(Dated: July 30, 2021)

We analyze a general method for the dissipative preparation and stabilization of volume-law entangled states of fermionic and qubit lattice systems in 1D (and higher dimensions for fermions). Our approach requires minimal resources: nearest-neighbour Hamiltonian interactions that obey a suitable chiral symmetry, and the realization of just a single, spatially-localized dissipative pairing interaction. In the case of a qubit array, the dissipative model we study is not integrable and maps to an interacting fermionic problem. Nonetheless, we analytically show the existence of a unique pure entangled steady state (a so-called rainbow state). Our ideas are compatible with a number of experimental platforms, including superconducting circuits and trapped ions.

Introduction—Quantum reservoir engineering is a powerful tool in quantum information processing. In its simplest form, it involves tailoring dissipative processes to stabilize non-classical quantum states [1, 2]; when generalized to stabilizing a subspace, it can also be used as a route to quantum error correction [3, 4]. Many experiments have implemented dissipation engineering in few-body quantum systems comprised of 1-2 qubits or bosonic modes (see e.g. [5–9]). Theoretical work has also considered extensions to truly many-body systems [10–12], though most proposals are experimentally daunting, as they require engineered dissipation on every site of an extended lattice system. More recent work demonstrated that for non-interacting bosons hopping on a 1D lattice, a single, local engineered squeezing dissipator can be sufficient to stabilize the entire extended system in a state with long-range entanglement [13, 14]; a subtle particle-hole symmetry was shown to be the key ingredient, allowing a generalization to higher dimensions [15]. These protocols are, however, limited to stabilizing Gaussian entangled states, whose use in quantum information is highly constrained [16].

Given this prior work, a natural question is whether a single localized dissipative process can prepare and stabilize more complex many-body entangled states. In particular, can this approach work in systems which have (unlike free bosons) a finite-dimensional local Hilbert space, e.g. lattices of fermions, hard-core bosons or qubits? In this Letter, we show the answer is, surprisingly, yes. We describe an extremely simple protocol exploiting symmetry and the dissipative analog of Cooper pairing to stabilize highly entangled “rainbow” states in 1D lattices of fermions and qubits (Fig. 1). Such rainbow states feature long-range, volume-law entanglement, and are known to be the ground states of highly structured, spatially non-uniform Hamiltonians [17, 18]. Our dissipative approach does not require the realization of such exotic Hamiltonians. Instead, it only uses nearest-neighbour Hamiltonian interactions (which may or may not be uniform) and a single localized dissipator placed in the middle of the lattice; the entangled rainbow state is the unique steady state irrespective of the size of the lattice. As we discuss, the resources required to implement our protocol already exist in a number of different quantum information processing architectures.

Our results also have interest in the context of more general studies of many-body driven dissipative system. The spin version of our problem cannot be mapped exactly to free fermions and, hence, is not integrable. Nonetheless, we are able to exactly describe the steady state. We discuss how qualitative features of the dynamics can be connected to a model of dissipative fermionic pairing with phase fluctuations. Note that our work is distinct from a recent proposal for using dissipation to generate entangled states in 1D qubit chains [19, 20]. These protocols also generated rainbow-like entangled states, but only if the system was initially prepared in a non-trivial, highly nonlocal entangled steady state. In contrast, our approach has in general a unique entangled steady state, and hence is completely independent of the initial state:
one can start from a trivial product state and still obtain the volume-law entangled rainbow state.

**Fermions—** We begin by considering non-interacting fermions, using this system to build up the key ideas that will enable our qubit protocol. We consider spinless fermions hopping on a 2N-site lattice with a tight binding Hamiltonian \( H_F = \sum_{i,j} H_{ij} \hat{c}_i^\dagger \hat{c}_j \), where \( H_{ij} \) is a Hermitian matrix, and \( \hat{c}_i \) annihilates a fermion at lattice site \( i \). \( H_F \) is readily diagonalized, with \( d_\alpha^\dagger = \sum_j \psi_\alpha[j] \hat{c}_j^\dagger \) creating a particle in an energy eigenstate with energy \( \epsilon_\alpha \) and real-space wavefunction \( \psi_\alpha[j] \). Note that we do not assume translational invariance.

Our goal is to now to introduce localized dissipation which stabilizes the entire lattice in a finite-density state with long-range entanglement. For non-interacting bosons, this can be accomplished by coupling a single site to a squeezed Markovian reservoir \([13–15]\). Such a reservoir attempts to enforce local pairing correlations on the coupled site. For spinless fermions, the Pauli exclusion principle excludes an identical approach. However, one can try the next simplest configuration: introduce a localized Markovian dissipative reservoir that attempts to stabilize fermionic pairing correlations on two adjacent sites \( j = \overline{0,1} \) (i.e. prepare them in the state \( (u - ve^{i\phi}d_0^\dagger d_1^\dagger)|00\rangle \)). This corresponds to simply cooling a pair of localized fermionic Bogoliubov modes. The system’s dynamics including this localized dissipative pairing is then described by a Lindblad master equation having the general form:

\[
\dot{\rho} = -i[H, \rho] + \Gamma_A D(\hat{\beta}_A)\rho + \Gamma_B D(\hat{\beta}_B)\rho \equiv \mathcal{L}[\rho],
\]

Here \( D(\hat{L})\rho = \hat{L}\rho\hat{L}^\dagger - \frac{1}{2}(\hat{L}^\dagger\hat{L}\rho + \rho\hat{L}^\dagger\hat{L}) \). For our fermion problem, we have \( H = H_F \) and

\[
\hat{\beta}_A = u\hat{c}_- - ve^{i\phi}\hat{d}_1^\dagger, \quad \hat{\beta}_B = u\hat{c}_+ + ve^{i\phi}\hat{d}_0^\dagger,
\]

where \( u = \sqrt{1 - v^2} \), with the pairing parameter \( v \) real and satisfying \( 0 \leq v \leq 1 \), and \( \Gamma_A, \Gamma_B \) parametrize the strength of the dissipation, and correspond to cooling rates of the two localized Bogoliubov modes \( \hat{\beta}_A, \hat{\beta}_B \), respectively. The dissipation in Eq. (1) induces an effective non-Hermitian Hamiltonian which includes pairing terms of the form \( (iuve^{i\phi}\hat{c}_-\hat{d}_1^\dagger - H.c.) \). Our system thus has the form of an unusual dissipative impurity problem, where the “impurity” corresponds to the local dissipative pairing terms. At a heuristic level, the dissipation injects Cooper pairs on these sites, which can then propagate outward in the lattice. Generically, Eq. (1) will lead to an impure steady state, with fluxes of Cooper pairs both into and out of the lattice. We note that quadratic fermionic models with dissipative pairing have been studied previously in the context of cold atoms \([12, 21–23]\), but unlike our work, these assumed pairing on every lattice site.

We next show that by imposing an additional (but very general) symmetry constraint on \( H_F \), we can ensure the existence of a pure steady state (independent of the values of \( \Gamma_A/B \)). The relevant symmetry is a chiral particle-hole symmetry \( \hat{C} \) such that \( \hat{C}\hat{d}_\alpha\hat{C}^{-1} = d^{\dagger}_{-\alpha} \), where \( \epsilon_{-\alpha} = -\epsilon_{\alpha} \). Writing \( \hat{C}\hat{c}_{\alpha}\hat{C}^{-1} = 1, \) this is equivalent to requiring \( [H^*, S^T] = [-H, S] \). The existence of \( \hat{C} \) implies that \( H_F \) has a large degenerate subspace of zero modes. For our dissipative dynamics to stabilize one of these zero modes, one only needs to impose an additional mild constraint on \( \hat{C} \): its action on the dissipation-coupled sites \( \overline{0,1} \) involves a real-space exchange operation. More specifically, we require that (up to an overall phase):

\[
\begin{pmatrix}
S_{\overline{00}} & S_{\overline{01}} \\
S_{\overline{10}} & S_{\overline{11}}
\end{pmatrix} = \begin{pmatrix}
0 & 1 \\
-1 & 0
\end{pmatrix}.
\]

