(Dated: August 2, 2021)

We numerically study the single particle localization and delocalization phenomena of an initially localized wave packet in the kicked Harper model (KHM) and Harper model subjected to quasi-periodic perturbation composed of \(M\) modes. Both models are localized in the monochromatically perturbed case \(M = 1\). KHM shows localization-delocalization transition (LDT) above \(M > 2\) as increase of the perturbation strength \(\epsilon\). In a time-continuous Harper model with the perturbation, it is confirmed that the localization persists for \(M = 2\) and the LDT occurs for \(M \geq 3\). In addition, we investigate the diffusive property of the delocalized wave packet for \(\epsilon\) above the critical strength \(\epsilon_c(\epsilon > \epsilon_c)\). We also introduce other type systems without localization, which takes place a ballistic to diffusive transition in the wave packet dynamics as the increase of \(\epsilon\). In both systems, the \(\epsilon\)-dependence of the diffusion coefficient well coincide with that in the other type system for large \(\epsilon(> 1)\).

I. INTRODUCTION

The quantum kicked rotor (KR), representing the dynamics of a periodically kicked pendulum, is a well studied as example of a classically nonintegrable system\(^{[1-3]}\). The dynamical localization of the quantum KR has been interpreted through a mapping to the Anderson tight-binding model for a particle in a disordered lattice\(^{[2]}\). Furthermore, in the KR systems, a transition from the dynamical localization to delocalization can be caused by second periodic series of kicks, and periodic modulation of the kick amplitude, and so on\(^{[4-6]}\).

Similar to the KR system, the existence of localization-delocalization transition (LDT) in the dynamics has been investigated in the kicked Harper model (KHM), whose classical counterpart is a non-integrable system\(^{[7,13]}\). There are three main dynamical states of the quantum wave packet, localized, normal diffusion, and ballistic spread, corresponding to the change of the potential strength. In that respect, it is the same as the Harper model without the kicks. However, in the case of the Harper model, at one point of the potential strength, the LDT takes place due to the duality of the system\(^{[14-16]}\). On the other hand, the phase diagram of the localized/delocalized state in KHM has a nested structure and is quite complicated\(^{[17-20]}\). Even in the case of this KHM, there is a study on the LDT that occurs when the second kick series or kick intensity modulation is applied.

For the periodically driven Hamiltonian systems, Floquet states represent the natural generalization of the stationary eigenstates for time-independent systems. Floquet engineering in the periodically kicked systems is interesting because they can exhibit more complex dynamics and allow more control through external driving in comparison to their static systems\(^{[21-24,26-29]}\).

Recently, the Anderson transition by using the KR has been experimentally explored using cold atoms in optical lattices\(^{[24,30,31,32]}\). It is also feasible to experimentally realize the dynamical localization transition through the diffusion of wave packets in the pulsed 1D incommensurate optical lattice such as the KHM\(^{[33]}\).

On the other hand, we also investigated the characteristics of the LDT in the polychromatically perturbed kicked Anderson model (KAM), and the results that correspond well with those in the KR have been obtained\(^{[34,35]}\). Note that in our previous paper, we used the expression Anderson map (AM) for the kicked Anderson model (KAM). However, regarding Harper model, many references use the expressions kicked Harper model and Harper model, so this paper also uses them. The dynamics is not solely determined by the strength \(\epsilon\) of the perturbation, but also the number of color \(M\) of the coherent perturbation. It was shown that for the time-continuous 1D Anderson model modulated by a quasi-periodic time-perturbation of \(M\) colors, if there are three or more color perturbations \((M \geq 3)\), the Anderson localized states without the perturbation can be delocalized, and the LDT occurs as the increase of \(\epsilon\)\(^{[40]}\).

