Continuous-variable quantum key distribution exploits coherent measurements of the electromagnetic field, i.e., homodyne or heterodyne detection. The most advanced security analyses developed so far relied on idealised mathematical models for such measurements, which assume that the measurement outcomes are continuous and unbounded variables. As any physical measurement device has finite range and precision, these mathematical models only serve as an approximation. It is expected that, under suitable conditions, the predictions obtained using these simplified models are in good agreement with the actual experimental implementations. However, a quantitative analysis of the error introduced by this approximation, and of its impact on composable security, have been lacking so far. Here we present a theory to rigorously account for the experimental limitations of realistic heterodyne detection. We focus on asymptotic security against collective attacks, and indicate a route to include finite-size effects.

I. INTRODUCTION

Quantum key distribution (QKD) is the art of exploiting quantum optics to distribute a secret key between distant authenticated users. Such a secret key can then be used as a one-time pad to achieve unconditionally secure communication. First introduced in the 80’s by Bennett and Brassard [1], QKD is now at the forefront of quantum science and technology. By encoding information into the quantum electromagnetic field, QKD allows for secure communication through an insecure communication channel, a task known to be impossible in classical physics.

Continuous-variable (CV) QKD denotes a family of protocols where information is carried by the phase and quadrature of the quantum electromagnetic field. A variety of protocols exist that differ in how the quadratures encode the information [2, 3]. However, when it comes to decoding, all CV QKD protocols exploit coherent representations of the field, i.e., either homodyne or heterodyne detection [4]. The strategic importance of CV QKD indeed relies on this choice of measurement, as homodyne and heterodyne detection are scalable and mature technologies. This is in contrast with discrete-variable architectures, that require bulky, high-efficiency, and low-noise single-photon detectors [5].

When modeling a CV QKD protocol, it is customary to describe its measurement outcomes as continuous and unbounded variables. In these models, homodyne detection measures one quadrature of the field, and heterodyne detection provides a joint measurement of both quadrature and phase [6]. These simplified models have revealed to be powerful tools due to their continuous symmetry. In fact, two fundamental theoretical results rely on this symmetry: the optimality of Gaussian attacks [7, 8, 9] and the Gaussian de Finetti reduction [10]. However, this symmetry is not exact and is broken by real-world physical devices. In fact, in actual experimental implementations, homodyne and heterodyne detection yield digital outcomes and have a finite range. While it is expected that, in some limit, the idealised measurement models describe actual physical devices well, up to now a quantitative analysis of this approximation was lacking. In particular, it was not known how to quantify the impact of these non-idealities on the secret key rate.

In this work we finally fill this important conceptual gap and present a theory to quantify the secret key rates obtained in actual QKD protocols that exploit actual measurement devices. While we focus on heterodyne detection, the same approach may be as well applied, with some modifications, to homodyne detection.

II. THE MODEL

In one-way QKD, one user (conventionally called Alice) prepares quantum states and sends them to the other user (called Bob), who measures them by heterodyne detection. The transmission is through an insecure quantum channel that may be controlled by an adversary (called Eve). This general scheme defines a prepare & measure (PM) protocol. In this work we focus on discrete-modulation CV QKD protocols where, on each channel use, Alice prepares a coherent state \( |\alpha\rangle \) whose amplitude is sampled from an \( M \)-ary set, \( \{\alpha_x\}_{x=0,...,M-1} \) with probabilities \( P_x \). This defines Alice’s \( M \)-ary random variable \( X \). An example is quadrature phase shift keying (QPSK), obtained for \( M = 4 \) and setting \( \alpha_x = \alpha x^2 \), \( P_x = 1/4 \).

In order to prove the security of these protocols, we need to consider a different, though formally equivalent, scenario where a bipartite quantum state \( \rho_{AB} \) is distributed to Alice and Bob, of which Eve holds a purification. This kind of setting defines an entanglement-based (EB) protocol. It is sufficient to prove the security of the EB protocol, from which the security of the PM protocol follows. In the EB protocol, the state \( \rho \) is a two-mode state, where \( a, a^\dagger \) and \( b, b^\dagger \) are the annihilation and cre-
ation operators for Alice and Bob, respectively. The EB representation of discrete-modulation CV QKD protocols is discussed in detail in [24].