To understand this requirement, note that because \( \epsilon_{-\alpha} = -\epsilon_{\alpha} \), the Hamiltonian remains diagonal under a Bogoliubov transformation, \( \gamma_\alpha = ud_\alpha + ve^{i\phi}d_0^\dagger \). The jump operators take on a purely cooling form in this basis (i.e. \( \hat{\beta}_A/B = \sum_\alpha q_{\alpha}^A/B\gamma_\alpha \)) if and only if Eq. (3) holds. We thus have a steady state of the dissipative dynamics in Eq. (1) that is the joint vacuum of all the \( \gamma_\alpha \). This is a pure Gaussian state |\( \psi_\alpha \rangle \) completely defined by its covariance matrix. We find that it only depends on the symmetry matrix \( S \) and the paring parameters \( u, v \) (see \([24]\) for further details):

\[
\langle \hat{c}_i^\dagger\hat{c}_j \rangle = v^2\delta_{ij}, \quad \langle \hat{c}_i\hat{c}_j \rangle = uvS_{ij},
\]

Crucially, as long as \( \hat{H}_F \) does not possess any single particle eigenstate whose wavefunctions vanish on both sites \( \overline{0,1} \), this is the unique steady state. Further, if the spectrum of \( \hat{H}_F \) is non-degenerate, we only need one jump operator \( \hat{\beta}_A \) or \( \hat{\beta}_B \), as either will cool all eigenmodes \([24]\). Note that the spatial structure of the steady state only depends on the particle-hole symmetry \( S \), and not on any other details of \( \hat{H}_F \).

We thus have an extremely general way of using localized pairing dissipation along with hopping dynamics to stabilize pure states with long range pairing correlations (as described by Eq. (4)). The only ingredient needed is that the Hamiltonian possess a particle-hole symmetry which acts as an exchange operation (c.f. Eq. (3)) on the two dissipation-coupled sites. This particle-hole symmetry ensures that \( \hat{H}_F \) has a zero-energy state in which the dissipation-coupled sites \( \overline{0,1} \) are in the pure state \( (u - ve^{i\phi}\hat{d}_0^\dagger)|00\rangle \), i.e. precisely the paired state annihilated by the dissipators \( \hat{\beta}_A, \hat{\beta}_B \).

There are many systems that possess the required symmetry for our scheme. A particularly simple example (that, surprisingly, will generalize to the case of spins) is a 1D lattice with 2N sites described by a Hamiltonian with nearest neighbour hopping that possesses an inversion symmetry about its midpoint. If the dissipation is attached to the two central sites of the lat-
tice, then one has the required particle-hole symmetry (with $S$ encoding inversion); this is true even if the hoppings are non-uniform, as long as they respect the mirror symmetry. One finds a unique steady state $|\psi\rangle = \prod_{i=1}^{N} \left( u - v(-1)^i \hat{c}_i^\dagger \sigma_i^- \right) |0\rangle$, whose non-local pair correlations correspond directly to the non-local nature of $S$. This state exhibits volume-law entanglement (see Fig. 1), and is known as a rainbow state \cite{17, 18}. As discussed in \cite{24}, many more examples are possible, including the 1D Su-Schrieffer-Heeger model \cite{25, 26} and the 2D Hofstadter model \cite{27}.

**Qubits**— Using the above fermionic setup as inspiration, we now ask whether a similar dissipative preparation scheme is possible for an array of coupled spins or qubits. We focus on the case of a simple 1D array having $2N$ sites and nearest neighbour tunneling, and the qubit version of our paired dissipation. The master equation is then given by Eq. (1) with $\mathcal{H} = \mathcal{H}_S$ and

$$\dot{\mathcal{H}}_S = -\sum_{i=-N}^{N} J_i \sigma_i^+ \sigma_{i+1}^- + \text{H.c.}, \quad \dot{\hat{\beta}}_A = u \sigma^+_{\bar{\mathcal{g}}} - v \sigma^-_{\bar{\mathcal{f}}}, \quad \dot{\hat{\beta}}_B = u \sigma^+_{\mathcal{T}} + v \sigma^-_{\bar{\mathcal{T}}}.$$

(5)

Here $\sigma_i^+ (\sigma_i^-)$ is the Pauli raising (lowering) operator on site $i$, and we use the convention that there is no 0th lattice site, giving a 2N-site lattice. We will constrain the hoppings to obey $J_i = J_{i-1}$, i.e. $\mathcal{H}$ has mirror symmetry about the middle of the lattice (i.e. the symmetry that in the free fermion case ensured the success of our scheme). Though more general placements are possible, for concreteness, we will take the dissipation-coupled sites $\bar{\mathcal{g}}$ and $\mathcal{T}$ to be the middle two sites of the lattice, i.e. $\bar{\mathcal{g}} = -1, \mathcal{T} = 1$. While the dissipators here may seem exotic, we show below how they can be realized in a number of platforms using existing experimental tools.

The above spin model can be readily mapped to fermions using the Jordan-Wigner (JW) transformation \cite{28}. However, it necessarily maps to an interacting fermionic model (in contrast to the quadratic system considered in Eq. (2)). The most convenient mapping to JW fermions $\hat{c}_i$ is given by the transformation

$$\hat{c}_i = \begin{cases} \left( \prod_{j=1}^{i} \hat{\sigma}_j^+ \right) \hat{\sigma}_i^- & 1 \leq i \leq N, \\ \left( \prod_{j=-N}^{i} \hat{\sigma}_j^+ \right) \left( \prod_{j=-N}^{i-1} \hat{\sigma}_j^- \right) \hat{\sigma}_i^- & -N \leq i \leq -1. \end{cases}$$

(7)

This corresponds to using site 1 as the reference for the string operators. Letting $\hat{\mathcal{N}}_{\text{tot}}$ be the total fermion number operator, our model can be expressed in terms of these fermionic degrees of freedom as:

$$\dot{\mathcal{H}}_S = \sum_{i \neq \bar{\mathcal{g}}, \mathcal{T}} J_i \hat{c}_i^\dagger \hat{c}_{i+1} + J_{-1} (-1)^{\hat{\mathcal{N}}_{\text{tot}}} \hat{c}_1^\dagger \hat{c}_{-1} + \text{H.c.},$$

(8)

$$\hat{\beta}_A = u \hat{c}_{-1} (-1)^{\hat{\mathcal{N}}_{\text{tot}}} - v \hat{c}_1^\dagger, \quad \hat{\beta}_B = u \hat{c}_1 + v \hat{c}_{-1} (-1)^{\hat{\mathcal{N}}_{\text{tot}}}.$$  

(9)

We see that the presence of the phase operator $(-1)^{\hat{\mathcal{N}}_{\text{tot}}}$ in both $\mathcal{H}_S$ and the dissipative terms ruins a mapping to free fermions. On a heuristic level, we can interpret this as a modification of Eq. (2) that now describes fluctuations in the phases of the Cooper pairs injected into the system by the reservoir. For the simple fermionic system described by Eq. (2), pairs are always injected with a fixed phase $\phi$; in contrast, in Eq. (8), they are injected with a phase $\pm 1$ that depends on the system’s parity. We stress that even with other gauge conventions for the JW transformation, it is not possible to eliminate these phase fluctuations (i.e. string operators) from the dissipators.

To better understand our system, we can re-write the nonlinear dissipation operators in terms of a fixed basis of local Bogoliubov operators $\hat{\beta}_A, \hat{\beta}_B$ (corresponding to Eq. (2) with $\phi = 0$). Defining $\hat{P}_\text{ev} = (1 + (-1)^{\hat{\mathcal{N}}_{\text{tot}}})/2$ as the projection operator onto even number-parity states, we have:

$$\hat{\beta}_A = \hat{\beta}_A \hat{P}_\text{ev} + \left[ (u^2 - v^2) \hat{\beta}_A + 2uv \hat{\beta}_B \right] (1 - \hat{P}_\text{ev}), \quad (10a)$$

$$\hat{\beta}_B = \hat{\beta}_B \hat{P}_\text{ev} + \left[ (u^2 - v^2) \hat{\beta}_B - 2uv \hat{\beta}_A \right] (1 - \hat{P}_\text{ev}). \quad (10b)$$

This provides a simple way to understand the phase fluctuation physics: it is as though the dissipation has a parity-dependent temperature. For even-parity states, the dissipation can only remove Bogoliubov excitations $\hat{\beta}_A, \hat{\beta}_B$, i.e. it acts like an effective zero temperature bath. In contrast, for odd-parity states and $v \neq 0$, we see that there are amplitudes for the dissipation to either create or destroy excitations (like an effective bath at a non-zero temperature).

