D}^i(0) = dD^i(0)/dt \). The spread of the distribution function in the velocity is consistent with the uncertainty principle with a reduced Planck constant, \( \hbar \to \hbar/N_s \).

D. Interactive microscopic systems

We have so far restricted our attention to non-interacting microscopic systems. It is natural to inquire about the condition on the strength of interactions among the systems which keeps this result valid. To find it we consider an interactive family of microscopic systems with the generator functional for the single system Green functions

\[
e^{\frac{i}{\hbar}W_s[\tilde{j}_1, \ldots, \tilde{j}_{N_s}]} = \int D[\tilde{x}] e^{\frac{i}{\hbar}S_s[\tilde{x}]+\frac{i}{\hbar} \sum_n \int dt \tilde{j}_n(t)\tilde{x}_n(t)},
\]

where \( S_s[\tilde{x}] = \sum_n S_{\rho_n}[\tilde{x}_n] \) denotes the action of the set of systems and \( \rho_n \) stands for the density matrix of the initial state of the \( n \)-the system. The generator functional can be written in the cluster expansion as

\[
W_s[\tilde{j}_1, \ldots, \tilde{j}_{N_s}] = \sum_{n_1=1}^{N_s} W_{s,n_1}[\tilde{j}_{n_1}] + \frac{1}{2} \sum_{n_1,n_2=1}^{N_s} W_{s,n_1,n_2}[\tilde{j}_{n_1}, \tilde{j}_{n_2}]
+ \frac{1}{3!} \sum_{n_1,n_2,n_3=1}^{N_s} W_{s,n_1,n_2,n_3}[\tilde{j}_{n_1}, \tilde{j}_{n_2}, \tilde{j}_{n_3}] + \cdots
\]

where the \( \ell \)-th term on the right hand side represents the \( \ell \)-body correlations. For sufficiently weakly coupled systems the contributions of the correlations to the generator functional

\[
\overline{W}[\tilde{j}] = W_s \left[ \frac{\tilde{j}}{N_s}, \ldots, \frac{\tilde{j}}{N_s} \right]
\]

are suppressed as \( N_s \to \infty \),

\[
\lim_{N_s \to \infty} \frac{1}{N_s} \sum_{n_1, \ldots, n_\ell} W_{s,n_1,\ldots,n_\ell}[\tilde{j}, \ldots, \tilde{j}] = 0,
\]

for \( \ell \geq 2 \) and the systems can be considered as independent. A sufficient condition of weakly coupled systems is that the each system is correlated with \( \mathcal{O}(N_s^0) \) others. This
condition is satisfied by clusterizing Green functions displaying a finite correlation length in the thermodynamical limit and indicates a mean-field critical exponent, that the fluctuations of the extensive quantities is growing with the square root of the volume.

IV. MEASUREMENT PROCESS

We have so far looked into the emergence of a classical trajectory for the effective dynamics of the average over a large set of independent systems. But the average coordinate is measured by an apparatus which is subject of quantum mechanics, as well, and it remains to be seen whether the process of the measurement preserves the classical nature of the average coordinate.

A. Measuring apparatus

We denote the coordinates of the degrees of freedom of the apparatus by \( y_n, n = 1, \ldots, N_a \) and assume the form \( S = S_x[\tilde{x}] + S_y[\tilde{y}] + \sum_{n=1}^{N_a} g_n \int dt \tilde{x}(t) y_n(t) \) for the action of the measured microscopic systems and the apparatus where the second and the third terms represent the action of the apparatus and the measured system-apparatus interaction, respectively and \( g_n = O(N_a^0) \). The result of the measurement is read of from a pointer, a macroscopic collective apparatus variable \( \bar{y} = \sum_n \kappa_n y_n/N_a \) with \( \kappa_n = O(N_a^0) \).

The generator functional for the apparatus Green functions,

\[
\begin{equation}
W_a[\tilde{j}_1, \ldots, \tilde{j}_{N_a}] = \int D[\tilde{y}] e^{i \frac{\hbar}{\beta} S_a[\tilde{y}] + \frac{\hbar}{\beta} \sum_n \int dt \tilde{j}_n(t) \tilde{y}_n(t)},
\end{equation}
\]

is written in the form

\[
W_a[\tilde{j}_1, \ldots, \tilde{j}_{N_a}] = \sum_{n_1=1}^{N_a} W_{a,n_1}[\tilde{j}_{n_1}] + \frac{1}{2} \sum_{n_1,n_2=1}^{N_a} W_{a,n_1,n_2}[\tilde{j}_{n_1}, \tilde{j}_{n_2}]
+ \frac{1}{3!} \sum_{n_1,n_2,n_3=1}^{N_a} W_{a,n_1,n_2,n_3}[\tilde{j}_{n_1}, \tilde{j}_{n_2}, \tilde{j}_{n_3}] + \cdots
\] (29)