In this work we focus on collective attacks, which are identified by the assumption that, over $n$ uses of the quantum channel, the state factorises and has the form $\rho_{AB}^\otimes n$.

On the receiver’s side, we assume that Bob measures by applying heterodyne detection. Ideally, heterodyne detection is a joint measurement of the field’s quadrature ($q$) and phase ($p$), whose output can be described as a complex variable $\beta = (q + ip)/\sqrt{2}$. Ideal heterodyne detection, applied on a state $\rho$, yields a continuous and unbounded output, with probability density $\frac{1}{\pi} \langle |\beta\rangle |\rho|\beta\rangle$, where $|\beta\rangle$ is the coherent state of amplitude $\beta$. In contrast, actual experimental realisations of heterodyne detection have measurement outcomes that are confined to a region in phase space, $\beta \in \mathcal{R}(R)$ and hence have a finite range. Here we assume that the region $\mathcal{R}(R)$ is defined by the condition $q,p \in [-R, R]$, for some $R > 0$. Furthermore, we consider a digitisation of this measurement such that each quadrature assumes $d = 2^n$ values, with each value corresponding to a unique $n$-bit string. This is obtained by binning the values of $q \in [-R, R]$ into $d$ non-overlapping intervals. For simplicity, we consider intervals of equal size,

$$I_j = [-R + 2(j - 1)R/d, -R + 2jR/d],$$

for $j = 1, \ldots, d$. The output $j$ is then associated to the event $q \in I_j$, which, in turn, we associate with the central value $q_j = -R + (j - 1)R/d + jR/d$. The same digitisation, when applied to both $q$ and $p$, yields a description of realistic heterodyne detection as a measurement with $d^2$ possible outputs. This defines Bob’s variable $Y$, which is a discrete random variable and assumes $d^2$ values. These discrete values can be conveniently labeled using the central points of each interval, i.e., $\beta_{jk} = (q_j + ip_k)/\sqrt{2}$.

If Bob obtains the average state $\rho_B$, then the probability of measuring $\beta_{jk}$ is

$$P_{jk} = \int_{\beta \in I_{jk}} \frac{d^2 \beta}{\pi} \langle |\beta\rangle |\rho_B|\beta\rangle,$$  

where the complex interval $I_{jk}$ is defined in such a way that $\beta \in I_{jk}$ if and only if $q \in I_j$ and $p \in I_k$, and $d^2 \beta = \frac{1}{4} dqdp$. Finally, there is a non-zero probability

$$P_0(R) = 1 - \int_{\beta \in \mathcal{R}(R)} \frac{d^2 \beta}{\pi} \langle |\beta\rangle |\rho_B|\beta\rangle$$

of an inconclusive measurement, when the amplitude lies outside the measurement range.

III. ASYMPTOTIC SECURITY OF CV QKD

In the limit that $n \to \infty$, the secret key rate (i.e., the number of secret bits that can be distilled per transmission of the signal) is given by the Devetak-Winter formula [14]:

$$r_\infty = \xi I(X; Y) - \chi(Y; E)_\rho,$$

where $I(X; Y)$ is the mutual information between Alice and Bob, and $\chi(Y; E)_\rho$ is the Holevo information (quantum mutual information) between Bob and Eve (here we assume reverse reconciliation on Bob’s data, which is optimal for long-distance communication). The factor $\xi \in (0, 1)$ accounts for the finite efficiency of error correction. While $I(X; Y)$ only depends on $X$ and $Y$, $\chi(Y; E)_\rho$ also depends on the quantum information held by Eve, which in general cannot be estimated directly. Likely, the property of extremality of Gaussian states [11, 12] allows us to write the upper bound

