(Dated: August 3, 2021)

In this work, the non-Markovian dynamics of excitation in the generalized Aubry-André-Harper model coupled to Ohmic-type environment, is discussed exactly by evaluating survival probability and inverse participation ratio. Contrary to the common belief that the localization would preserve the information of initial state against dissipation into environment, it is found that the strong localization can enhance the dissipation of quantum information. By a thorough examination, we show that the non-Markovianity induced by the memory effect of environment is responsible for this behavior. Under this circumstance, the exchange of energy between the system and its environment may lead to the interference in the reduced energy levels of system, which is responsible to the stability of the system. As for the strong localization, the difference between the reduced energy levels becomes large such that the environment cannot feedback enough energy into system. As a result the initial-state information dissipates eventually. This explanation is verified by the increase of the coupling strength, which reduces greatly the decaying of quantum information.

I. INTRODUCTION

A closed quantum system can display resistance to the thermalization under its own intrinsic dynamics when it is localized, e.g. induced by static disorder [1], a linear potential with spatial gradient [2], or the existence of special subspace in Hilbert state [3, 4]. Much experimental evidence for the breaking of ergodicity have been presented, e.g. in ultracold atomic fermions [5] or in superconducting systems [6]. However in practice, no realistic systems can be immune from the coupling to environment. The recent studies found that even though the system is driven to the thermal equilibrium finally, the localization decays logarithmical slowly [7]. This stretched decay of localization provides a large time window where the non-ergodic character in the system becomes apparent [8].

Whereas localization would be detrimental to transport of quantum particles in systems, it is found recently that increasing disorder can enhance the transport [9]. Furthermore, combined with the environment-induced dephasing, the localized system can display robust quantum transport [10]. These findings imply that the interplay of localization and environment-induced decoherence can intrigue complex dynamics in quantum systems. Thus it motivates us to reconsider the robustness of localization on a fundamental point that the system is dissipative because of the coupling to environment. For this purpose, we study the non-Markovian dynamics of single excitation in a one-dimensional lattices system coupled to bosonic environment. Different from Markovian treatment in previous work [2], the non-Markovian dynamics of excitation can display strong dissipation or stable oscillation, significantly dependent on the localization of initial state, as well as the coupling strength of system and environment. More important, we find that strong localization may enhance the decaying of excitation, rather than preserve excitation in the system. We argue that this counter intuitive feature is a consequence of the interplay of localization and non-Markovian dynamics.

The work is divided into five sections. In Sec.II the model is introduced, and the dynamical equation for excitation is derived. Then in Sec.III the time evolution of excitation is discussed for different cases, focused on the role of localization in initial state and the coupling strength. Subsequently a physical explanation for the observations is provided in Sec.IV. Finally further discussion and conclusion is given in Sec.V.

II. MODEL AND DYNAMICAL EQUATION

In this work, we focus on the open dynamics of single excitation in a generalized Aubry-André-Haper (GAAH) model with the Hamiltonian [11]

\[
H_S = \lambda \sum_{n=1}^{N} \left( c_n^\dagger c_{n+1} + c_{n+1}^\dagger c_n \right) + \Delta \frac{\cos(2\pi \beta n + \phi)}{1 - a \cos(2\pi \beta n + \phi)} c_n^\dagger c_n, \tag{1}
\]

where \(N\) denotes the number of lattice site, \(c_n(c_n^\dagger)\) is the annihilation (creation) operator of excitation at the \(n\)-th lattice site. For a quasiperiodic modulation, we chose \(\beta = (\sqrt{3} - 1)/2\) with respect of the recent experimental verification of delocalization-localization transition [9]. The onsite potential is a smooth function of parameter \(a\) in open interval \(a \in (-1, 1)\). When \(a = 0\), Eq. (1) reduces to the standard Aubry-André-Haper model [12], in which a delocalization-localization phase transition can
occur when $\Delta = 2\lambda$. Whereas for $a \neq 0$, GHH model exhibits an exact mobility edge (ME) following the expression [11]:

$$aE_c = \text{sign}(\lambda) (2|\lambda|-|\Delta|).$$

$E_c$ is a special value of eigenenergy, which separates the extended eigenstates from the localized ones. The coexistence of localized and delocalized state is a typical feature of GAAH model, which leads to the complex dynamics of excitation in the system. In order to avoid the boundary effect, the periodic boundary condition $c_n = c_{n+N}$ is adopted. Since the work focuses on the robustness of the system, $\phi = \pi$ is chosen without loss of generality. For simplicity, $\hbar = \lambda = 1$ is supposed in the following discussion. Recently, the localization properties of GAAH model has been investigated experimentally in optical lattices [13].