The apparatus is called weakly coupled if the correlations among the coordinates become suppressed as \( N_a \to \infty \),

\[
\lim_{N_a \to \infty} \frac{1}{N_a^\ell} \sum_{n_1, \ldots, n_\ell=1}^{N_a} W_{a,n_1,\ldots,n_\ell} \left[ g_{n_1} \tilde{\sigma} \tilde{x}_{cl} + \frac{\kappa_{n_1}}{N_a} \tilde{J}, \ldots, g_{n_\ell} \tilde{\sigma} \tilde{x}_{cl} + \frac{\kappa_{n_\ell}}{N_a} \tilde{J} \right] = 0,
\] (30)
for $\ell \geq 2$. The generator functional for the pointer Green functions is

$$e^{\frac{i}{\hbar} W_P[\tilde{J}]} = \int D[\tilde{x}] D[\tilde{y}] e^{\frac{i}{\hbar} S_n[\tilde{x}] + \kappa \sum_n g_n \int dt \tilde{x}(t) \tilde{y}_n(t) + \frac{i}{\hbar} \int dt \tilde{J}(t) \tilde{y}(t)}$$

(31)

where the matrix $\tilde{\sigma} = \text{Diag}(1, -1)$ takes care of the relative minus sign in the system-apparatus interaction term. The indistinguishability of the measured systems can be taken into account by summing over the permutations $\pi \in S_{N_s}$ on the right hand side, by calculating the path integral with the closing condition $x_{n,+}(t_f) = x_{\pi(n),-}(t_f)$ and by dividing the sum with $N_s!$. However this is not necessary as long as we do not attempt to distinguish the $N_s$ systems by the measurement. The systems may have local interaction obeying the condition (27).

The integration over the microscopic system coordinates simplifies this expression to

$$e^{\frac{i}{\hbar} W_P[\tilde{y}]} = \int D[\tilde{y}] e^{\frac{i}{\hbar} N_a W_a \left[ \frac{\kappa_1}{N_a} \tilde{y}_1 + \ldots + \frac{\kappa_{N_a}}{N_a} \tilde{y}_{N_a} \right] + \mathcal{O}(N_a^{-1})}$$

and

$$W_P[\tilde{y}] = W_a \left[ g_1 \tilde{x}_{cl} + \frac{\kappa_1}{N_a} \tilde{y}_1 + \ldots + g_{N_a} \tilde{x}_{cl} + \frac{\kappa_{N_a}}{N_a} \tilde{y}_{N_a} \right] + \mathcal{O}(N_a^{-1}).$$

(32)

(33)

In the case of a weakly coupled apparatus one has a further simplification,

$$W_P[\tilde{J}] = \sum_{n=1}^{N_a} W_{a,n} \left[ g_n \tilde{x}_{cl} + \frac{\kappa_n}{N_a} \tilde{J} \right],$$

(34)

leading to harmonic pointer effective action

$$S_Q[\tilde{y}] = \frac{N_a}{2} \int dt dt' [\tilde{y}(t) - \tilde{y}_{cl}(t)] \tilde{G}^{-1}_P(t, t') [\tilde{y}(t') - \tilde{y}_{cl}(t')] + \mathcal{O}(N_a^0)$$

(35)

containing the pointer trajectory

$$\tilde{y}_{cl}(t) = \frac{1}{N_a} \sum_{n=1}^{N_a} \kappa_n \frac{\delta W_{a,n}[\tilde{J}]}{\delta \tilde{J}(t)} |_{\tilde{J} = g_n \tilde{x}_{cl}}$$

(36)

and propagator

$$\tilde{G}_P(t, t') = \frac{1}{N_a} \sum_{n=1}^{N_a} \kappa_n^2 \frac{\delta^2 W_{a,n}[\tilde{J}]}{\delta \tilde{J}(t) \delta \tilde{J}(t')} |_{\tilde{J} = g_n \tilde{x}_{cl}},$$

(37)

cf. eq. (10). What we see here in the limit $N_s, N_a \to \infty$ is that a classical trajectory, $\tilde{x}_{cl}(t)$, generates another one, $\tilde{y}_{cl}(t)$. The amplification of the microscopic $\tilde{x}_{cl}(t)$ to a macroscopic $\tilde{y}_{cl}(t)$ is linear in a harmonic apparatus, discussed in some details in appendix B.