$$\chi(Y; E)_\rho \leq f_\chi(\gamma_A(\rho), \gamma_B(\rho), \gamma_{AB}(\rho)),$$

where $f_\chi$ is a known function of the covariance matrix (CM) elements [13]

$$\gamma_A(\rho) := \frac{1}{2} \text{Tr}[(a^\dagger a + a a^\dagger)\rho],$$

$$\gamma_B(\rho) := \frac{1}{2} \text{Tr}[(b^\dagger b + b b^\dagger)\rho],$$

$$\gamma_{AB}(\rho) := \frac{1}{2} \text{Tr}[(a^\dagger b^\dagger + a b)\rho].$$

In conclusion, estimating the CM suffices to obtain a universal upper bound on the Holevo information, which holds for collective attacks in the limit of $n \to \infty$. The asymptotic key rate is thus bounded as

$$r_\infty \geq \xi I(X; Y) - f_\chi(\gamma_A(\rho), \gamma_B(\rho), \gamma_{AB}(\rho)).$$

Since $f_\chi$ is an increasing function of $\gamma_A$ and $\gamma_B$, and a decreasing function of $\gamma_{AB}$ [13], estimating upper bounds on $\gamma_A$, $\gamma_B$ and a lower bound on $\gamma_{AB}$ suffices to bound the asymptotic key rate.

IV. PHOTON-NUMBER CUTOFF

The technical difficulties in the analysis of CV QKD arise because the quantum information carriers reside in a Hilbert space with infinite dimensions. To overcome this issue we need to impose a cutoff in the Hilbert space. As we do not want to impose such a cutoff in an arbitrary way, we follow a data-driven approach. Define the following operators on Bob’s side:

$$W_R = \int_{|\beta| > 2R^2} \frac{d^2 \beta}{\pi} |\beta\rangle \langle |\beta|,$$

and

$$V_R = \sum_{n > 2R^2} |n\rangle \langle n|,$$

where $|n\rangle$ is the Fock state with $n$ photons. Renner and Cirac showed that [10]

$$V_R \leq 2W_R.$$
From the experimental data, Bob can estimate the probability $P_B(R)$ as in Eq. \((17)\). We then obtain
\[ \text{Tr}(V R P_B) \leq 2 \text{Tr}(W R P_B) \leq 2 P_B(R). \] (13)
This shows that the probability that Bob receives more than $2R^2$ photons is no larger than $2P_B(R)$. The gentle measurement lemma \([17]\) then yields
\[ \|\rho_{AB} - \tau_{AB}\|_1 \leq 2 \sqrt{2P_B(R)}, \] (14)
where
\[ \tau_{AB} = \frac{(I \otimes \Pi)\rho_{AB}(I \otimes \Pi)}{\text{Tr}(\Pi \rho_B)}, \] (15)
and
\[ \Pi = I - V_R = \sum_{n \leq 2R^2} |n\rangle \langle n| \] (16)
is the projector onto the subspace with up to $2R^2$ photons, and $\| \cdot \|_1$ is the trace norm. In conclusion, though $\rho$ is generic, an experimental estimation of the probability $P_B(R)$ allows us to determine the proximity of $\rho$ to a state with finite-dimensional support.

V. CONTINUITY OF THE HOLEVO INFORMATION

In the EB representation, the two-mode state $\rho_{AB}$ is measured, on Bob’s side, by heterodyne detection. In general, $\rho_{AB}$ resides in a Hilbert space with infinite dimensions. However, as discussed above, it is close in trace norm to the state $\tau_{AB}$ in Eq. \((15)\). Note that $\tau_{AB}$ has a finite support in a space of dimensions $M \times [2R^2 + 1]$.

The Holevo information is a continuous functional of the state. By applying the continuity bound of Shirokov we obtain \([18]\)
\[ \chi(Y; E)_R \leq \chi(Y; E)_\tau + \delta, \] (17)
where
\[ \delta = \epsilon \log d^2 + 2(1 + \epsilon) \log (1 + \epsilon) - 2 \epsilon \log \epsilon, \] (18)
and $\epsilon = 2 \sqrt{2P_B(R)}$.