In this work, we study the dynamical localization transition in the periodically kicked Harper and Harper models which are perturbed by the quasiperiodic oscillations. Specifically, in the KHM of \(2 \leq M < \infty\), there are LDTs and the characteristics are similar to those of the KAM. However, in the Harper model, the case of \(M = 2\) is completely localized on the small side of \(\epsilon\), and tends to persist the localization even on the large side of \(\epsilon\), and the LDT has not been observed. In other words, in the time-continuous Harper model with coherent multicolor perturbation, the DLT does not occur in the case of \(M = 2\) corresponding to three degrees of freedom system, and the LDT occurs only in a case of \(M \geq 3\), as seen in 1D Anderson model\(^{[41]}\).

It should be noticed that the persistence of the localization for \(1 \leq M < \infty\) is mathematically claimed...
in the regime of weak enough dynamical perturbations and strong disorder potential [42-44]. In this regard, the present paper reports the details of novel results on dynamical delocalization in the Harper model with the quasi-periodic perturbation. Of particular interest to us is dependence on the two parameters of coherent polychromatic perturbation, i.e., number of the colors \( M \) and perturbation strength \( \epsilon \).

Furthermore, in the other type system without localization, which is related to both the KHM and Harper models, we report the change in how the wave packet spreads when the perturbation strength is increased with respect to the ballistic spreading in the unperturbed Bloch state. It is shown that a dynamical transition from ballistic to diffusive spread results. Hereinafter, this transition is referred to as a ballistic-diffusive transition (BDT) of wave packet spreading. The timescale for the transition from ballistic to diffusive depends on the strength \( \epsilon \) as well as \( M \). This result also corresponds well with the results for the KAM and Anderson models.

In Sec. II, we introduce the model and the basic property. Section III explores the dynamical localization-delocalization transition when perturbed by quasi-periodic oscillation with the component \( \{ \omega_i \} \). Of particular interest to us is dependence on the two parameters of coherent polychromatic perturbation, i.e., number of the colors \( M \) and perturbation strength \( \epsilon \).

Section IV focuses on the dynamical localization-delocalization transition when perturbed by quasi-periodic oscillation with the component \( \{ \omega_i \} \). Of particular interest to us is dependence on the two parameters of coherent polychromatic perturbation, i.e., number of the colors \( M \) and perturbation strength \( \epsilon \).

In Sec. II, we introduce the model and the basic property. Section III explores the dynamical localization-delocalization transition when perturbed by quasi-periodic oscillation with the component \( \{ \omega_i \} \). Of particular interest to us is dependence on the two parameters of coherent polychromatic perturbation, i.e., number of the colors \( M \) and perturbation strength \( \epsilon \).
unperturbed Harper model is an integrable system. The
eigenvalue problem of the periodically kicked system can
be replaced with the eigenvalue problem of the tight-
binding system by the Maryland transform. (See Ap-
pendix[A]) Without loss of generality, mainly for a fixed
value $V = 5$ to be localized we investigate the LDT with
increasing of $M$ and $\epsilon$ of the quasi-periodic perturbation
in the next section.

Furthermore, we examine the LDT for a time-
continuous system in which $\delta_1(t)$ is replaced by 1 in the
Hamiltonian $H_{map}(t)$. This model was introduced as an
model for electron in a two-dimensional crystal in an ex-
ternal magnetic field, and we call it Harper model in
this paper. [There are also references that describes this
model as Aubry-Andre model or Aubry-Andre-Harper
model.] It can be said that the KHM system is a map
version of the Harper model.

The nature of the unperturbed Harper model ($\epsilon = 0$)
has long been well studied physically and mathemati-
cally. It has been also shown that the LDT exists in
the unpertubed A-type Harper model due to the duality
[16 18]. For $V > 1$ all eigenstates are localized and the
spectrum is pure point. For $V > 1$ the localization length
$\xi$ is given $\xi = \frac{1}{\log V}$ independent on the energy. In this
case, the increase in $V$ causes a monotonous decrease in
$\xi$. For $V < 1$ the states are extended and the spectrum is
absolutely continuous. For the critical value $V = V_c = 1$
eigenstates are critical and the spectrum is singular con-
 tinuous. It is also numerically suggested that spread of
an initially localized wavepacket is localized for $V > 1$,
and is ballistic for $V < 1$ and is diffusive for $V = 1$
respectively. [16]