The fluctuations may naturally play an important role in determining the relation between the $\tilde{x}_{cl}(t)$ and $\tilde{y}_{cl}(t)$. The fluctuations within a macroscopic apparatus may become decisive
according to (36) when some non-linearities generates unstable apparatus states where the condition (30) is violated, the typical example of non-clusterizing Green functions being a phase transition, cf. some early attempts to realize measurements in this manner [43–47]. Such instabilities can be turned into an efficient non-linear amplifier [48, 49], the case of Wilson’s cloud chamber is taken up briefly below. The quantum fluctuations of the measured microscopic system may play an important role through the ignored $O(N_s^{-1})$ contributions on the right hand side of (33). The experimental demonstration of such quantum fluctuations is the goal of interferometry of molecules [50].

### B. Particle cloud chamber

An example of a strongly coupled apparatus is Wilson’s chamber [51, 52] containing a radioactive atom emitting say an $\alpha$ particle. The chamber is filled up with the mixture of air and water molecules and its volume is suddenly extended to bring the mixture into supersaturation. The ionization, caused by the $\alpha$-particle triggers the condensation of water molecules into droplets along straight classical trajectory.

The elementary unites of the apparatus are the water molecules and they should be handled by a statistical description. In a stable thermodynamical phase these molecules can be considered as an ideal gas however the homogeneous unstable supersaturated state can approximately be taken into account by assuming a strong attractive interaction among the water molecules within the droplet size $r_{dr}$, supposed to be much larger than the wavelength of the $\alpha$-particle, $r_{dr} \gg \lambda_\alpha$. We have an apparatus which is weakly (strongly) coupled at distances $\ell \gg r_{dr}$ ($\ell \ll r_{dr}$). Two other important parameters of the chamber are used below, the ratio of the water molecule density on the two sides of the first order phase transition, in the droplet and in the supersaturated region, $n_{dr}/n_{ss}$, and the average time needed for an ionization to take place, $\tau_i$. The action of the full system is the sum of the action (A5) for the $\alpha$-particle with finite $t_i$ and $t_f$, an action for the water molecules, $S_{a}[y_1, \ldots, y_{N_a}]$, and the interaction term, assumed to be $g \int dt n(x_{\alpha}(t))$ where the density of water molecules, $n(x)$, is taken along the $\alpha$-particle trajectory $x_{\alpha}(t)$.

We follow the ionization perturbatively and suppose that at order $N_m$ the ionizations which take place at the time and space, $t_j, x_j, j = 1, \ldots, N_m$, are separated spatially more than the droplet size, $|x_{j+1} - x_j| > r_{dr}$, an assumption to be justified later. By neglecting
the interactions among the droplets the contribution to the probability of propagation of the \(\alpha\)-particle from \(x_i = x_0 = x_{0,\pm}\) at \(t = t_i = t_0\) to \(x_f = x_{N_m+1} = x_{N_m+1,\pm}\) at \(t = t_f = t_{N_m+1}\) is

\[
\prod_{j=1}^{\ell} \int d^3\tilde{x}_j \prod_{j'=0}^{\ell} D_0(x_{j'+1,+,t_{j'+1} - t_{j'}}) \prod_{j''=0}^{\ell} D_0^*(x_{j''+1,-,t_{j''+1} - t_{j''}}) \tag{38}
\]

up to a trajectory independent constant where

\[
D_0(x, t) = \left( \frac{m}{2\pi i\hbar t} \right)^{\frac{3}{2}} e^{\frac{i m}{\hbar t} x^2} \tag{39}
\]
denotes the free propagator. This is a Gaussian integral and can simply be calculated up to a time-dependent constant by evaluating the integrand at the saddle point. It is easy to show by recursion in \(N_m\) that the saddle point is a straight line, \(x_j = (t_j - t_0)(x_{\ell+1} - x_0)/(t_{\ell+1} - t_0) + x_0\) in agreement with second order perturbation expansion in the operator formalism [53, 54].

A pointer variable, the center of mass of the corresponding droplet, is formed dynamically at each each ionization. The number of elementary constituents, the water molecules, in a droplet, is large enough to render the pointer classical. In a good approximation the ionization depletes the water density in a sphere of radius \(r_{dr}(n_{dr}/n_{ss})^{1/3}\). The next droplet should be formed at a place where there are sufficient water molecules around, justifying \(|x_{j+1} - x_j| > r_{dr}\). Hence the apparatus can be considered as weakly coupled in the selection of the ionization location and the definition of the pointer value is guided by the integrand of (38).

We have a single \(\alpha\)-particle, \(N_s = 1\), hence one expects large fluctuations around the saddle point which in turn renders the value of the pointer almost random. However a closer look at the integrand of (38) reveals that this is not the case. In fact, let us evaluate the integral by a coarse-graining in two steps: We divide the volume of the chamber into small cubes of size \(r_{dr}\) and integrate first within the cubes and after that sum over them. One finds that the assumption \(r_{dr} \gg \lambda_\alpha\) leads to a strong suppression of the integral within a cube owing to a fast phase oscillation unless the centers of the cubes correspond to the motion of a free particle. Therefore the chain of droplets of a single \(\alpha\)-particle lies on a straight line within the resolution of the size of the droplets.