Equations (10) also lead to an important conclusion: despite the additional nonlinearity and phase fluctuations in our spin model, the steady state $|\psi_{ss}\rangle$ (c.f. Eq. (4)) of our simple free fermion model in Eq. (2) is also a steady state of the spin model. This steady state (which here is a rainbow state, given the mirror symmetry of $\mathcal{H}$) has a definite even number parity, and hence the Liouvilian acting on this state is identical to the free fermion Liouvilian. At a heuristic level, this state has a definite number parity, and hence phase-fluctuations are irrelevant. Returning to our original qubit degrees of freedom, the pure steady state takes the form:

$$|\psi_{ss}\rangle = \prod_{i=1}^{N} (u + (-1)^i v \sigma^+_i \sigma^-_i)|0\rangle.$$  

(11)

Equations (10) also lets us show that as long as $v^2 \neq 1/2$, this steady state is unique \cite{24}. We thus have a central result of this Letter: any initial state of our qubit array (irrespective of its purity or entanglement) will relax into this volume-law entangled pure state. Further, $|\psi_{ss}\rangle$ remains the unique pure steady state even if one realizes just a single pairing dissipator (e.g. if $\Gamma_B = 0$). This result holds independently of the magnitude of the hopping
parameters $J_j/\Gamma_A$, and even in the presence of additional Hamiltonian terms that preserve the mirror symmetry of $\mathcal{H}_S$ [24].

Dynamics and multi-stability— While the qubit and free-fermion dissipative arrays share the same pure steady state, the models have strikingly different dynamics. This is a direct consequence of the form of the dissipators given in Eqs. (10). The phase fluctuations in the fermionic representation of the qubit model lead to slower overall relaxation, due to the effective non-zero temperature and excitation-creation associated with odd-parity states. As can be seen from Eqs. (10), this odd parity heating increases as $v$ is increased from 0, with an amplitude $\propto v \sqrt{T - v^2}$. For free fermions, there is no heating: the dissipative dynamics always corresponds to removing excitations, irrespective of the system state.

Shown in Fig. 2a is the numerically-calculated dissipative spectrum of the Liouvillians for the free fermion and qubit versions of our model as a function of the pairing parameter $v^2$. For free fermions, the relaxation rates are independent of $v^2$; one can show that for large $N$, the slowest relaxation rate (dissipative gap) scales as $1/N^3$ [24]. In stark contrast, the relaxation rates in the qubit model depend on $v^2$, with the emergence of an extremely small dissipative gap as $v^2 \rightarrow 1/2$. Fig. 2b demonstrates that this emergent slow timescale manifests itself directly in observable quantities. We see that for both the qubit and free-fermion models, the average particle numbers relax on a similar timescale $\sim 1/\Gamma_A$. The average parity relaxes on the same timescale for fermions, but for the qubit model, exhibits exponentially slower relaxation. This is a direct manifestation of the effective phase fluctuations encoded in Eq. (8).

The case $u^2 = v^2 = 1/2$ is also of special interest.

Eqs. (10) indicates that in this case, the dissipation can only remove excitations from even parity states, and can only add excitations to odd parity states. This immediately leads to multi-stability, as if the system starts in a state with $2m$ Bogoliubov excitations, it will forever be stuck in a manifold of states having either $2m$ or $2m - 1$ excitations. This immediately leads to at least $N + 1$ steady states (see [24] for more details). We stress that there is no multi-stability in the free-fermion model.

Experimental Implementation— The basic qubit master equation in Eqs. (5) and (6) could be realized in a variety of platforms. Linear arrays of tunnel-coupled qubits have been realized in many systems, including trapped ions [29–31] and superconducting qubits [32–34]. The required dissipation on sites $j = -1,1$ could be achieved by driving these qubits with two-mode squeezed light via transmission lines or waveguides [35]. In this case, $\Gamma_A/B$ would represent the waveguide coupling rates, and $v/u = \tanh r$, with $r$ the squeezing parameter. While such a scheme could be realized by driving superconducting qubits with two-mode squeezed microwave radiation generated by a Josephson parametric amplifier [36, 37], implementation routes that do not require non-classical microwaves or light are also possible. The required dissipator can be realized by coupling qubits $j = -1,1$ to a common dissipative bosonic mode (e.g. a lossy microwave cavity), and then either modulating the qubit frequencies, or modulating the qubit-resonator couplings (as was recently achieved [38]). By interfering e.g. a red sideband process on one qubit with a blue sideband process on the second qubit, the required dissipator can be achieved (with $u,v$ being determined by the modulation amplitudes). Interfering red and blue sideband processes has been used previously in both trapped ion [39] and super-
conducting qubit experiments for reservoir engineering of bosonic modes, but not to control qubit dissipation in the way we suggest. More details on this modulation approach, and on the resilience of our scheme to disorder and unwanted dissipation (i.e. qubit dephasing and relaxation) are presented in [24].

Conclusions – We have demonstrated that the combination of spatially-localized pairing dissipation with symmetry contrained Hamiltonian dynamics can be used generically to stabilize entangled states in systems with locally-constrained Hilbert spaces. These states can exhibit long range, volume-law entanglement. In the case of a qubit array, our setup corresponds to a dissipative spin chain that is equivalent to an interacting fermionic model, which can be interpreted in terms of dissipative Cooper pairing with phase fluctuations. Our ideas are compatible with a number of different experimental platforms, and could provide an important resource for a variety of quantum information processing protocols.

I. FERMIONS

In the main text, we show that when equipped with the appropriate chiral symmetry, the fermionic master equation (see Eq. (1) in the main text) has the rainbow state as its unique pure steady state. In this section, we provide a detailed proof for this result. Recall the Hamiltonian and jump operators:

\[
\hat{H}_F = \sum_{i,j=1}^{2N} H_{ij} \hat{c}_i^\dagger \hat{c}_j = \sum_{\alpha=-N}^{N} \epsilon_\alpha \hat{d}_\alpha^\dagger \hat{d}_\alpha,
\]

where there is no 0th \( \alpha \) index to be consistent with a lattice of size \( 2N \). Our strategy is to find a new set of Bogoliubov energy eigenmodes \( \hat{\gamma}_\alpha \), so that the dissipators cool these modes into vacuum in the steady state limit. In the following, we first show that the Hamiltonian is invariant under a set of Bogoliubov transformations if it has a built-in chiral symmetry, and then discuss conditions for the system to have the desired pure steady state. As we will discuss, the condition is equivalent to requiring that the restriction of chiral symmetry transformation to the dissipator sites is given by a \( \sigma_y \) Pauli matrix.