In order to find the non-Markovian dynamics of localization in GAAH, the bosonic reservoirs with different frequency $\omega_c$ is introduced as environment. The Hamiltonian can be written as

$$H_B = \sum_k \omega_k b_k^\dagger b_k,$$

where $b_k$ ($b_k^\dagger$) is the annihilation (creation) operator of reservoir $k$. The system is coupled to the environment via particle-particle exchanging,

$$H_{int} = \sum_{k,n} (g_k b_k c_n^\dagger + g_k^* b_k^\dagger c_n),$$

where $g_k$ is the coupling amplitude between the system and reservoir $k$. The complexity of dynamics is determined by the spectral density

$$J(\omega) = \sum_k |g_k|^2 \delta(\omega - \omega_k),$$

which characterizes the energy structure of the system plus the system-environment interaction. In this work, Ohmic-type spectral density is chosen,

$$J(\omega) = \eta \omega \left( \frac{\omega}{\omega_c} \right)^{s-1} e^{-\omega/\omega_c},$$

where $\eta$ characterizes the coupling strength between the system and the environment. Eq. [6] characterizes the damping movement of electrons in a potential, and can simulate a large class of thermal environment. The environment can be classified as sub-Ohmic ($s < 1$), Ohmic ($s = 1$) or super-Ohmic ($s > 1$) [14]. Without loss of generality, we focus on the Ohmic case ($s = 1$) since it characterizes the typical dynamics of dissipation in the system. $\omega_c$ is the cutoff frequency of the environment spectrum, beyond which the spectral density starts to fall off; hence, it determines the regime of reservoir frequency, which is dominant for dissipation. In general, the value of $\omega_c$ depends on the specific environment. In this work, $\omega_c = 10$ is set in order to guarantee that the highest energy level in $H_S$ is embedded into the continuum of environment.

Now it is ready to derive the dynamical equation for single excitation initially in the system. Conventionally at any time $t$ the state of system plus environment can be written as

$$|\psi(t)\rangle = \left( \sum_{n=1}^N \alpha_n(t)|1_n\rangle \otimes |0\rangle^{\otimes M} + |0\rangle^{\otimes N} \otimes \left( \sum_{k=1}^M \beta_k(t)|1_k\rangle \otimes |0\rangle^{\otimes (M-1)} \right) \right),$$

where $|1_n\rangle = c_n^\dagger|0\rangle$ denotes the occupation of the $n$-th lattice site, $|0\rangle$ is the vacuum state of $b_k$, and $|1_k\rangle = b_k^\dagger|0\rangle_k$, and $M$ denotes the number of the reservoir mode. Substituting Eq. (7) into Schrödinger equation and reducing $\beta_k(t)$, one can get the integrodifferential equation for $\alpha_n(t)$,

$$\frac{i}{\hbar} \frac{\partial}{\partial t} \alpha_n(t) = [\alpha_{n+1}(t) + \alpha_{n-1}(t)] + \Delta \cos(2\pi \beta n + \phi)\alpha_n(t)$$

$$-i \sum_{n=1}^N \int_0^t d\tau \alpha_n(\tau) f(t-\tau),$$

where $i$ is the square root of negative 1, and the non-Markovian memory kernel $f(t-\tau)$ is defined as

$$f(t-\tau) = \int_0^\infty d\omega J(\omega) e^{-i\omega(t-\tau)}.$$

It is evident that the population amplitude of $\alpha_n(t)$ is correlated significantly to its past values. For Ohmic-type spectral density Eq. [6], $f(t-\tau) = \frac{\eta}{\omega_c^{s-1}} \frac{\Gamma(s+1)}{\Gamma(s+1/\omega_c^{s+1})}$.

It should be pointed out that the Markovian limit can be obtained by replacing $\alpha_n(\tau)$ in Eq. [8] with its current value $\alpha_n(t)$. As a result, the last term on the right hand of Eq. [7] contributes a positive term to Eq. [8], which depicts the decaying of $\alpha_n(t)$. Thus we claim in this place that the non-Markovian property is responsible completely for the exotic dynamics of excitation, as will shown in the following.