Figure [2] shows the MSD in the unperturbed Harper
model when the potential strength $V$ is changed from the
localized side ($V > 1$) to the delocalized side ($V < 1$).
Although there are fluctuations, it changes from $m_2 \sim t^0$
in the case of localization to a ballistic spread of $m_2 \sim t^2$
via diffuse $m_2 \sim t^3$ in the case of the critical state. When
$V < 1$, it is ballistic regardless of the value of $V$. That
is,

$$ m_2(t) \sim \begin{cases}
  t^0 \text{(localization)} & V > 1 \\
  t^1 \text{(normal diffusion)} & V = V_c = 1 \\
  t^2 \text{(ballistic spreading)} & V < 1
\end{cases} \quad (7) $$

Using the A-type Harper model, we fixed at $V = 1.3$ as
an unperturbated localized side, and investigate the LDT
by imposing $f_\epsilon(t)$, with comparing with results in the
already reported 1D kicked Anderson and the Anderson
models [39 40].

### III. DYNAMICAL LOCALIZATION-DELOCALIZATION TRANSITION

In this section, we set to the certain localized state in
the KHM with $V = 5$ and Harper model with $V = 1.3$,
respectively. We study how the dynamical property by
changing the parameters $M$ and $\epsilon$ of the perturbation
$f_\epsilon(t)$ in the A-type system.

#### A. Kicked Harper model: case of A-type

Figure [3] shows the MSD when $M = 1$ in the log-log
plots. When $\epsilon$ is small, it is clearly completely localized.
Even when $\epsilon$ increases, it spreads diffusely within the ini-
tial time, but as time passes, the $t$—linear growth begins
to wither and the wave packet tends to be localized. As
a result, no transition to the delocalized state is seen. The persistence of localization in the case of $M = 1$ is consistent with the result for addition of ac-field to the 1DDS. \[49, 50\]

As shown in Fig.\[4\] for $M \geq 2$ the $M$–dependence of the critical strength $\epsilon_c$ indicates the inverse power-law

$$
\epsilon_c \propto \frac{1}{(M-1)}.
$$

(9)

The same $M$–dependence can be obtained even when $V = 10$, as seen in Fig.\[4\]. This difference in $\epsilon_c$ due to $V$ can be interpreted by the Maryland transform in Appendix A. According to the Maryland transform, the diagonal term is saturated in the region $V > V^* (\equiv 0.38)$ and the effect of the potential strength $V$ is saturated, and the nature of the off-diagonal term depends on $\epsilon V$, so the transition point $\epsilon_c$ at $V = 10$ can be interpreted as a half of the transition point at $V = 5$.

It can also be seen that in $\epsilon > \epsilon_c$, $m_2(t)$ asymptotically becomes to normal diffusion for $t \to \infty$. Therefore, we can expect that the quasi–periodically driven system also may delocalize even in the absence of coupling with its environment.

### B. Harper model: case of A-type

Is the phase transition phenomenon in the case of KHM observed when using the Harper model? The potential strength is fixed at $V = 1.3$, and the time-dependence of the MSD for the cases of $M = 1$ and $M = 2$ is shown in the Fig.\[5\]. Obviously, if $\epsilon$ is small, it is localized, and the localization persists even for $\epsilon \sim 0.6$ beyond the region that can be regarded as a perturbation. Although it can be seen that it is completely localized in the sense that $D = \frac{m_2}{\epsilon^2} \to 0$ can be guessed. Also for $M = 2$, at least $m_2 \propto t^{2/3}$ does not appear even if $\epsilon$ is increased to $\epsilon \geq 0.65$. (See Fig.\[5\].) As a result, it also tends to be localized even for $M = 2$, which is also the same as the result for the 1D Anderson model with a random sequence as $V(n)$. 