This implies that, by paying a small penalty, which is linear in $\epsilon$, we can replace $\rho$ with the finite-dimensional state $\tau$. We thereby obtain the following bound on the asymptotic key rate,
\[ r_\infty \geq \xi I(X; Y) - f_X(\gamma_A(\tau), \gamma_B(\tau), \gamma_{AB}(\tau)) - \delta. \] (19)

By comparing with Eq. \((9)\), we note that this bound depends on the CM of $\tau$. However, $\tau$ is only a mathematical tool and does not describe the state that is prepared and measured in the experimental realisation of the protocol. The only state that is physically accessible is $\rho$. Below we show how we can estimate the CM of $\tau$ by measuring $\rho$ with realistic heterodyne detection. In particular, our goal is to find an upper bound on $\gamma_B(\tau)$ and a lower bound on $\gamma_{AB}(\tau)$.

VI. SEMIDEFINITE PROGRAMMING

In the EB representation, Alice prepares the bipartite state
\[ \Psi_{AA'} = \sum_{x=0}^{M-1} \sqrt{P_x} |\psi_x\rangle_A \otimes |\alpha_x\rangle_{A'}. \] (20)
Alice keeps the mode $A$ and sends $A'$ to Bob. The vectors $|\psi_x\rangle$ are mutually orthogonal and span an $M$-dimensional subspace of Alice’s mode $A$. Note that Alice’s reduced state is
\[ \rho_A = \sum_{x, x' = 0}^{M-1} \sqrt{P_x P_{x'}} \langle \alpha_x | \alpha_{x'} \rangle |\psi_x\rangle \langle\psi_{x'}| =: \sigma. \] (21)

The equivalence with the PM protocol is obtained by noticing that a projective measurement of $A'$ in the basis $\{ |\psi_x\rangle \}_{x=0, \ldots, M-1}$ prepares the mode $A$ in the coherent state $|\alpha_x\rangle$ with probability $P_x$. A good choice for the vectors $|\psi_x\rangle$’s is presented in Ref. \([24]\).

Our goal is to bound the key rate using the data collected by Alice and Bob, where Bob’s measurement is modeled as realistic heterodyne detection with finite range and precision. We follow the seminal ideas of Refs. \([19, 20]\) and achieve this by semi-definite programming (SDP). As an example, we apply linear SDP, as done in Ref. \([19]\), to bound the CM of the state $\tau$, but we remark that our theory can also apply to non-linear SDP as in Ref. \([20]\).

Let $\rho_B(x)$ be the state received by Bob given that Alice sent $|\alpha_x\rangle$. Alice and Bob can experimentally estimate the probability mass distribution
\[ P_{jk|x} = \int_{I_{jk}} \frac{d^2 \beta}{\pi} \langle \beta | \rho_B(x) | \beta \rangle, \] (22)
which can be used as a constraint in the SDP that we later formulate. We can also consider linear combinations of the parameters $P_{jk|x}$, which obviously are also experimentally accessible. Here we consider the quantities
\[ v := \sum_{j,k=1}^d |\beta_{jk}|^2 P_{jk}, \] (23)
\[ c := \sum_{x=0}^{M-1} \sum_{j,k=1}^d \frac{\alpha_x \beta_{jk} + \alpha_k \beta_{jk}}{2} P_{jk|x}, \] (24)
(where $\bar{\cdot}$ denotes complex conjugation) which are the expectation values of the variance and the covariance between Alice’s and Bob’s variables.