The strong short range attractive force among the water molecules plays several roles. It drives the amplification, mentioned at the end of section IV A, in such a peculiar manner
that the classical trajectory of the pointer(s) is formed in a weakly coupled apparatus and the homogeneous integral measure in (38) is justified. In addition it is responsible of the suppression of quantum fluctuations at \( N_s = 1 \) and places the chain of ionizations along a classical trajectory. Finally, it regenerates the pointer variable in a dynamical manner for each measurement, i.e. droplet. This mechanism is a dynamical realization of the hypothetical step, the type 1 sudden quantum state change of Neumann [55] or alias collapse of the wave function.

But which classical trajectory is chosen where the wave function collapses to? Let us follow the propagation of the \( \alpha \)-particle from \( t = t_i \) at \( x = x_i \). The time and location of the first ionization is chosen randomly. This step, the core of the measurement problem, remains unsolved but as soon as this step is made the rest follows from a semiclassical picture: The first step breaks the initial \( SO(3) \) symmetry into the \( SO(2) \) subgroup, consisting of rotation around \( x_1 - x_0 \). This symmetry is approximately preserved by the successive ionizations which line up with an average separation \( \tau_i (x_1 - x_0) / (t_1 - t_0) \) along a straight line.

V. SUMMARY

The proposal is put forward in this work that one can avoid the logical conflict between quantum and classical physics when the latter is considered as the macroscopic limit of the former. The quantum generalization of the central limit theorem is given by showing the narrowing of the probability distribution of the average observable in over a \( N_s \) independent identical system as \( N_s \to \infty \). A classical trajectory is recovered for the coordinates in this limit. Therefore the idea is to regard classical physics as the limit of large but finite quantum systems where the size of Avogadro’s number suppresses quantum fluctuations for all practical purposes. The conditions on the strength of the correlations among the microscopic systems are given to preserve the simplicity of the result. The observation over a discrete set of times reveal a discrete dynamics, characteristic at the time scale of the observations.

The inclusion of the measuring apparatus into considerations allows us to find some simple qualitative amplifying mechanisms in the measuring process. In order to have a non-linear amplification we need correlations among the constituents of the apparatus beyond the limit the applicability of the quantum central limit. It is argued that Wilson’s cloud
chamber represents a simple set of both weakly and strongly correlated constituents where on the one hand one can use the central limit theorem for the pointer variable and on the other hand one can retain the quantum fluctuations of the ionising particle.

The droplet formation in the chamber is a dynamical realization of the assumed collapse of the wave function. This view suggests that Neumann’s postulate of a sudden change of the quantum state can be avoided and the impulsive nature of the quantum jump results from a large number in the dynamics, \( N_s \), which generates new time scales. The main problem of measurement theory, the choice of the observed spectrum value of an observable, remains untouched by these considerations.

The central limit theorem, used in this work, relies on a set of independent or weakly coupled microscopic systems. One may continue this line of thought and reach more realistic models by moving away from the vicinity of a Gaussian fixed point. This step implies to the quantum renormalization group [38] requiring the use of quantum field theoretical methods.

**Appendix A: CTP scheme**

The scheme to embark the macroscopic limit should cover classical and quantum physics and include closed and open systems. This is achieved by the CTP formalism [39, 40] which is simplest to motivate by remarking that the expectation value

\[
\langle \psi | A | \psi \rangle = \sum_{m,n} c_m c_n^* \langle m | A | n \rangle \quad (A1)
\]

of the observable \( A \) in the pure normalized state \( | \psi \rangle = \sum_m c_m | m \rangle \) involves two representatives of the same state, a bra and a ket, progressing in opposite direction in time. The summation is over the quantum fluctuations in the basis \( \{ | m \rangle \} \). The factorisability of the coefficients \( c_m c_n^* \) indicates the independence of the quantum fluctuations in the bra and the ket. However the fluctuations become correlated in mixed states, requiring the formal reduplication of the degrees of freedom, say \( x \rightarrow \bar{x} = (x_+, x_-) \), \( p \rightarrow \bar{p} = (p_+, p_-) \), etc. We give a minimalist summary of the salient features of this formalism applied for quantum systems.
1. Generator functional