A. Bogoliubov transformation

We first assume the Hamiltonian has chiral symmetry \( \hat{C} \hat{d}_\alpha \hat{C}^{-1} = \hat{d}_{-\alpha} \), and we label the eigenenergies such that \( \epsilon_{-\alpha} = -\epsilon_\alpha \). We can now define Bogoliubov modes \( \hat{\gamma}_\alpha \), where the pairing amplitudes \( u^2 + v^2 = 1 \) are chosen to be compatible with the jump operators \( \hat{\beta}_A, \hat{\beta}_B \) as

\[
\hat{\gamma}_\alpha = u \hat{d}_\alpha + ve^{i\phi_\alpha} \hat{d}_{-\alpha}, \quad (S3a)
\]

\[
\hat{\gamma}_{-\alpha} = u \hat{d}_{-\alpha} - ve^{i\phi_\alpha} \hat{d}_\alpha, \quad (S3b)
\]

so that the inverse transformation is given by

\[
\hat{d}_\alpha = u \hat{\gamma}_\alpha - ve^{i\phi_\alpha} \hat{\gamma}_{-\alpha}, \quad (S4a)
\]

\[
\hat{d}_{-\alpha} = u \hat{\gamma}_{-\alpha} + ve^{i\phi_\alpha} \hat{\gamma}_\alpha, \quad (S4b)
\]

Substituting these relations into the diagonalized Hamiltonian, a few lines of algebra let us show that

\[
\hat{H}_F = \sum_{\alpha=1}^{N} \left( \epsilon_\alpha \hat{d}_\alpha^\dagger \hat{d}_\alpha + \epsilon_{-\alpha} \hat{d}_{-\alpha}^\dagger \hat{d}_{-\alpha} \right)
\]

\[
= \sum_{\alpha=1}^{N} \left[ (\epsilon_\alpha u^2 - \epsilon_{-\alpha} v^2) \hat{\gamma}_\alpha^\dagger \hat{\gamma}_\alpha - (\epsilon_\alpha v^2 - \epsilon_{-\alpha} u^2) \hat{\gamma}_{-\alpha}^\dagger \hat{\gamma}_{-\alpha} + uv(\epsilon_\alpha + \epsilon_{-\alpha}) \left( e^{i\phi_\alpha} \hat{\gamma}_\alpha^\dagger \hat{\gamma}_{-\alpha} + e^{-i\phi_\alpha} \hat{\gamma}_{-\alpha}^\dagger \hat{\gamma}_\alpha \right) \right]. \quad (S6)
\]

Note that above relation holds for generic Hamiltonians. When \( \hat{H}_F \) has chiral symmetry, i.e. when \( \epsilon_{-\alpha} = -\epsilon_\alpha \), we can further simplify above equation to show that the Hamiltonian is invariant under the Bogoliubov transformation.
\[ \hat{H}_F = \sum_{\alpha=1}^{N} \epsilon_\alpha (\hat{d}_\alpha \hat{d}_\alpha - \hat{d}_\alpha^{\dagger} \hat{d}_{-\alpha}^{\dagger}) = \sum_{\alpha=1}^{N} \epsilon_\alpha \left( \hat{\gamma}_\alpha \hat{\gamma}_\alpha - \hat{\gamma}_\alpha^{\dagger} \hat{\gamma}_{-\alpha}^{\dagger} \right). \] (S7)

We now consider how the jump operators transform under the Bogoliubov transformation. For concreteness we focus on the jump operator \( \hat{\beta}_A \), but our result holds for \( \hat{\beta}_B \) as well. Without loss of generality, we fix the jump operators phase to \( \phi = 0 \) hereafter. Noting that the eigenmodes are related to the real space mode operators via eigenmode wavefunctions \( \psi_\alpha[j] \) as \( \hat{d}_\alpha = \sum_j \psi_\alpha[j] \hat{c}_j^\dagger \), and making use of the inverse Bogoliubov transformations in Eq. (S4), we can rewrite the jump operator in terms of the Bogoliubov modes as

\[ \hat{\beta}_A = \sum_{\alpha=1}^{N} \left[ \left( u^2 \psi_\alpha[0] + v^2 e^{-i\phi_\alpha} \psi_\alpha[1]^* \right) \hat{\gamma}_\alpha + \left( u^2 \psi_\alpha[0] - v^2 e^{-i\phi_\alpha} \psi_\alpha[1]^* \right) \hat{\gamma}_{-\alpha} \right] - uv \left( e^{i\phi_\alpha} \psi_{-\alpha}[0] + \psi_\alpha[1]^* \right) \hat{\gamma}_\alpha^\dagger + uv \left( \psi_{-\alpha}[1]^* - e^{i\phi_\alpha} \psi_\alpha[0] \right) \hat{\gamma}_{-\alpha}^{\dagger}. \] (S8)

When the jump operator \( \hat{\beta}_A \) acts as purely cooling operator on modes \( \hat{\gamma}_\alpha \), the system will have the Bogoliubov vacuum as its steady state, which in turn requires the coefficients for the creation operators \( \hat{\gamma}_\alpha^{\dagger}, \hat{\gamma}_{-\alpha}^{\dagger} \) to vanish in the above equation. Assuming nontrivial pairing in the Bogoliubov modes, i.e. \( uv \neq 0 \), we obtain following constraints on the eigenmode wavefunctions

\[ e^{i\phi_\alpha} \psi_{-\alpha}[0] + \psi_\alpha[1]^* = \psi_{-\alpha}[1]^* - e^{i\phi_\alpha} \psi_\alpha[0] = 0, \quad \forall \alpha > 0. \] (S9)

When the condition in Eq. (S9) is valid, the jump operator in Eq. (S8) simplifies into a linear combination of lowering Bogoliubov operators as

\[ \hat{\beta}_A = \sum_{\alpha=1}^{N} \psi_\alpha[0] \hat{\gamma}_\alpha + \psi_{-\alpha}[1]^* \hat{\gamma}_{-\alpha}. \] (S10)

Thus, any system exhibiting a chiral symmetry satisfying the constraints in Eq. (S9) will relax into the vacuum of Bogoliubov modes \( \hat{\gamma}_\alpha \).

It is important to note that for the system to have a unique, pure steady state as specified above, we need that all of the eigenmodes have a nonzero overlap with all the dissipation sites. When the energy spectrum is non-degenerate, the constraints in Eq. (S9) guarantee that \( |\psi_\alpha[0]| = |\psi_{-\alpha}[1]| \), and so this is equivalent to stating that all of the eigenmodes have a nonzero overlap with \textit{either} of the dissipation sites. If the spectrum is degenerate, then we can always construct a new eigenmode out of two degenerate ones that has zero overlap with one dissipation site but not the other. In this case, to guarantee uniqueness, we also need to use the orthogonal dissipator \( \hat{\beta}_B = u \hat{c}_1 + v \hat{c}_1^\dagger \) which stabilizes the exact same steady state, and guarantees that an eigenmode that overlaps with only one of the dissipation sites is also cooled. In either case, we can never have uniqueness if there exists an eigenmode in the spectrum that does not overlap with both dissipation sites.

**B. Constraint on chiral symmetry**

Here we show an intuitive way to understand the constraint given by Eq. (S9): it amounts to requiring that the chiral symmetry \( \hat{C} \) acts in a very restricted way on the dissipator sites 0, 1. To see this, we first rewrite the constraint in a more familiar form

\[ \begin{pmatrix} \psi_{-\alpha}[0] \\ \psi_{-\alpha}[1]^* \end{pmatrix} = e^{-i\phi_\alpha} \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix} \begin{pmatrix} \psi_\alpha[0] \\ \psi_\alpha[1]^* \end{pmatrix}, \quad \forall \alpha > 0. \] (S11)

To connect this equation to chiral symmetry, we first note that given a single-particle spectrum that has chiral symmetry (i.e., \( \epsilon_{-\alpha} = -\epsilon_\alpha \)), there are infinite ways to construct a generalized chiral symmetry operator \( \hat{C} \). More specifically, we can explicitly construct \( \hat{C} \) for a set of generic phases \( e^{i\theta_\alpha} \), by requiring that the following relation holds

\[ \hat{C} \hat{d}_\alpha \hat{C}^{-1} = e^{i\theta_\alpha} \hat{d}_\alpha^{\dagger}, \quad \hat{C} \hat{d}_{-\alpha} \hat{C}^{-1} = e^{i\theta_{-\alpha}} \hat{d}_{-\alpha}^{\dagger}, \quad \forall \alpha > 0. \] (S12)
Formally, the freedom in choosing the phases $e^{i\theta_\alpha}$ in the chiral symmetry operator can be attributed to the $U(1)$ gauge symmetry associated to each eigenmode; the total system exhibits $U(1)^N$ symmetry. We can thus rewrite $\hat{C}$ as a transformation on the real space modes $\hat{C}_i \hat{C}^{-1} = \sum_j S_{ij} \hat{C}_j$, where $S$ is a unitary matrix to preserve the canonical anticommutation relations. Substituting $\hat{d}_\alpha^\dagger = \sum_j \psi_\alpha[j] \hat{c}_j\dagger$ into the equation, we can explicitly compute matrix elements of $S$ as

$$S_{ij} = \sum_{\alpha=1}^N (e^{i\theta_\alpha} \psi_\alpha[i] \psi_{-\alpha}[j] + e^{i\theta_{-\alpha}} \psi_\alpha[j] \psi_{-\alpha}[i]).$$  \hspace{1cm} (S13)$$