Note that the parameters $v = \text{Tr}(V \rho)$ and $c = \text{Tr}(C \rho)$
are the respective expectation values of the operators

\[ V = \sum_{j,k=1}^d |\beta_{jk}|^2 \int_{\mathcal{I}_{jk}} \frac{d^2 \beta}{\pi} |\beta\rangle\langle \beta|, \]

(25)

\[ C = \frac{1}{2} \sum_{x=0}^{M-1} \sum_{j,k=1}^d \alpha_x \beta_{jk} |\psi_x\rangle\langle \psi_x| \otimes \int_{\mathcal{I}_{jk}} \frac{d^2 \beta}{\pi} |\beta\rangle\langle \beta| + \text{h.c.}. \]

(26)

Similarly, we can write \( 1 - P_0(R) \) as the expectation value of the operator

\[ U = \int_{\beta \in \mathcal{R}(R)} \frac{d^2 \beta}{\pi} |\beta\rangle\langle \beta|. \]

(27)

Denote as \( \tilde{\gamma}_B(\tau) \) the optimal value of the semidefinite program

\[
\begin{align*}
\text{maximize} \quad & \quad \frac{1}{2} \text{Tr}[\Pi(b'b + bb')\Pi \rho_B] \\
\text{subject to} \quad & \quad \text{Tr}(V \rho_B) \leq v, \\
& \quad \text{Tr}(U \rho_B) \geq 1 - P_0(R), \\
& \quad \text{Tr}(\rho_B) = 1.
\end{align*}
\]

Taking into account normalisation, we obtain the upper bound on \( \gamma_B(\tau) \),

\[ \gamma_B(\tau) \leq \frac{\tilde{\gamma}_B(\tau)}{\text{Tr}(\Pi \rho_B)} \leq \frac{\tilde{\gamma}_B(\tau)}{1 - 2P_0(R)}. \]

(29)

Similarly, consider the optimal value \( \tilde{\gamma}_{AB}(\tau) \) of the semidefinite program

\[
\begin{align*}
\text{minimize} \quad & \quad \frac{1}{2} \text{Tr}[(a' \Pi b \Pi + a \Pi b \Pi) \rho_{AB}] \\
\text{subject to} \quad & \quad \text{Tr}[(I \otimes V) \rho_{AB}] \leq v, \\
& \quad \text{Tr}(C \rho_{AB}) \geq c, \\
& \quad \text{Tr}[(I \otimes U) \rho_{AB}] \geq 1 - P_0(R), \\
& \quad \text{Tr}_{B}(\rho_{AB}) = \sigma, \\
& \quad \text{Tr}(\rho_{AB}) = 1,
\end{align*}
\]

(30)

from which we obtain the lower bound

\[ \gamma_{AB}(\tau) \geq \frac{\tilde{\gamma}_{AB}(\tau)}{\text{Tr}[(I \otimes \Pi) \rho_{AB}]} \geq \tilde{\gamma}_{AB}(\tau). \]

(31)

Note that the projector \( \Pi \) does not appear in all the constraints. For this reason, we cannot simply replace \( \rho \) with \( \tau \), and the optimal values of the semidefinite programs remain defined in an infinite dimensional Hilbert space. However, when numerically solving these semidefinite programs, we find solutions of the form \( \Pi \rho_B \Pi \) and \((I \otimes \Pi) \rho_{AB}(I \otimes \Pi)\). This suggests that the presence of the projector operator \( \Pi \) in the objective function suffices to make the problem effectively finite-dimensional (see the Appendix for further detail). To numerically evaluate the optimal values of these semidefinite programs, we derive the corresponding dual programs, which are more efficient to evaluate, and detail this in the Appendix.

VII. QPSK: SECRET KEY RATES

As a concrete example, we apply our theory to QPSK encoding, where \( \alpha_x = |\alpha|^2 \) and \( P_x = 1/4 \), for \( x = 0, 1, 2, 3 \). To align with the symmetry of our model of realistic heterodyne detection, we set \( \alpha = |\alpha|e^{i\pi/4} \). For completeness, we discuss the EB state in detail in the Appendix. We simulate a Gaussian channel from Alice to Bob, which is characterised by the loss factor \( \eta \in [0, 1] \) and the excess noise variance \( u \geq 0 \).