The bra and the ket dynamics within the time interval $t_i < t < t_f$ can be captured by the generator functional of the connected Green functions for the observable in the basis in question, the coordinate in our case,

$$e^{i \hbar W[j]} = \text{Tr}[U[t_f, t_i; j+] \rho(t_i) U[t_i; -j-]]$$

(A2)

where $U[t_f, t_i; j]$ denotes the time evolution operator for the time interval $(t_i, t_f)$ with $t_i \leq t_m \leq t_f$ in the presence of a time-dependent external source in the Hamiltonian, $H \rightarrow H - jx$, and $\rho(t_i)$ stands for the initial density matrix. The generating functional is an analytic functional for stable dynamics and the connected Green functions are defined by the functional Taylor expansion,

$$W[j] = \sum_{n=0}^{\infty} \frac{1}{n!} \sum_{\sigma_1, \ldots, \sigma_n} \int dt_1 \cdots dt_n j_{\sigma_1}(t_1) \cdots j_{\sigma_1}(t_1) D_{\sigma_1, \ldots, \sigma_n}(t_1, \ldots, t_n)$$

(A3)

with $\tilde{j} = (j_+, j_-)$. The path integral representation of this generator function is

$$e^{i \hbar W[j]} = \int D[\tilde{x}] e^{i \tilde{S}[\tilde{x}] + i \int dt \tilde{j}(t) \tilde{x}(t)}$$

(A4)

where the action is given by

$$\tilde{S}[\tilde{x}] = S_s[x_+] - S_s[x_-] + \frac{i}{2} \epsilon \int dt [x_+^2(t) - x_-^2(t)]$$

(A5)

where $S_s[x]$ denotes the traditional action of the closed dynamics and the last term assures the convergence of the path integral. The integration is over the trajectory pairs $\tilde{x}_\pm(t) = (x_+(t), x_-(t))$, $t_i < t < t_f$, satisfying the closing condition $x_+(t_f) = x_-(t_f)$ which represents the trace operation in(A2) and the convolution with the initial state is suppressed for easier readability. The closing of the trajectories couples $x_+$ and $x_-$, breaks the translation invariance in time and violates the energy conservation. To eliminate such a formal problems we take the limit $t_f \rightarrow \infty$. This limit is non-trivial [41] however a simple way to find it for a harmonic oscillator is given below.

The unitarity of the closed dynamics of the full observed system and its environment imposes important constraints on the generator functional $W[j]$. The unitarity holds for arbitrary physical realisable external source, $j_\pm = \pm j$, hence the conservation of the probability and the definition (A2) imply $W[j]|_{j_+ = -j_-} = 0$. A surprising corollary is that all
Green function of $x_d = x_+ - x_-$ is vanishing and the quantum fluctuations, represented by $x_d$, are "invisible" alone, without coupling them to observables. Another important result of the unitarity is the invariance of the generator functional under the change the final time $t_f$ in the presence of physical source, $j_\pm = \pm j$.

2. Propagator

The propagator

$$D_{\sigma,\sigma'}(t, t') = -i\hbar \begin{pmatrix} \langle T[x(t)x(t')] \rangle & \langle x(t')x(t) \rangle \\ \langle x(t)x(t') \rangle & \langle T[x(t)x(t')] \rangle^* \end{pmatrix}$$  \hspace{1cm} (A6)$$

is symmetric, $D_{\sigma',\sigma'}(t, t') = D_{\sigma,\sigma}(t', t)$, and the identity $T[AB] + (T[AB])^\dagger = AB + BA$ implies $D_{++} + D_{--} = D_{+-} + D_{-+}$. The source $j_\pm = \pm j$ can be realized by external physical devices and generates the expectation value

$$\langle x_\pm(t) \rangle = \int_{-\infty}^{\infty} dt [D_{\pm,+}(t, t') - D_{\pm,-}(t, t')] j(t')$$  \hspace{1cm} (A7)$$

which is real and independent of the choice of the sign $\pm$. These constraints allow us to represent the propagator in terms of three real functions, $D^n(t, t') = D^n(t', t)$, $D^i(t, t') = D^i(t', t)$ and $D^f(t, t') = -D^f(t', t)$,

$$\tilde{D} = \begin{pmatrix} D^n + iD^i & -D^f + iD^i \\ D^f + iD^i & -D^n + iD^i \end{pmatrix}.$$  \hspace{1cm} (A8)$$

The components $D^n$ and $D^f$ are called near and far Green's function by analogy with classical electrodynamics.

The propagator is easy to find in the operator formalism for a harmonic oscillator of mass $m$ and frequency $\omega_0$,

$$\tilde{D}(t, t') = -\frac{i}{2m\omega_0} \begin{pmatrix} e^{-i|t-t'|\omega_0} & e^{i(t-t')\omega_0} \\ e^{i(t-t')\omega_0} & e^{-i|t-t'|\omega_0} \end{pmatrix}.$$  \hspace{1cm} (A9)$$