![FIG. 3: (Color online) The double-logarithmic plots of $m_2(t)$ as a function of time for different values of the perturbation strength $\epsilon$ in the polychromatically perturbed A-type Harper map of $V = 5$ with (a)$M = 1$, (b)$M = 2$, (c)$M = 3$, (d)$M = 7$. $h = 1/8$. The values of $\epsilon$ used are $\epsilon = 0.0002, 0.0020, 0.0040, 0.0080, 0.0200, 0.1800$ from bottom to top in the panel (a), $\epsilon = 0.0001, 0.0005, 0.0010, 0.0017, 0.0019, 0.0020, 0.0030$ from bottom to top in the panel (b), $\epsilon = 0.0001, 0.0005, 0.0007, 0.0009, 0.0012, 0.0015, 0.0020$ from bottom to top in the panel (c), and $\epsilon = 0.0001, 0.0002, 0.00028, 0.0004, 0.0005, 0.0006$ from bottom to top in the panel (d), respectively. The dashed lines have slope 1 in the panel (a), slope 1 and 2/3 in the panel (b), slope 1 and 1/2 in the panel (c), and slope 1 and 1/4 in the panel (d), respectively.](image3)

![FIG. 4: (Color online) The critical perturbation strength $\epsilon_c$ as a function of $(M - 1)$ for A-type kicked Harper model with $V = 5$ and $V = 10$. The black solid line shows $\epsilon_c \propto 1/(M - 1)$.](image4)
Figure 5 shows the result of $m_2(t)$ for $M \geq 3$ when $\epsilon$ is increased. First, the results for $M = 3$ with different parameters are given in Fig. 5(a) and (b). As seen in Fig. 5(a), it is clearly localized in the region $\epsilon < 0.5$, but it changes around $\epsilon > 0.7$ and appears to be asymptotic to diffusive one $m_2 \sim t^{3/2}$. Figure 5(b) is the result by using the random initial phase $\{\theta_i\}$. It is a similar result to the Fig. 5(a). If $\epsilon$ is small, it is localized, but if $\epsilon \sim 0.5$, the fluctuation becomes large, and if $\epsilon > 0.65$, it becomes diffusive $m_2 \sim t^{3/2}$. As a result, in the A-type perturbed Harper model of $M = 3$, we can see a transition from a localized to a delocalized dynamics take place at a certain critical value of the strength parameter, but it is difficult to specify a clear critical point $\epsilon_c$ at which subdiffusion such as $m_2 \sim t^{3/2}$ appears.

Figure 5(c) and (d) show the result of $M = 4$ and $M = 5$, respectively. It is also seen that the change from the localized state to the normal diffusion as in the case of $M = 3$. In the case of $M = 4$, it is clearly localized for $\epsilon < 0.3$, and becomes $m_2 \sim t^{4/3}$ for $\epsilon > 0.4$. In the case of $M = 5$, it is clearly localized for $\epsilon < 0.2$, and becomes $m_2 \sim t^{4/3}$ for $\epsilon > 0.4$.

However, unlike the case of the KHM, a clear subdiffusion ($m_2 \sim t^\alpha$, $0 < \alpha < 1$) cannot be detected during the transition from the localized ($m_2 \sim t^0$) to delocalized ($m_2 \sim t^1$) dynamical property by increasing $\epsilon$. From the whole, the transition point $\epsilon_c$ tends to decrease with $M$. The overall tendency corresponds well to the case of KAM and Anderson model where $V(n)$ is random sequence, but KHM and Harper model without sample average may not detect a clear transition point in the present stage.

### IV. Transition from Ballistic Spreading to Normal Diffusion

In this section, we study the characteristics of the wave packet spreading in the B-type KHM and Harper model ($L = 0$) with the coherent oscillation $f_c(t)$. If $\epsilon = 0$, the potential term disappears, so both KHM and Harper model are periodic systems, and the localized wave packet spreads ballistically:

$$m_2(t) \sim t^2.$$  \hspace{1cm} (10)

In appendix A for the KHM, we can also see that the diagonal term in the Maryland transformed tight binding model does not depend on the site $n$, so it becomes a ballistic motion. In the B-type cases, $V$ and $\epsilon$ play the same role, so basically fix it as $V = 1$ and we investigate
the dynamics while changing \( M \) and \( \epsilon \) of the coherent oscillation part.