Or equivalently, the $S$ matrix transforms the eigenmode wavefunctions under chiral symmetry as

$$\psi_{-\alpha}[i] = e^{-i\theta_{-\alpha}} \sum_j S_{ij} \psi_\alpha[j]^*.$$  \hspace{1cm} (S14)$$

Comparing the above equation to Eq. (S11), we can see that the latter is equivalent to imposing a constraint on the restriction of $S$ matrix onto dissipator sites, i.e. we require the following condition to hold

$$\begin{pmatrix} S_{00} & S_{01} \\ S_{10} & S_{11} \end{pmatrix} = e^{i\theta_{-\alpha} - i\phi_\alpha} \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}, \quad \forall \alpha > 0.$$  \hspace{1cm} (S15)$$

The equation above can only be satisfied if we pick the chiral symmetry phases such that $\theta_{-\alpha} - \phi_\alpha$ are identical for all $\alpha > 0$. The remaining constant phase can be gauged away by a global gauge transformation, so that when above condition is satisfied, we can construct a chiral symmetry of the system satisfying following condition

$$\begin{pmatrix} S_{00} & S_{01} \\ S_{10} & S_{11} \end{pmatrix} = \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix}.$$  \hspace{1cm} (S16)$$

This reproduces Eq. (3) in the main text.

When the condition in Eq. (S16) is valid, we can further restrict the form of the chiral symmetry matrix $S$. From Eq. (S13) we have

$$S_{ii} = \sum_{\alpha=1}^N (e^{i\theta_\alpha} + e^{i\theta_{-\alpha}}) \psi_\alpha[i] \psi_{-\alpha}[i],$$  \hspace{1cm} (S17)$$

so that for $S_{00} = S_{11} = 0$ to hold, and assuming all eigenmodes have nontrivial overlap with the dissipator sites $|\psi_\alpha[0]| = |\psi_{-\alpha}[1]| \neq 0$, we need to choose the chiral symmetry phases such that

$$e^{i\theta_{-\alpha}} = -e^{i\theta_\alpha}.$$  \hspace{1cm} (S18)$$

Thus, when above condition holds, the chiral symmetry matrix $S$ is antisymmetric, and Eq. (S13) simplifies as

$$S_{ij} = \sum_{\alpha=1}^N e^{i\phi_\alpha} (\psi_\alpha[i] \psi_{-\alpha}[j] - \psi_\alpha[j] \psi_{-\alpha}[i]).$$  \hspace{1cm} (S19)$$

C. Steady state structure

We now further investigate properties of the pure steady state, which is the vacuum state of the Bogoliubov modes $\hat{\gamma}_\alpha$. Since the state is Gaussian, we can fully characterize it via its covariance matrix. Fixing the gauge of the chiral symmetry such that Eq. (S16) holds, we can explicitly compute the correlators of the steady state as

$$\langle \hat{c}_i \hat{c}_j \rangle = v^2 \sum_{\alpha} (\psi_\alpha[i]^* \psi_\alpha[j]) = v^2 \delta_{ij},$$  \hspace{1cm} (S20)$$

$$\langle \hat{c}_i \hat{c}_j \rangle = uv \sum_{\alpha} e^{i\phi_\alpha} (\psi_\alpha[i] \psi_{-\alpha}[j] - \psi_\alpha[j] \psi_{-\alpha}[i]) = uv S_{ij}.$$  \hspace{1cm} (S21)$$
D. Fermion Examples

Let us consider the Hamiltonian \( \hat{H}_F = \sum_{j=-N}^{N-1} J_j \hat{c}^\dagger_j \hat{c}_{j+1} + h.c. \) with a reflection symmetry \( J_j = J_{-j-1} \) about the center. Sites are labeled from \(-N, \ldots, -1, 1, \ldots, N\), with no 0th lattice site, giving exactly 2N sites (note that the chiral pairing condition requires an even number of lattice sites). There is a chiral symmetry that reflects across this symmetry axis, with symmetry matrix \( S_{ij} = (-1)^i \text{sgn}(j) \delta_{i-j} \), where \( \text{sgn}(\cdot) \) denotes the sign function. Noting that the restrictions of \( S \) onto pairs of sites \((l, -l)\) are given by \( i(-1)^l \sigma^y \), we can construct dissipators that are compatible with the condition in Eq. (S16):

\[
\hat{\beta}^l_A = u \hat{c}_{-l} + (-1)^l v \hat{c}^\dagger_l, \quad \hat{\beta}^l_B = u \hat{c}_l - (-1)^l v \hat{c}^\dagger_{-l},
\]

(S22)

As discussed, this dissipator will relax the lattice into the pure, unique steady state with correlators \( \langle \hat{c}^\dagger_i \hat{c}_j \rangle = v^2 \delta_{ij} \), and \( \langle \hat{c}_i \hat{c}_j \rangle = uv(-1)^i \text{sgn}(j) \delta_{i,-j} \). We can explicitly express the steady state as

\[
|\psi\rangle = \prod_{i=1}^{N} (u - (-1)^i v \hat{c}^\dagger_{-i} \hat{c}^\dagger_i)|0\rangle,
\]

(S23)

which is annihilated by the dissipators \( \hat{\beta}^l_{A,B} \), as expected. On any given \((l, -l)\) pair of lattice sites, this state is a coherent superposition of having \( u^2 \) probability of no fermions, and \( v^2 \) probability of two fermions. Thus, even if the dissipator is located across the central two lattice sites of the chain, it will induce long distance correlations between every pair of lattice sites, all the way down to the two ends of the chain.

This chiral symmetry is not limited to simple 1D chains. Any bipartite lattice with a single mirror symmetry that maps one sublattice into the other allows for this chiral symmetry. To see this, assume there is an arbitrary, number conserving Hamiltonian sitting on a 2N site lattice. Now, suppose there exist sublattices \( A, B \) each with \( N \) sites such that the Hamiltonian allows hopping from \( A \leftrightarrow B \), but not \( A \leftrightarrow A \) or \( B \leftrightarrow B \). This lattice already has a chiral symmetry; the mapping

\[
\hat{C} \hat{c}_i \hat{C}^{-1} = \begin{cases} \hat{c}^\dagger_i & i \in A, \\ \hat{c}_i & i \in B, \end{cases}
\]

(S24)

sends \( \hat{H} \rightarrow -\hat{H} \) since there is only hopping between sublattices. To guarantee the \( \sigma^y \), if we now assume that there is some inversion symmetry \( \hat{P} \hat{c}_i \hat{P}^{-1} = \hat{c}_{-i} \) where \( \hat{P}^2 = 1, \hat{P} : A \rightarrow B \), and \( \hat{P} \hat{H}_F \hat{P}^{-1} = \hat{H}_F \), then \( \hat{C} \hat{P} \) is another chiral symmetry of the Hamiltonian, and, once again denoting its matrix as \( S \),

\[
\begin{pmatrix} S_{i,i} & S_{i,-i} \\ S_{-i,i} & S_{-i,-i} \end{pmatrix} = \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix}
\]

(S25)

by construction. This symmetry is also preserved with onsite energies so long as sites mapped to each other under the mirror symmetry have opposite energies, i.e. terms of the for \( E_i (\hat{c}^\dagger_i \hat{c}_i - \hat{c}^\dagger_{-i} \hat{c}^-_{-i}) \).