Its expression in the frequency space is

$$\tilde{D}_{\omega_0}(\omega) = \int dt e^{i\omega(t-t')} \tilde{D}_{\omega_0}(t-t')$$

$$= \frac{1}{m} \sum_n \begin{pmatrix} \frac{1}{\omega^2 - \omega_n^2 + i\epsilon} & -2\pi i\delta(\omega^2 - \omega_n^2)\Theta(-\omega) \\ -2\pi i\delta(\omega^2 - \omega_n^2)\Theta(\omega) & -\frac{1}{\omega^2 - \omega_n^2 - i\epsilon} \end{pmatrix},$$  \hspace{1cm} (A10)$$
or

\[ D^\omega_0 (\omega) = P \frac{1}{m(\omega^2 - \omega_0^2)}, \]
\[ D^f_\omega (\omega) = -i \frac{\pi}{m} \delta(\omega^2 - \omega_0^2) \text{sign}(\omega), \]
\[ D^i_\omega (\omega) = -\frac{i}{m} \delta(\omega^2 - \omega_0^2), \]

(A11)

where \( P \) denotes the principal part. The limit \( t_i \to -\infty, t_f \to \infty \) is trivial to carry out in (A9) yielding the action of a harmonic oscillator,

\[ \tilde{S}_{HO} = \frac{1}{2} \int_{-\infty}^{\infty} dt dt' \tilde{x}(t) \tilde{D}^{-1}(t - t') \tilde{x}(t'). \]

(A12)

3. Inverse propagator

The propagator (A9) displays time translation invariance and \( D^n, D^f \) and \( D^i \) are commutative, leading to the inverse with the block structure

\[ \tilde{D}^{-1} = \begin{pmatrix} (\tilde{D}^{-1})^n + i(\tilde{D}^{-1})^i & (\tilde{D}^{-1})^f - i(\tilde{D}^{-1})^i \\ -(\tilde{D}^{-1})^f - i(\tilde{D}^{-1})^i & -(\tilde{D}^{-1})^n + i(\tilde{D}^{-1})^i \end{pmatrix} \]

(A13)

where \((\tilde{D}^{-1})^a = (\tilde{D}^{-1})^n \pm (\tilde{D}^{-1})^f = (\tilde{D}^{-1})^{-1} \) and \((\tilde{D}^{-1})^i = -(\tilde{D}^{-1})^n D^i(D^a)^{-1} \). In particular, the kernel of the harmonic oscillator action,

\[ \tilde{D}^{-1}_\omega (\omega) = m \begin{pmatrix} (\omega^2 - \omega_0^2) & 1 & 0 \\ 0 & -1 & i \epsilon \\ 1 & -2 \Theta(-\omega) & 1 \end{pmatrix}, \]

(A14)

gives

\[ (D^{-1}_\omega)^n = m(\omega^2 - \omega_0^2), \]
\[ (D^{-1}_\omega)^f = i m \text{sign}(\omega) \epsilon, \]
\[ (D^{-1}_\omega)^i = m \epsilon, \]

(A15)

when the Lorentzian Dirac-delta

\[ \delta(\omega) = \frac{\epsilon}{\pi(\omega^2 + \epsilon^2)} \]

(A16)

is used in the propagator. The CTP action for a closed dynamics, defined by the action \( S[x] \) can be defined by

\[ \tilde{S}[\tilde{x}] = S_s[x_+] - S_s[x_-] + \frac{\epsilon}{\pi} \int dt dt' \frac{x^-(t)x^+(t')}{t - t' + i \epsilon} + \frac{i \epsilon}{2} \int dt [x^+(t) + x^-(t)]. \]

(A17)
The comparison with eq. (A5) reveals that the coupling of the trajectories at the final time is replaced in the limit $t_f \to \infty$ by an infinitesimal, time translation invariant coupling over the whole time evolution.

The block structure of the inverse propagator is similar to $\tilde{\sigma} \tilde{D} \tilde{\sigma}$ where $\tilde{\sigma} = \text{Diag}(1, -1)$ is the “metric tensor” of the CTP formalism. The calculation of the propagator, given by the Schwinger-Dyson resumed form as in eq. (B3), is facilitated by noting that the multiplication of the block matrices

$$\hat{A}_\sigma = \sigma \hat{A} = \begin{pmatrix} A^n + iA^i & -A^f + iA^i \\ -A^f - iA^i & A^n - iA^i \end{pmatrix}$$

yields the relations

$$(A_{\sigma_1} \cdots A_{\sigma_n})^r_a = A^r_{\sigma_1} \cdots A^r_{\sigma_n}$$

$$(A_{\sigma_1} \cdots A_{\sigma_n})^i = \sum_{j=0}^{n} (A_{\sigma_1} \cdots A_{\sigma_j})^r A^i_{\sigma_{j+1}} (A_{\sigma_{j+2}} \cdots A_{\sigma_n})^a.$$  \hspace{1cm} (A19)

4. Continuous spectrum

While the spectrum of finite systems is usually discrete the density of state becomes so high for macroscopic systems that the resolution of the elementary spectrum lines is impossible within the time available for observations. Hence models with continuous spectrum are better suited to described the macroscopic limit.