A. Kicked Harper model: case of B-type

In the case of the B-type KHM with \( M = 1 \) and \( M = 5 \), the time-dependence of MSD is given in Fig.7. In both cases, when \( \epsilon \) is small, the growth of \( m_2(t) \) slightly deviates from ballistic spreading at the initial time, but it goes to ballistic as \( t \to \infty \). It can be seen that when \( \epsilon \) becomes large, it gradually approaches normal diffusion, \( m_2(t) \sim t^1 \), from the initial stage. That is, if \( M \geq 1 \), there is a transition from ballistic to normal diffusion, although it is also difficult to accurately determine the value of \( \epsilon_c \) of the transition. The asymptotic diffusive behavior is expected as a generic feature of decoherence, which takes place when noise is introduced into a system.

Figure 8 is an estimate of the diffusion coefficient \( D \) in the normal diffusion region. The \( \epsilon \)-dependencies are a little complicated, but in all cases \( D \) tends to decrease with increasing \( \epsilon \). Incidentally, it has been reported that in the case of KAM, it decreases monotonously with \( D \propto \epsilon^{-2} \).

FIG. 7: (Color online) The double-logarithmic plots of \( m_2(t) \) as a function of \( t \) for various strength \( \epsilon \) in the B-type perturbed kicked Harper model of \( V = 1 \) with (a) \( M = 1 \) and (b) \( M = 5 \). \( h = 1/8 \). The values of \( \epsilon \) used are \( \epsilon = 0.1, 0.2, 0.4, 0.7, 1.0 \) from top to bottom in the panel (a), and \( \epsilon = 0.1, 0.2, 0.4, 0.8, 1.0 \) from top to bottom in the panel (b), respectively. The dashed lines indicate normal diffusion \( m_2 \sim t^1 \) and ballistic spreading \( m_2 \sim t^2 \).

FIG. 8: (Color online) Diffusion coefficient \( D \) as a function of \( \epsilon \) in the B-type perturbed kicked Harper model of \( V = 1 \), \( h = 1/8 \).

B. Harper model: case of B-type

In the case of the B-type Harper model with several \( M \), the time-dependence of MSD is given in Fig.9. When \( M = 1 \) in the Fig.9(a), it shifts to the normal diffusion side at the initial time, but when \( \epsilon \) becomes large, we can see that it gradually approaches \( m_2(t) \sim t^2 \) for \( t \to \infty \). On the other hand, as shown in Fig.9(c)-(d) for \( M \geq 3 \), the MSD shows ballistic spreading in the initial stage, but it is asymptotic to normal diffusion \( m_2(t) \sim t^1 \) in \( t \to \infty \). As seen in Fig.9(b), even when \( M = 2 \), it shows a tendency of \( m_2(t) \sim t^2 \) for \( t \to \infty \). Figure 10 is an estimate of the diffusion coefficient \( D \) in the region showing the normal diffusion. \( D \) decreases as \( \epsilon \) increases [41].

FIG. 9: (Color online) The double-logarithmic plots of \( m_2(t) \) as a function of \( t \) for various strength \( \epsilon \) in the B-type perturbed Harper model of \( V = 1 \), \( h = 1/8 \). The values of \( \epsilon \) used are \( \epsilon = 0.7, 0.8, 0.9, 1.1, 1.3 \) from top to bottom in the B-type perturbed Harper model of \( V = 1 \) with (a) \( M = 1 \), (b) \( M = 2 \), (c) \( M = 3 \) and (d) \( M = 5 \), \( h = 1/8 \). The dashed lines indicate normal diffusion \( m_2 \sim t^1 \) and ballistic spreading \( m_2 \sim t^2 \). Note that the axes are in the logarithmic plot.
FIG. 10: (Color online) Diffusion coefficient $D$ as a function of $\epsilon$ in the B-type perturbed Harper model of $V = 1, \hbar = 1/8$.