First, we compute the expected value for the mutual information,

\[ I(X; Y) = H(Y) - H(Y|X), \]

(32)

where \( H(Y) \) is the entropy of Bob’s measurement outcome, and \( H(Y|X) \) is the conditional entropy for given input state prepared by Alice. If Alice prepares the coherent state \( |\alpha_x\rangle \), with \( \alpha_x = (q_x + ip_x)/\sqrt{2} \), then the state \( \rho_B(x) \) received by Bob is described by the Wigner function \( W_x(q,p) \), where \([8]\)

\[ W_x(q,p) = \frac{1}{\pi(2u + 1)} e^{-(q - \sqrt{u}q_x)^2 + (p - \sqrt{u}p_x)^2}/2(u + 1). \]

(33)

From this, we obtain the probability density of measuring \( \beta = (q + ip)/\sqrt{2} \) by ideal heterodyne detection,

\[ \frac{1}{\pi} \langle \beta|\rho_B(\beta)|\beta\rangle = \frac{1}{2\pi(u + 1)} e^{-\frac{(q - \sqrt{u}q_x)^2 + (p - \sqrt{u}p_x)^2}{2(u + 1)}}, \]

(34)

and, in turn, the probability of measuring \( \beta \in \mathcal{I}_{jk} \),

\[ P_{jk|x} = \frac{1}{\pi} \int_{\beta \in \mathcal{I}_{jk}} d^2 \beta \langle \beta|\rho_B(\beta)|\beta\rangle = P_{j|x} P_{k|x}, \]

(35)

where

\[
\begin{align*}
P_{j|x} &= \frac{1}{2} \text{erf} \left[ \frac{(2 + d - 2j)R + d\sqrt{\eta} q_x}{d\sqrt{2}(u + 1)} \right] \\
& \quad - \frac{1}{2} \text{erf} \left[ \frac{(d - 2j)R + d\sqrt{\eta} q_x}{d\sqrt{2}(u + 1)} \right].
\end{align*}
\]

(36)

For QPSK encoding, the conditional mutual information then reads (log in base 2)

\[ H(Y|X) = -\frac{1}{4} \sum_{x=0}^{3} \sum_{j,k=1}^d P_{jk|x} \log P_{jk|x}. \]

(37)

The probability distribution of \( Y \) is obtained by averaging over \( X \), \( P_{jk} = \frac{1}{4} \sum_{x=0}^3 P_{jk|x} \), and the entropy of \( Y \) is

\[ H(Y) = -\sum_{j,k=1}^d P_{jk} \log P_{jk}. \]

(38)
R(squares) and to the non-asymptotic regime once suitable confidence in-
security against collective attacks thus directly extends

Similarly, we compute the expected values for the esti-
mated parameters \( v \) and \( c \). From Eq. (26), we obtain

\[
\text{Tr}(\mathcal{C}_{\rho AB}) = \frac{1}{4} \sum_{x=0}^{3} \sum_{j,k=1}^{d} q_x q_j + p_x p_k P_{jk|x} \\
\text{Tr}(\mathcal{V}_{\rho B}) = \sum_{j,k=1}^{d} \frac{q_j^2 + p_k^2}{2} P_{jk}.
\]

This allows us to compute the expected asymptotic values of the constraint parameters \( v \) and \( c \), and \( P_0(R) \), and then to solve the SDPs to obtain the estimates for the CM elements \( \gamma_B(\tau) \), \( \gamma_{AB}(\tau) \). In turn, this yields a lower bound on the asymptotic secret key rate against general collective attacks. Examples are shown in Fig. 1 for \( \alpha = 0.5 \), and \( u = 0.001 \). The figure shows that, as expected, by increasing \( R \), and for \( d \) large enough, the secret key rate converges towards the value expected for ideal heterodyne detection (which has been recently computed in Ref. [24]). Our theory allows us to compute the deviation from this ideal rate in a quantitative way.