The continuous spectrum version of our harmonic model for the measuring apparatus is defined by the spectral density

$$\rho(\omega) = \frac{i}{2\pi} D^{-+}(\omega)$$  \hspace{1cm} (A20)

is vanishing for $\omega \leq 0$ and is non-negative for $\omega \geq 0$, $D^I(\omega) = \text{sign}(\omega)iD^i(\omega)$, when the initial state is the ground state. The propagator can then be brought into the form

$$\tilde{D}(\omega) = 2 \int_0^\infty d\Omega \rho(\Omega) \tilde{D}_\Omega(\omega)$$  \hspace{1cm} (A21)

assuming that the normal modes are rescaled to have the same mass, $m$.

As of a phenomenological motivated parameterization, the Drude-like $O(\Omega^{-1})$ spectral function produces divergent Green functions for $t = 0$ hence it is better to use

$$\rho(\Omega) = \Theta(\Omega) \frac{\chi^2 \Omega \Lambda}{(\Lambda^2 + \Omega^2)^2}.$$  \hspace{1cm} (A22)
giving

\[ D^r(\omega) = \frac{\lambda^2 \pi}{2m(\omega + i\Lambda)^2}, \]
\[ D^i(\omega) = \frac{\lambda^2 \pi |\omega| \Lambda}{m(\omega^2 + \Lambda^2)^2}, \]
\[ (D^{-1})^r(\omega) = \frac{2m}{\lambda^2 \pi (\omega + i\Lambda)^2}, \]
\[ (D^{-1})^i(\omega) = \frac{4m\Lambda |\omega|}{\lambda^2 \pi}, \] (A23)

in particular,

\[ D^r(t) = -\Theta(t)\frac{t\lambda^2 \pi e^{-\Lambda t}}{4m\Lambda}, \]
\[ D^i(t) = -\frac{\lambda^2}{\pi m \Lambda} \int_0^\infty dz \cos z \Lambda t \left( \frac{z^2 + 1}{z^2 + 1} \right)^2, \] (A24)

and \( D^i(0) = -\lambda^2 / 2\pi m \Lambda. \)

Appendix B: Gaussian measuring apparatus

We assume that the measuring apparatus of section IV A follows a harmonic dynamics with normal coordinates \( y_n, \) \( n = 1, \ldots, N_a, \) obeying the action

\[ S_a[\tilde{y}] = \frac{1}{2} \sum_{n=1}^{N_a} \int dt dt' \tilde{y}_n(t) \tilde{G}_{n}^{-1}(t, t') \tilde{y}_n(t'), \] (B1)

with time translation invariance, \( \tilde{G}(t, t') = \tilde{G}(t - t'). \)

1. Continuous measurement

The pointer action (35) now contains the trajectory

\[ \tilde{y}_{cl,\sigma}(t) = \frac{1}{N_a} \sum_n \kappa_n g_n \int dt' G_{D,n}^r(t, t') \tilde{x}_{cl}(t') \] (B2)

and the propagator

\[ \tilde{G}_{P}(t, t') = \frac{1}{N_a} \sum_n \kappa_n^2 \tilde{G}_{D,n}(t, t'), \] (B3)

where

\[ \tilde{G}_{D,n}(t, t') = \left[ \tilde{G}_{n}^{-1} + \frac{g_n}{N_s} \tilde{D} \tilde{\sigma} \right]^{-1}(t, t') \] (B4)
is the $n$-th normal mode propagator given in a form reminiscent of a Schwinger-Dyson resumed expression, the second term in the denominators being the self energy. It is a characteristic feature of the harmonic dynamics that the self energy remains a simple one-loop expression, the loop summation running over the index $n$. The inverse propagator in the denominator is usually an unbounded operator but the expansion in the self energy is possible and leads to a geometrical series showing that the pointer excitations spend part of their life-time in the measured system. This contribution is $\mathcal{O}(N^{-1})$, the impact of the pointer-microscopic system interaction on the apparatus propagator is suppressed in the thermodynamical limit.