C. Comparison of A-type and B-type systems

As seen in this subsection, even in the case of B-type system, the MSD diffuses normally by increasing $\epsilon$, and the diffusion coefficient decreases. On the other hand, as seen in the previous section, even in A-type system, for $\epsilon > \epsilon_c$, $m_2(t)$ gradually approaches the normal diffusion for $t \to \infty$. Indeed, it is easy to imagine that the A-type system asymptotically approaches the B-type system with the increase of $\epsilon$, because the time-dependent part of the Hamiltonian (1) can be rewritten:

$$\epsilon V(n) \left[ \frac{L}{\epsilon} + f(t) \right] \delta_1(t).$$

Here, the $\epsilon-$dependence of the diffusion coefficient in the normal diffusion region is observed in a wide region of $\epsilon$, and the relationship between A-type and B-type systems is shown.

In fact, Fig. 11 shows the $\epsilon-$dependence of the diffusion coefficient evaluated by the KHM. In the A-type system, the diffusion coefficient increases with an increase of $\epsilon$ when $\epsilon > \epsilon_c$, and the effect saturates at a certain level. On the other hand, in B-type system, the diffusion coefficient decreases monotonically as $\epsilon$ increases, and it can be seen that $D$ falls to the same level as A-type system for $\epsilon$ on the order of $O(1)$. Also, for $\epsilon > 0.3$, $M-$dependence of the diffusion coefficient has almost disappeared.

Furthermore, as shown in Fig. 12, similar results are obtained for the A-type and B-type systems of the time-continuous Harper model. In this case, in A-type system, increasing $\epsilon$ also increases $D$ and peaks around $\epsilon \approx 1$ then decreases, and approaches the same constant level as B-type system around $\epsilon \approx 1$.

V. SUMMARY AND DISCUSSION

In the present paper, we investigated the dynamical property of the initially localized wave packet in coherently perturbed kicked Harper and Harper models.

In the A-type systems ($L = 1$), localization-delocalization transition (LDT) appeared with increasing the perturbation strength $\epsilon$. The critical value $M_c$ which appear the LDT is $M_c = 2$ for KHM and $M_c = 3$ for Harper model in a sense that at $M = 2$, the LDT is not caught and shows localization. The property for the number of the color $M$ is summarized in table I. The table also describes the localized and delocalized transitions in the multidimensional Anderson model that corresponds to the 1D Anderson map and Anderson model with the quasiperiodic perturbation. In the case of KHM, if $M + 1$ can be identified with the spatial dimension $d$,
the existence of the LDT is a qualitatively consistent result with those of the LDT in $d$-dimensional Anderson model. However, in the time-continuous systems, the critical number of the colors, degrees of freedom, is not $d = M + 1 = 2$ but $d = 3$, unlike the periodically kicked quantum maps such as KAM and KHM. We hope that this study will be useful for studying the long-time behavior of the dynamics in high-dimensional random systems and multi-degree-of-freedom quantum systems that cannot be calculated directly.

The well-studied Harper model points out that the multifractality of the level statistics and the dynamics of the wave packet show universal behavior at critical point $V = V_c = 1$. Our results suggest that in a general localized systems, there is a transition point $\epsilon_c$ of the perturbation strength corresponding to the number of color $M$ of the quasi-periodic perturbation, and there are characteristic critical dynamics at the point. It controls the quantum coherence that causes the localization.

In the B-type systems ($L = 0$), the sharp ballistic-diffusive transition (BDT) of the dynamics of the wave-packet can be observed with the increase of the strength $\epsilon$. The dynamical motion depends on the number of the color $M$. The result is summarized in table III. In this case, no localized state occurs, but it may be more realistic in terms of investigating how the scattering of the one-particle problem changes due to the addition of coherent perturbations to the periodic system of $\epsilon = 0$. Furthermore, it was shown that in both the KHM and Harper model, the A-type system becomes one equivalent to the B-type system in the normal diffusion region of $\epsilon >>> 1$. The asymptotic diffusive behavior is expected as a generic feature of decoherence, which takes place when noise is introduced into a system.

This work may lead to a deeper understanding of dynamical localization and quantum diffusion in quasi-periodic systems. It also provides insight into the control of localized and delocalized states by coherent perturbations in the Floquet engineering.