Given this symmetry matrix, we can immediately then read off that the steady state solution will be a rainbow state which pairs lattice sites which get mapped to each other under the reflection symmetry \( \hat{P} \). As mentioned in the main text, many exotic lattice models exhibit these simple symmetry conditions, including the Hofstadter lattice with a quarter flux and the Su-Schrieffer-Heeger model, [S1].

![Figure S1](image-url)

FIG. S1. (a) A 2D nearest neighbor hopping Hamiltonian with two sites coupled to an engineered reservoir. With certain constraints on the hopping amplitudes, the steady state is a pure entangled state with a non-rainbow form. Pictured are 7 possible bonds; \( J_1, \ldots, J_4 \) are all free parameters, with the remaining 3 constrained by the symmetry conditions. (b) The correlators \( \langle \hat{c}^\dagger_i \hat{c}_j \rangle = v^2 \delta_{ij} \) as expected. (c) The anomalous correlators show Bell state entanglement between the two sites coupled to the dissipation, but sites 0, 1, are entangled with superpositions of sites 2, 3.
The chiral symmetry can also be used to create more complex steady states that are not rainbows, see Fig. S1. However, there is some constraint on the complexity of the correlations we can produce. Let us begin by noting that, given \( \mathcal{C} \) as defined in the main text, \( \mathcal{C}^2 \) is a unitary symmetry which commutes with \( \mathcal{H} \), the Hamiltonian. Further, we know \( S \sim \sigma^y \) on the dissipation sites, and \( (\sigma^y)^2 = 1 \), so \( \mathcal{C}^2 \) also commutes with the jump operator. Therefore, \( \mathcal{C}^2 \) is a strong symmetry of this system [S2]. This means that if \( \mathcal{C}^2 \neq 1 \), there will always be multiple steady states, and we lose the uniqueness condition. This is not a contradiction of our previous results; it simply states that such a strong symmetry will always imply the existence of dark states not cooled by the dissipator.

Hence, any unique steady state will always be a “generalized” rainbow state, in the sense that correlators always exactly swap two modes. In a true rainbow state, these modes are individual lattice sites, but they can be more complicated looking in real space [S3, S4].

II. QUBIT STEADY STATE

In the main text, we have shown that a spin version of the general master equation also has the rainbow state as its steady state. Here we present detailed derivations for this result. Again using a master equation of the form of Eq. (1), the spin system has Hamiltonian and dissipators:

\[
\mathcal{H}_S = -\sum_{i=1}^{N-1} J_i (\hat{\sigma}^+_i \hat{\sigma}^-_{i+1} + \hat{\sigma}^+_i \hat{\sigma}^-_{i-1}) - J_{-1} \hat{\sigma}^+_1 \hat{\sigma}^-_1 + \text{H.c.,}
\]

\[
\hat{\beta}_A = u \hat{\sigma}^-_k - v (-1)^k \hat{\sigma}^+_k, \quad \hat{\beta}_B = u \hat{\sigma}^-_k - v (-1)^k \hat{\sigma}^+_k.
\]

Defining the spin counterpart of vacuum state \(|0\rangle\) via the relation \( \hat{\sigma}^-_k |0\rangle \equiv 0 \), we can write the rainbow entanglement state as

\[
|\psi\rangle = \prod_{i=1}^{N} \left( u + (-1)^i v \hat{\sigma}^+_i \hat{\sigma}^+_i \right) |0\rangle.
\]

It is straightforward to see that this state is a steady state by noting that the rainbow state is a dark state of both the Hamiltonian and the jump operators, i.e.,

\[
\mathcal{H}_S |\psi\rangle = \hat{\beta}_A |\psi\rangle = \hat{\beta}_B |\psi\rangle = 0.
\]

We can prove the above equation by directly applying the spin Hamiltonian and jump operators on the rainbow state in the spin basis.

Alternatively, we could also transform to the fermion model via the standard Jordan-Wigner transformation (defining fermion number operators \( \hat{n}_j \equiv \hat{c}^\dagger_j \hat{c}_j \))

\[
\hat{\sigma}^-_i = \begin{cases} (-1)^{i+N} \hat{n}_j \hat{c}_i & -N \leq i \leq -1, \\ (-1)^{i+N} \hat{n}_j \hat{c}_i + \sum_{j=1}^{i-1} \hat{n}_j \hat{c}_i & 1 \leq i \leq N. \end{cases}
\]

The string operators are chosen such that the fermionic version of the Hamiltonian is quadratic

\[
\mathcal{H}_S = \sum_{i=1}^{N-1} J_i \left( \hat{c}^\dagger_{i+1} \hat{c}_i + \hat{c}^\dagger_{i-1} \hat{c}_{i-1} \right) + J_{-1} \hat{c}^\dagger_1 \hat{c}_1 + \text{H.c.,}
\]

whereas the jump operators depend on nontrivial string operators as

\[
\hat{\beta}_A = (-1)^k u (\sum_{j=-N}^{k} \hat{n}_j \hat{c}_{-k} - v \hat{c}^\dagger_k (\sum_{j=-N}^{k} \hat{n}_j + \sum_{j=1}^{k} \hat{n}_j),
\]

\[
\hat{\beta}_B = (-1)^k u (\sum_{j=-N}^{k} \hat{n}_j \hat{c}_{-k} - v \hat{c}^\dagger_k (\sum_{j=-N}^{k} \hat{n}_j).
\]

The rainbow state can be rewritten in terms of fermionic operators as

\[
|\psi\rangle = \prod_{i=1}^{N} \left( u + (-1)^i v \hat{c}^\dagger_i \hat{c}^\dagger_i \right) \sum_{j=-N}^{N} \hat{n}_j |0\rangle
\]

\[
= \prod_{i=1}^{N} (u - (-1)^i v \hat{c}^\dagger_{-i} \hat{c}^\dagger_{-i}) |0\rangle,
\]
which is the same as the fermion steady state in Eq. (S23), so that we have $\hat{H}_S|\psi\rangle = 0$. We next show that $|\psi\rangle$ is also a dark state of the jump operator $\hat{\beta}_A$, and we note that similar argument works for $\hat{\beta}_B$ as well. Although $|\psi\rangle$ is not an eigenstate of string operators, it pairs excitations on $(-l, l)$ sites, so that we have

$$(-)^{\hat{n}_j + \hat{n}_{-j}}|\psi\rangle = |\psi\rangle, \quad \forall j.$$  

(S35)

Noting that we can rewrite the jump operator as

$$\hat{\beta}_A = (-)^{k + \sum_{j=-N}^{j} \hat{n}_j} \left[ u\hat{c}_{-k} + (-)^{k} v\hat{c}_{k} \right] (-)^{\sum_{j=1}^{k} (\hat{n}_j + \hat{n}_{-j})},$$

we can derive its action on the rainbow state as

$$\hat{\beta}_A|\psi\rangle = (-)^{k + \sum_{j=-N}^{j} \hat{n}_j} \left[ u\hat{c}_{-k} + (-)^{k} v\hat{c}_{k} \right]|\psi\rangle = 0.$$  

(S37)

Thus, we have proved that the rainbow state is a steady state of the spin master equation.

### A. Uniqueness

In the following, we will prove that when the dissipator acts on the center pair of $(1, -1)$ sites, the rainbow state is also the unique steady state solution of the spin master equation for most choice of parameters (when $u \neq v$). For this specific location of the dissipator, the problem is clearest using a different Jordan Wigner transformation than Eq. (S30), which uses a reference site of 1 in the center of the lattice, as opposed to $-N$ at the end, as was presented in the main text. The benefit of this is the jump operators have only a factor of overall parity $(-1)^{\bar{N}}$, where we define $\bar{N} \equiv \sum_j \hat{c}_j^\dagger \hat{c}_j$, but the Hamiltonian is no longer identical:

$$\hat{H}_S = \sum_{i=1}^{N-1} J_i \left( \hat{c}_i^\dagger \hat{c}_{i+1} + \hat{c}_{i-1}^\dagger \hat{c}_i \right) + J_{-1} (-1)^{\bar{N}} \hat{c}_{-1}^\dagger \hat{c}_1 + \text{H.c.},$$

(S38)

$$\hat{\beta}_A = u\hat{c}_{-1} (-1)^{\bar{N}} - v\hat{c}_1^\dagger, \quad \hat{\beta}_B = u\hat{c}_1 + v\hat{c}_{-1}^\dagger (-1)^{\bar{N}}.$$  

(S39)

The jump operator now effectively injects BCS pairs with a fluctuating phase that depends on the total occupation of the system.