The inverse pointer propagator is given by $(G^{-1}_P)^{\tilde{r}} = (G^{\tilde{r}}_P)^{-1}$ and

$$(G^{-1}_P)^i(t, t') = -\int dt_1 dt_2 (G^{-1}_P)^i(t, t_1) G^i(t_1, t_2) (G^{-1}_P)^a(t_2, t')$$

(B5)
in terms of $\tilde{G}_P$. The probability distribution of the pointer trajectories is given by

$$p[\tilde{y}] = e^{-\frac{N_a}{2} \int dt dt' [\tilde{y}(t) - \tilde{y}_{cl}(t)][(G^{-1}_P)^i(t, t')][\tilde{y}(t') - \tilde{y}_{cl}(t')]}$$

(B6)

up to a normalization factor and the decoherence is displayed by

$$\text{Im} S_P[\tilde{y}] = \frac{N_a}{2} \int dt dt' t y_d(t) (G^{-1}_P)^i(t, t') t y_d(t'),$$

(B7)

cf. (11) and (13). The first moments, the expectation values of the coordinates, satisfy the classical equation of motion in a harmonic dynamics therefore a harmonic apparatus shows no genuine quantum effects and serves only as a linear amplifier.

2. Discrete sequence of measurements

To decouple the mass-shell singularities of the apparatus we consider measurements, performed at a discrete time series, $t_\ell \ell = 1, \ldots, N_m$, and described by time-dependent coupling constants, $g_n(t) = g_n \sum_\ell \delta(t - t_\ell)$. Note that despite the discrete set of the measurement times the pointer is supposed to be followed continuously in time. The influence of the microscopic systems on the apparatus is encoded by the distribution of the average coordinate at the measurement times,

$$\chi(\tilde{x}) = \delta(x_{N_m, d}) e^{-i \frac{N_a}{2} (\tilde{x} - \tilde{x}_{cl}) \tilde{D}^{-1}(\tilde{x} - \tilde{x}_{cl})}.$$  

(B8)
It is important to bear in mind that the index $\ell$ is suppressed in this and the following expressions and the inverse matrix in the exponent is defined by $\sum_{\sigma'' \ell''} D_{(\sigma, \ell), (\sigma'', \ell'')}^{-1} = \delta_{\sigma, \sigma'} \delta_{\ell, \ell'}$. i.e. $\tilde{D}_{\ell, \ell'}^{-1} \neq \tilde{D}^{-1}(t_{\ell}, t_{\ell'})$. The unitarity of the time evolution imposes $\tilde{x}_{d, N_m} = 0$ at the last measurement.

The generator functional for the connected pointer Green functions,

$$e^{\frac{1}{\hbar} W[\tilde{J}]} = \int D[\tilde{y}] e^{\frac{1}{\hbar} \sum_n \int dt dt' \tilde{y}_n(t) \tilde{G}_n^{-1}(t, t') \tilde{y}_n(t') + \frac{i}{\hbar} \int dt \tilde{J}(t) \tilde{y}(t) + \frac{i}{\hbar} \sum_n \int dt \tilde{x}(t) \tilde{y}_n(t)}, \quad (B9)$$

leads after performing some Gaussian integrals to the pointer quantum action,

$$S_P[\tilde{y}] = \frac{1}{2} \int dt dt' [\tilde{y}(t) - \tilde{y}_{cl}(t)] \tilde{G}_{P, discr}^{-1}(t, t') [\tilde{y}(t') - \tilde{y}_{cl}(t')], \quad (B10)$$

where

$$\tilde{y}_{cl}(t) = \tilde{G}_{r}(t) \tilde{\sigma} \frac{1}{1 - \frac{N_a}{N_s} \tilde{D} \tilde{G}_{gg} \tilde{\sigma}} \tilde{x}_{cl}. \quad (B11)$$

stands for the classical pointer trajectory $\tilde{y}_{c, \pm} = \tilde{y}_{cl}$ with

$$\tilde{y}_{cl}(t) = G_{r}(t) \frac{1}{1 - \frac{N_a}{N_s} \tilde{D} \tilde{G}_{gg} \tilde{\sigma}} \tilde{x}_{cl}. \quad (B12)$$

The inverse matrix, the second factor on the right hand, acts on the vector $\tilde{x}_{cl}$ and represents the “stroboscope physics” and the first factor, $G_{r}(t)$, embeds the result into the continuous time pointer dynamics. The pointer propagator,

$$\tilde{G}_{P, discr}(t, t') = \tilde{G}_{r}(t) + \frac{1}{N_a} \sum_n \tilde{G}_n^{-1} \tilde{G}_{g}(t), \quad (B13)$$

is given in terms of the free propagator,

$$\tilde{G}_{n, 2}(t, t') = \frac{1}{N_a} \sum_n \kappa^2_n \tilde{G}_n(t, t'), \quad (B14)$$

and the averages Green functions

$$\tilde{G}_{r}(t) = \frac{1}{N_a} \sum_n \kappa_n g_a \tilde{G}_n(t, t\ell),$$

$$\tilde{G}_{g, 2}(t, t') = \frac{1}{N_a} \sum_n g^2_a \tilde{G}_n(t, t\ell). \quad (B15)$$

The inverse on the right hand sides of (B11) and (B13) is taken for $2N_m - 1 \times 2N_m - 1$ matrices (indices are suppressed).