**Appendix A: Maryland transform**

We can regard the time-dependent harmonic perturbation $f(t)$ as the dynamical degrees of freedom. To show this we introduce the classically canonical action-angle operators ($\hat{J}_j = -i\hbar \frac{\partial}{\partial \phi_j}, \phi_j$) representing the harmonic perturbation as the linear modes, and we call them the color modes. Each quantum oscillator has the action eigenstates $|n_j \rangle$ with the action eigenvalue $J_j = n_j \hbar \ (n_j: \text{integer})$ and the energy $n_j \hbar \omega_j$. Thus the system is regarded as a quantum autonomous system of $(M + 1)$-degrees of freedom spanned by the quantum states $|n > \sum_{j=1}^{M} |n_j >$. Then the autonomous Hamiltonian $H_{aut}$ that include the color modes becomes

$$H_{aut}(\hat{p}, \hat{q}, \{\hat{J}_j\}, \{\phi_j\}) = 2 \cos(\hat{p}/\hbar) + 2V \cos(\hat{q}) \left[ L + \frac{\epsilon}{\sqrt{M}} \sum_j M \cos \phi_j \right] \delta(t) + \sum_{j=1}^{M} \omega_j \hat{J}_j$$

(A1)

Let us consider an eigenvalue equation

$$e^{-i \hat{A} \gamma} e^{-i \hat{B} \gamma} e^{-i \hat{C} \gamma} |u\rangle = e^{-i \gamma} |u\rangle,$$

(A2)

where

$$\hat{A} = (2V L \cos(\hat{q}) + \sum_j \omega_j \hat{J}_j)/\hbar,$$

$$\hat{B} = \cos(\hat{q}) \frac{\epsilon}{\sqrt{M}} \sum_j M \cos \phi_j /\hbar,$$

$$\hat{C} = 2 \cos(\hat{p}/\hbar)/\hbar$$

(A3)

for the time-evolution operator. $\gamma$ and $|u\rangle$ are the quasi-eigenvalue and quasi-eigenstate. Here, if the eigenstate representation of $\hat{J}_j$ is used, $\hat{J}_j |m_j\rangle = m_j \hbar |m_j\rangle (m_j \in \mathbb{Z})$. 

we can obtain the following \((M+1)\)–dimensional tight-binding expression by the Maryland transform \([38]\):

\[
D(n, \{m_j\})u(n, \{m_j\}) + \sum_{n', \{m'_j\}} \langle n, \{m_j\}|\hat{t}_{KHM}|n', \{m'_j\}\rangle u(n', \{m'_j\}) = 0 \quad (A4)
\]

where \(\{m_j\} = (m_1, ..., m_M)\). Here the diagonal term is

\[
D(n, \{m_j\}) = \tan \left[ \frac{2VL \cos(2\pi Qn) + \hbar \sum_{j}^{M} m_j \omega_j}{2\hbar} \right] - \frac{\gamma}{2} \quad (A5)
\]

and the \(\hat{t}_{KHM}\) of the off-diagonal term is

\[
\hat{t}_{KHM} = i e^{-i \frac{\hbar}{\sqrt{\gamma}} \cos(q) \sum_{j}^{M} (\cos \phi_j - \phi_j)} - e^{\frac{i}{2} \cos(\phi) / \hbar} - e^{\frac{i}{2} \cos(\phi) / \hbar} \quad (A6)
\]

In the cases of A-type systems \((L = 1)\), there exists \(2V^* = 2\pi \hbar\), that is \(V^* \simeq 0.38\) for \(h = 1/8\), where the effect of the the fluctuation width of the diagonal term is saturated for the change of the potential strength \(V\) in the form of a tangent function \((A5)\). Therefore, for \(V > V^*\) the delocalization can be caused by increase in \(\epsilon\) in the off-diagonal term in the form of \(2eV\).

[45] However, there is no mathematical proof of the LDT for the wavepacket dynamics except for the localization case. In addition, it is proven that in the one-dimensional tight-binding model with the potential with a finite period the spectrum is absolutely continuous and wavepacket shows ballistic motion $m_2 \sim t^2$.