We can decompose this into two different systems - one where $(-1)^{\bar{N}} = 1$ (even parity) and $(-1)^{\bar{N}} = -1$ (odd parity). Now, we know that by the chiral symmetry arguments Section I, we can rewrite $\hat{P}_{ev}\hat{H}_S\hat{P}_{ev} = \sum_{\alpha} \epsilon_{\alpha} \hat{\gamma}_\alpha^\dagger \hat{\gamma}_\alpha$, where $\hat{P}_{ev}$ projects into the even parity space. Define $\hat{\beta}_A = u\hat{c}_{-1} - v\hat{c}_1^\dagger$ and $\hat{\beta}_B = u\hat{c}_1 + v\hat{c}_{-1}^\dagger$, its orthogonal compliment, which correspond to the jump operator in the even parity sector. Also by the arguments in Section I A, we know that we can rewrite $\hat{\beta}_{A/B}$ as linear combinations of $\hat{\gamma}_\alpha$, i.e. there exists some set of coefficients $M_{A,\alpha}, M_{B,\alpha}$ such that

$$\hat{\beta}_A = \sum_{\alpha} M_{A,\alpha} \hat{\gamma}_\alpha,$$

(S40)

$$\hat{\beta}_B = \sum_{\alpha} M_{B,\alpha} \hat{\gamma}_\alpha.$$  

(S41)

Next, observe that

$$\hat{P}_{ev}\hat{H}_S\hat{P}_{ev} - (1 - \hat{P}_{ev})\hat{H}_S (1 - \hat{P}_{ev}) = 2J\hat{c}_{-1}^\dagger \hat{c}_1 + \text{H.c.} = 2J \hat{\beta}_A^\dagger \hat{\beta}_B + \text{H.c.},$$

(S42)

$$\Rightarrow (1 - \hat{P}_{ev})\hat{H}_S (1 - \hat{P}_{ev}) = \sum_{\alpha} \epsilon_{\alpha} \hat{\gamma}_\alpha^\dagger \hat{\gamma}_\alpha - 2J \sum_{\alpha, \gamma} M_{A,\alpha} M_{B,\gamma} \hat{\gamma}_\alpha^\dagger \hat{\gamma}_\gamma + \text{H.c.},$$  

(S43)

where $(1 - \hat{P}_{ev})$ projects into the odd parity space. Thus, both $\hat{P}_{ev}\hat{H}_S\hat{P}_{ev}$ and $(1 - \hat{P}_{ev})\hat{H}_S (1 - \hat{P}_{ev})$ conserve the total number of excitations in Bogoliubov modes $\hat{\gamma}_\alpha$. Now, notice that

$$\{((-1)^{\bar{N}}, \hat{\beta}_{A/B}\} = 0,$$
FIG. S2. Plotted are the set of \(2N + 1\) possible values for the number of Bogoliubov modes excited, where the \(m\)th state level has degeneracy \((2^N_m)\). (a) shows for \(u \neq v\) where the steady state is unique and corresponds to the vacuum state at the bottom of the tower. The blue arrows show cooling, and the red heating. The arrows on the left of the tower begin in even parity states, and the right side odd parity states. (b) shows the same, except now \(u = v\). This corresponds to odd parity states having only heating, creating \(N + 1\) steady states that exist in the manifold spanned by \(\{2m, 2m - 1\}\) Bogoliubov excitations.

and so every quantum jump takes you from the even to the odd parity sector, and vice versa. Incidentally, this also tells us that parity is a weak symmetry [S2]. We can see this by observing that

\[
\mathcal{D}[\hat{\beta}_{A/B}] \left( (-1)^{\hat{N}} \hat{\rho}(-1)^{\hat{N}} \right) = \frac{1}{2} \left( 2 \hat{\beta}_{A/B} (-1)^{\hat{N}} \hat{\rho}(-1)^{\hat{N}} \hat{\beta}_{A/B}^\dagger - \hat{\beta}_{A/B}^\dagger \hat{\beta}_{A/B} (-1)^{\hat{N}} \hat{\rho}(-1)^{\hat{N}} - (-1)^{\hat{N}} \hat{\rho}(-1)^{\hat{N}} \hat{\beta}_{A/B}^\dagger \hat{\beta}_{A/B} \right) 
\]

\(\text{(S44)}\)

\[
= \frac{1}{2} \left( 2 (-1)^{\hat{N}} \hat{\beta}_{A/B} \hat{\beta}_{A/B}^\dagger (-1)^{\hat{N}} - (-1)^{\hat{N}} \hat{\beta}_{A/B}^\dagger \hat{\beta}_{A/B} (-1)^{\hat{N}} - (-1)^{\hat{N}} \hat{\beta}_{A/B} \hat{\beta}_{A/B}^\dagger (-1)^{\hat{N}} \right) 
\]

\(\text{(S45)}\)

\[
= (-1)^{\hat{N}} \left( \mathcal{D}[\hat{\beta}_{A/B}] \hat{\rho} \right) (-1)^{\hat{N}}. 
\]

\(\text{(S46)}\)

This, along with commuting with the Hamiltonian, gives us

\[
\mathcal{L}[(-1)^{\hat{N}} \hat{\rho} (-1)^{\hat{N}}] = (-1)^{\hat{N}} \mathcal{L}[\hat{\rho}] (-1)^{\hat{N}},
\]

\(\text{(S47)}\)

which is the definition of a weak symmetry. This means that in the steady state, there are no coherences between positive and negative parity states, and so it makes sense to talk about the “even” and “odd” sectors of the system in the steady state.

Now, \(\hat{\beta}_{A,B}\) are the jump operators in the even parity sector. In the odd parity sector, the jump operators are

\[
\hat{\beta}_{A} = uc_{-1} + uc_{1}^\dagger = (u^2 - v^2) \hat{\beta}_{A} + 2uv \hat{\beta}_{B}, 
\]

\(\text{(S48)}\)

\[
\hat{\beta}_{B} = uc_{-1} - uc_{1}^\dagger = (u^2 - v^2) \hat{\beta}_{B} - 2uv \hat{\beta}_{A}, 
\]

\(\text{(S49)}\)

and so we see that the jump operator in the odd-parity section is a linear combination of both heating and cooling in the even parity section. When \(u \neq v\), the odd parity section has both heating and cooling elements, while the
even parity section is strictly cooling. If we construct a tower of Hilbert spaces labeled by the number of Bogoliubov excitations from 0 to $2N$, then we can observe that every level can decay to another level except for the manifold with no Bogoliubov excitations. Hence, the unique steady state is the Bogoliubov vacuum, see Fig. S2.

B. $u = v$ Degeneracy

However, exactly when $u = v$, we have that the odd-parity section is purely heating, since in that limit we have $\tilde{\beta}'_A = -\tilde{\beta}'_B$ and $\tilde{\beta}'_B = \tilde{\beta}'_A$. Since $\mathcal{H}$ conserves Bogoliubov number, we know that if you start with $2m$ Bogoliubov modes, then the dynamics can take you into the space with $2m - 1$ excitations through the purely cooling jump operator. Then, you enter the odd parity section, and so now the dynamics can only take you into the space with $2m$ excitations, through the purely heating jump operator. This creates a set of $N + 1$ isolated manifolds, exactly matching the number of steady states. Further, we know that each steady state must be an incoherent mixture of having $2m$ and $2m - 1$ Bogoliubov excitation, or having exactly zero Bogoliubov excitations. Hence, the only pure steady state is the Bogoliubov vacuum. Finally, we can see that the only way to end up in the Bogoliubov vacuum is to start there since ceil$(N_{Bog}/2)$ is conserved, where ceil rounds up to the nearest integer, and $N_{Bog}$ is the number of Bogoliubov excitations, i.e. $N_{Bog} = \sum \gamma^\dagger_\alpha \gamma_\alpha$, see Fig. S2.