### III. Non-Markovian Dynamics of Excitation

As for the existence of ME, we focus on the evolution of excitation initially in the highest excited eigenstate (ES) of $H_S$ [13]. Thus from Eq. [2], the higher eigenenergy means the stronger localization in the eigenstate [11]. Moreover since ES is embedded in the continuum of environment, the occurrence of bound state is excluded in the discussion [17]. We introduce the survival probability $SP = |\langle \psi(t)|ES \rangle|^2$ to characterize the influence of dissipation. In addition, the inverse participation ratio (IPR), defined as $\text{IPR} = \sum_{n=1}^N |\alpha_n(t)|^4$, is also calculated to find the varying of localization in the system.
Both of the two quantities have been used extensively to explore the dynamics of localization in disordered many-body systems [10].

The following discussion focuses on two cases, \( a = 0 \) and \( a = 0.5 \) respectively, which display the distinct feature of localization in the system. For the former case, a delocalization-localization transition can occur in the system when \( \Delta = 2 \), which separates the delocalized phase (\( \Delta < 2 \)) from the localized phase (\( \Delta > 2 \)). Whereas the transition is absent in the latter, and instead ME \( E_C \) happens, which separates the localized eigenstates (\( E > E_C \)) from the extended eigenstates (\( E < E_C \)).

Finally it should be pointed out that it is difficult to find the analytical solution to Eq. (8) Thus we have to rely on the numerics. Our method is to transform the integral into the summation with suitable step length. By solving Eq. (8) iteratively, \( \alpha_n(t) \) can be determined for any times \( t \). However, the computational cost grows exponentially as the number of step and the lattices number \( N \). In order to find the long-time behavior, \( N \) is restricted to 21 such that \( t = 1200 \) can be reached in a moderate cost of computation.

A. \( a = 0 \)

In Fig. 1 the time evolution of SP and IPR is plotted for different values of \( \Delta \). As shown in Fig. 1(a1) and (a2), both of SR and IPR display fast decaying when the system is in delocalized phase (\( \Delta < 2 \)). With the increase of \( \Delta \), it is evident that the decay of IPR becomes very slow with the increase of \( \Delta \), as shown in Fig. 1(a2). Meanwhile, a stable oscillation is developed for SP, as shown for \( \Delta = 2.5 \) in Fig. 1(a1) and for \( \Delta = 3.4 \) in Fig. 1(b1). As for ES is localized in these cases, it manifests the robustness of localization against dissipation. This finding is different from the previous results in Refs. [7], where the localized system would become thermal equilibrium eventually because of the coupling to environment. This difference can be attributed to the influence of memory kernel \( f(t-\tau) \), which would lead to the interference of the back action of excitation in environment to the system and the decaying into environment.

However with further increase of \( \Delta \), we find that both SP and IPR present significant decaying, as shown for \( \Delta = 6, 10 \) in Fig. 1(b1) and (b2). This strange feature means that the strong localization may enhance the lost of quantum information, rather than preserve quantum information against decoherence. However, one can also note that in contrast to the super-exponential decaying of extended state, the strong localized state decays exponentially instead. In experiments, it implies that one can still differentiate the extended phase from the localized one by checking the process of decoherence.

B. \( a = 0.5 \)

In order to gain further understanding of the localization-enhance dissipation, we now focus on the case of \( a \neq 0 \). A distinguished feature in this situation is the occurrence of ME [11]. Consequently the energy eigenstate of \( H_S \) may behave localized or extended, decided by the relationship of the eigenvalue \( E \) and \( E_c \) in Eq. (2). As a result one cannot classify the system as localized or extended simply. It should be pointed out that dependent on the sign of \( a \), the maximal localized state can be exchanged between the ground state and the highest excited state of \( H_S \) [11]. Since the work focuses on the interplay of localization and dissipation, \( a = 0.5 \) is
chosen, and thus ES has the largest localization. As for $a < 0$, the ground state is localized maximally instead. With respect of $\omega_k > 0$, the coupling to environment would renormalize it as a dissipationless bound state. So this special situation is excluded in our discussion.

In Fig. 2, the evolution of SR or IPR is presented for different values of $\Delta$. Two selected cases $\Delta = 0.5, 0.76$ are studied first, for which ES is extended or has the eigenvalue very closed to $E_\alpha$. It is evident that both SP and IPR decay slowly when $\Delta = 1$. As expected, one can note that both SP and IPR decay slowly when $\Delta = 1$. Moreover it is found that the oscillation tends to disappear or becomes decaying when $\Delta$ deviates from the two special values, as shown in Fig. 1 and 2. Thus it is crucial for the understanding of localization-enhanced dissipation to disclose the underlying mechanism of the stability.

In general, the periodic oscillation of SP is a manifestation of the interference of eigenstates, which makes the system populating on the eigenstates temporally. In order to verify this point, it is necessary to determine the eigenstates by solving Schrödinger equation

$$H |\psi_E\rangle = E |\psi_E\rangle,$$  (10)

in which $H = H_S + H_B + H_{int}$ is the total Hamiltonian, and the eigenstate can be written generally as $|\psi_E\rangle = \left(\sum_{n=1}^N \alpha_n |1\rangle^0 \otimes (N-1) \right) \otimes |0\rangle^M \otimes |0\rangle^N \otimes \left(\sum_{k=1}^M \beta_k |1\rangle_k \otimes (M-1)\right)$. Substitute $|\psi_E\rangle$ into Eq. (10) and reduce $\beta_k$, and then

$$\left(\alpha_{n+1} + \alpha_{n-1}\right) = \Delta \cos(2\pi \beta_n + \phi) \alpha_n + \int_0^\infty \frac{J(\omega)}{E - \omega} \sum_{n=1}^N \alpha_n = E\alpha_n. \quad \text{(11)}$$

Through solving Eq. (11), the reduced energy eigenstate and eigenvalue of the system can be obtained, which is dominant over the evolution of excitation.

In Appendix, Eq. (11) is solved numerically for $a = 0, \Delta = 2.5$ and $a = 0.5, \Delta = 1$ respectively. It is found that the difference between the real parts of the two highest energy level is consistent to the frequency of oscillation of SR in numerics; For $a = 0$ and $\Delta = 2.5$, the frequency of SR is $\sim 2\pi/77.8 = 0.08076$. Whereas the difference between real parts of the former two largest $E$ is $2.952238 - 2.882305 = 0.069933$. Similarly for $a = 0.5$ and $\Delta = 1$, the frequency of SR is $\sim 2\pi/57.6 = 0.109083$.

**Figure 2:** (Color online) The logarithmic plotting for the time evolution of SP (right column) and IPR (left column) when $a = 0.5$ for different values of $\Delta$. The initial state is chosen as the highest excited state of $H_S$ in all plots. The other parameters are same as those in Fig. 1.
The difference is $2.705113 - 2.605926 = 0.099187$. The slight discrepancy can be attributed to the numerical errors. In addition, the overlap of initial state and the largest reduced eigenstate can also be evaluated; For $a = 0, \Delta = 2.5$, $|\langle ES|\psi_{ES}\rangle|^2 = 0.498776$, which is consistent to the extremal maximum of SP 0.496809, extracted from the data in Fig. 1. Similar feature can also be observed for $a = 0.5, \Delta = 1$; it is found that $|\langle ES|\psi_{ES}\rangle|^2 = 0.4471716$, which is consistent to the extremal maximum of SP 0.405453, extracted from the data in Fig. 2. Moreover, it is found that the imaginary part of highest reduced level has a magnitude of order $\sim 10^{-6}$ for both $a = 0$ and $a = 0.5$. It means that the decaying of SP and IPR is so slow that both of them cannot display discernable descent in numerical simulation of up to $t \sim 10^3$.

The influence of coupling strength $\eta$ is also explored by the comparative plotings of SP and IPR for $\eta = 0.1$ (solid line) and $\eta = 0.5$ (dashed line) respectively. It is evident that as for $a = 0, \Delta = 2.5$ and $a = 0.5, \Delta = 1$, both SP and IPR show negligible changing, as shown in Fig. 3(b) and (c). In contrast, the significant rising can be observed when $\Delta = 6$, as shown in Fig. 3(c) and (f). Moreover a significant oscillation is developed with the increase of $\eta$ in Fig. 3(c). As for the extended initial state, the influence of $\eta$ seems weak, as shown in Fig. 3(a) and (d). This picture implies that the non-Markovianity may be crucial for the robustness of localization against dissipation. This point is verified analytically by evaluating the reduced energy levels; In Table 1, the first two excited energy levels are presented for $\eta = 0.1$ and 0.5 respectively, in order to explain the observation in Fig. 3. It is evident that the increase of $\eta$ significantly compresses the imaginary part of the reduced energy level $E$ when $\Delta$ is large. In contrast, the influence is negligible when the initial state is extended.