III. EXPERIMENTAL IMPLEMENTATION

A. Sideband Driving

The correlated dissipator required in our scheme can be readily generated by coupling the two qubits to a single lossy cavity mode (i.e. an engineered reservoir), and driving the appropriate side processes. There are various possible ways to implement the sideband driving: one could either drive the coupling strengths between the qubits and the cavity, or modulate the qubit frequency. Here we present a protocol that makes use of qubit frequency modulation, which can be realized via e.g. flux tunable transmon qubits.

We consider two qubits (Pauli operators $\hat{\sigma}^x_1$ and $\hat{\sigma}^x_2$) coupled to a lossy cavity mode (annihilation operator $\hat{a}$, frequency $\omega_c$, loss rate $\kappa$). The qubit 1 (2) has resonance frequency $\omega_1$ ($\omega_2$) and is coupled to the cavity mode with coupling strength $g_1$ ($g_2$), and we drive the frequencies of qubits 1 and 2 at the red and blue sideband frequencies $\omega_r = \omega_1 - \omega_c$ and $\omega_b = \omega_2 + \omega_c$, respectively (Fig. S3). The system Hamiltonian in the lab frame is given by

$$\mathcal{H} = \omega_1 \hat{a}^\dagger \hat{a} + \frac{1}{2} (\omega_1 + \xi_1 \omega_r \cos(\omega_r t)) \hat{\sigma}^x_1 + \frac{1}{2} (\omega_2 + \xi_2 \omega_b \cos(\omega_b t)) \hat{\sigma}^x_2 + (\hat{a} + \hat{a}^\dagger)(g_1 \hat{\sigma}^+_1 + g_2 \hat{\sigma}^+_2).$$

Going into the rotating frame defined by the unitary transformation

$$\hat{U} = \exp \left\{ -i \omega_r \hat{t} \hat{a}^\dagger \hat{a} - \frac{i}{2} \omega_1 \hat{t} + \xi_1 \sin(\omega_r t) \hat{\sigma}^z_1 - \frac{i}{2} (\omega_2 + \xi_2 \sin(\omega_b t)) \hat{\sigma}^z_2 \right\},$$

the rotating frame Hamiltonian $\mathcal{H}'$ is given by

$$\mathcal{H}' = \hat{U}^\dagger \mathcal{H} \hat{U} - i \hat{U}^\dagger \hat{U}$$

$$= g_1 \left( e^{-i \omega_r \hat{t}} \hat{a}^\dagger + e^{i \omega_r \hat{t}} \hat{a} \right) e^{-i \omega_1 \hat{t} - i \xi_1 \sin(\omega_r t) \hat{\sigma}^z_1} + g_2 \left( e^{-i \omega_b \hat{t}} \hat{a}^\dagger + e^{i \omega_b \hat{t}} \hat{a} \right) e^{-i \omega_2 \hat{t} - i \xi_2 \sin(\omega_b t) \hat{\sigma}^z_2} + \text{H.c.}. \quad (S52)$$

Making use of the identity

$$e^{i \xi \sin(\omega t)} = \sum_{n=-\infty}^{\infty} J_n(\xi) e^{in\omega t},$$

where $J_n(\xi)$ are Bessel functions, we can rewrite the rotating frame Hamiltonian as

$$\mathcal{H}' = \left( e^{-i \omega_r \hat{t}} \hat{a}^\dagger + e^{i \omega_r \hat{t}} \hat{a} \right) \sum_{n=-\infty}^{\infty} \left[ g_1 J_n(\xi_1) e^{-i(\omega_1 + n\omega_r) \hat{t}} \hat{\sigma}^z_1 + g_2 J_n(\xi_2) e^{-i(\omega_2 + n\omega_b) \hat{t}} \hat{\sigma}^z_2 \right] + \text{H.c.}. \quad (S55)$$
FIG. S3. (a) By placing two qubits 1,2 with frequencies $\omega_{1,2}$ in a lossy cavity with frequency $\omega_c$ and decay rate $\kappa$, then modulating the qubit frequencies with red and blue sidebands $\omega_r,\omega_b$, we can engineer the desired dissipation. (b) Shows a schematic of the necessary frequencies needed for the design.

FIG. S4. Shown is the concurrence across the ‘rainbows’ of the rainbow state with additional dephasing and relaxation for a 6 (left) and 8 (right) site lattice. Note that the first bond, coupled directly to the engineered dissipator, is more persistent, and the other two are identical, despite being different distances from the reservoir.

Since we drive the qubits at sideband resonances $\omega_r = \omega_1 - \omega_c$ and $\omega_b = \omega_2 + \omega_c$, the rotating terms are resonant when $n = -1$. Using the standard rotating wave approximation, we assume that all off-resonant terms rotate rapidly and average to zero, leaving us with the effective Hamiltonian

$$\hat{H}' \approx \hat{a}^\dagger (g'_1 \hat{\sigma}_1^- + g'_2 \hat{\sigma}_2^+) + H. c., \quad (S56)$$

where $g'_i = J_{-1}(\xi_i)g_i \ (i = 1, 2)$.

Intuitively, this tells us that the cavity can absorb a photon if one of two resonant processes occurred – either qubit 1 lost an excitation, or qubit 2 gained one. In the limit where the cavity decays much faster than qubit dynamics, i.e., when $\kappa \gg g_{1,2}$, then we can integrate out the cavity mode to get an effective jump operator acting jointly on the qubits. If we define $g'_1 = u\gamma$, $g'_2 = v\gamma$ with $u^2 + v^2 = 1$, then we obtain the effective jump operator $\hat{\beta}_A = \sqrt{g^2/\kappa(u\hat{\sigma}_1^- + v\hat{\sigma}_2^+)}$, which is of the proper form.

B. Additional Dissipation

We now consider the robustness of our steady state in the presence of additional local dissipation. In Fig. S4, we consider the effects of local dephasing (relaxation) with a strength $\gamma_{\text{rel}} \ (\gamma_{\phi})$, respectively, by plotting the concurrence.
between pairs of sites \((l, -l)\). In all of the plots, the engineered dissipation couples to the first bond with a strength \(\Gamma\), and the Hamiltonian hopping \(J = \Gamma\). The master equation is now given by

\[
\mathcal{L}[\hat{\rho}] = -i[\hat{H}, \hat{\rho}] + \Gamma \left( \mathcal{D}[\hat{\beta}_A] + \mathcal{D}[\hat{\beta}_B] \right) \hat{\rho} + \sum_i \mathcal{D}[\hat{L}_i^\alpha] \hat{\rho}, \tag{S57}
\]

where the qubit lattice Hamiltonian \(\hat{H}\) and the dissipators \(\hat{\beta}_A, \hat{\beta}_B\) are again given by

\[
\hat{H} = J \sum_j \hat{\sigma}_{j}^+ \hat{\sigma}_{j+1}^- + \text{H. c.}, \quad \hat{\beta}_A = u \hat{\sigma}_{-1}^- + v \hat{\sigma}_1^+ + \hat{\sigma}_{1}^-, \quad \hat{\beta}_B = u \hat{\sigma}_{1}^- + v \hat{\sigma}_{-1}^+, \tag{S58}
\]

The local dephasing (relaxation) dissipator \(\hat{L}^\phi_i\) for \(\alpha = \phi\) (\(\alpha = \text{rel}\)) are given by

\[
\hat{L}^\phi_i = \sqrt{\gamma_\phi} \hat{\sigma}_i^z, \quad \hat{L}_i^{\text{rel}} = \sqrt{\gamma_{\text{rel}}} \hat{\sigma}_i^- . \tag{S59}
\]

We choose \(u, v\) to maximize concurrence on each of the entanglement bonds, starting from the 1st, innermost bond, to the \(N\)th, outermost bond in a \(2N\) particle lattice, as is depicted in Fig. 1.

---