Conclusively we have shown that the robustness of SP or IPR is a consequence of the interference of the reduced energy levels. Physically the interference comes from the periodic exchange of energy between the system and environment, which can be enhanced by the increasing of $\eta$. Another important observation is the distinct response of the extended state and localized state to the non-Markovianity. As shown in the previous discussion, the extended state is always fragile even if the non-Markovianity is occurring. In contrast, the stability of localized state can be significantly enhanced by the non-Markovianity. Physically this difference could be attributed to the property of equilibrium of the state; the extended state would tend to become equilibrated with its surroundings, while the localized state would keep the property of nonequilibrium.

**V. CONCLUSION**

In conclusion, the non-Markovian dynamics of excitation, initially embedded in the highest excited state of GAAH model coupled to Ohmic-type environment, is studied by evaluating SP and IPR. By solving the dynamical equation exactly, SP and IPR can be obtained for any times. An important observation is that not only the stable oscillation, but also the enhanced decaying can be found for SP and IPR when the localization of initial state is moderate or strong, measured by $\Delta$. This finding is distinct from the common intuition that localization would protect the quantum information against dissipation. In order to gain further understanding, the reduced energy levels of system is determined analytically by solving the reduced Schrödinger equation. It is found that the stable oscillation of SP and IPR is a result of the interference of the reduced energy levels. The interference characterizes the periodic exchange of energy between system and environment, which stems from the
memory effect of environment. As a consequence, the environment can feedback appropriate energy into the system, which induces the periodic population of system. However, the exact treatment of particle interaction can modify greatly the dynamics of the system. In the following discussion, this choice guarantees that the role of interaction is to delocalize the system by the duality induced by the quasi periodicity. Finally it must be admitted that the appearance of the localization-enhanced dissipation can occur only if the initial state is localized. As for extended state, it always behaves dissipation. The increase of strength of disorder $\Delta$ can only stretch the process of dissipation. This feature also implies the robustness of ME, which is protected by the duality induced by the quasi periodicity.

Finally it must be admitted that the appearance of particle interaction can modify greatly the dynamics of excitation in the system. However, the exact treatment of non-Markovian dynamics in interacting many-body systems is a challenging task. In another point, the recent studies on the disordered many-body systems have shown that the role of interaction is to delocalize the system.

With respect that the localization-enhanced dissipation is state-dependent only, one may conjecture that it may survive from the interaction.

Appendix

The integral $\int_0^\infty d\omega \frac{J(\omega)}{E-\omega}$ in Eq. (11) is divergent for $E > 0$. Thus in order to determine $E$, we apply the Sokhotski-Plemelj (SP) formula to evaluate the integral. The SP formula is written as

$$\lim_{\epsilon \to 0} \int_{x-x_0}^{x+x_0} \frac{1}{x-x_0 + \pm i \epsilon} = P \int_{x-x_0}^{x+x_0} \frac{1}{x-x_0} \mp \frac{i \pi}{2} \delta(x-x_0),$$

(A1)

in which $P$ denotes the principle value of Cauchy. Thus one gets

$$\lim_{\epsilon \to 0} \int_0^\infty d\omega \frac{J(\omega)}{\omega - E - i \epsilon} = \frac{1}{\pi} \int_0^\infty d\omega \frac{J(\omega)}{\omega - E} + \frac{i \pi}{2} J(E).$$

(A2)

In this derivation, the case of $-i \epsilon$ is chosen. As shown in the following discussion, this choice guarantee $E$ has a negative imaginary part which characterizes the dissipation in dynamics.

The reduced energy $E$ can be decided by finding zero points of coefficient determinant in Eq. (11). In Fig. A1 the contour plots for the vanishing real (solid-blue line) and imaginary (dashed-red line) of coefficient determinant are presented respectively for (a) $a = 0, \Delta = 2.5$ and (b) $a = 0.5, \Delta = 1$, in which the crossing point of the two lines corresponds to the value of reduced energy $E$. The two inner panels in each plot show details for the former two $E$ with largest real part. The rigorous value of $E$ and the energy state can be decided by recurrently solving eigenequation Eq. (10). Finally one gets $E_1 = 2.952238 \times 10^{-5}$, $E_2 = 2.882305 \times 5.312399 \times 10^{-5}$ for case (a) and $E_1 = 2.705113 \times 7.091364 \times 10^{-5}$, $E_2 = 2.605926 \times 6.029 \times 10^{-5}$ for case (b).

Table I: The comparison of the first two excited energy levels with $\eta = 0.1$ and $\eta = 0.5$, which are obtained by solving Eq. (11). The parameters are chosen as the same in Fig. 3.