In the non-asymptotic, finite-size regime, Alice and
Bob can estimate confidence intervals for their expected variance and covariance. The constraints in the semidefinite programs can thus be replaced by

\[
\text{Tr}(\mathcal{V}_{\rho B}) \leq v + \delta v, \quad \text{Tr}(\mathcal{C}_{\rho AB}) \geq c - \delta c, \quad \text{and \ Tr}(\mathcal{U}_{\rho B}) \geq 1 - P_0(R) - \delta P.
\]

The security against collective attacks thus directly extends to the non-asymptotic regime once suitable confidence intervals are obtained. Other finite-size effects due to the

VIII. CONCLUSIONS

In CV QKD information is decoded by a coherent mea-
surement of the quantum electromagnetic field, i.e., ho-
maryne or heterodyne. These are mature technologies and represent the strategic advantage of CV QKD over discrete-variable architectures. This applies to both con-
tinuous [2, 3, 10, 17] and discrete-modulation protocols [4, 19, 24].

Ideal homodyne and heterodyne detection, which are measurements of the quadratures of the field, possess a continuous symmetry that plays a central role in our theoretical understanding of CV QKD. It underpins the property of extremality of Gaussian attacks [3, 11, 12] and allows for the Gaussian deFinetti reduction [10]. However, this symmetry is only approximate in realis-
tic homodyne and heterodyne detection that are implemented in actual experiments. This follows directly from the finite range and precision that actual measurement devices must have. While it is expected that, in practice, these measurements are well approximated by their ideal-
as models in some regimes, a quantitative assessment of the error introduced by this approximation, and of its impact on the secret key rate, has so far been elusive.

Here we fill this gap and present a theory to quantify the security of CV QKD with real, imperfect, heterodyne detection. We combine the continuity of the Holevo in-
formation [15] with a data-driven photon-number cutoff [16] and the gentle measurement lemma [17], to estimate of the quadrature covariance matrix using semidefinite programs. We expect that a similar approach, though with some modifications, may be developed to analyse non-ideal homodyne detection.

This result is not only conceptually important, but will also help to improve the reliability of practical CV QKD protocols, both with continuous and discrete modulation. In fact, to obtain robust bounds on the secret key rates, the practitioner of CV QKD needs to carefully assess the impact of non-idealities in the measurement devices, including the effects of finite range and precision considered in this work.

Appendix A: Holevo information

Consider a two-mode state $\rho_{AB}$ shared between Alice and Bob. We denote $a$, $a^\dagger$, and $b$, $b^\dagger$ the annihilation and creation operators on Alice’s and Bob’s mode, respectively. Their local quadrature and phase operators are $q_A = (a + a^\dagger)/\sqrt{2}$, $p_A = (a - a^\dagger)/(i\sqrt{2})$, $q_B = (b + b^\dagger)/\sqrt{2}$, $p_B = (b - b^\dagger)/(i\sqrt{2})$. The symmetrically ordered CM $\gamma'(\rho)$ of the two-mode state $\rho$ is defined as

$$\gamma'(\rho) = \left( \begin{array}{cc} A & C \\ C^T & B \end{array} \right),$$

where $A$, $B$, $C$ are $2 \times 2$ matrices. We denote as $\nu_+$ and $\nu_-$ the symplectic eigenvalues of $\gamma'(\rho)$. When Bob measures his mode by ideal heterodyne detection, the conditional state of Alice has CM

$$\gamma'(\rho_{A|B}) = A - C(B + 1/2)^{-1}C^T.$$

We denote $\nu_0$ as the symplectic eigenvalue of $\gamma(\rho_{A|B})$.

The property of extremality of Gaussian states yields the following bound on the Holevo information:

$$\chi(Y; E)_\rho \leq F_\chi(\gamma'(\rho)),$$

where

$$F_\chi(\gamma'(\rho)) = g(\nu_+ - 1/2) + g(\nu_- - 1/2) - g(\nu_0 - 1/2),$$

and for any $x > 0$ the function $g$ is defined as

$$g(x) := (x + 1)\log_2(x + 1) - x\log_2 x,$$

and $g(x) := 0$ if $x = 0$.

It is possible to show \cite{12} that the function $F_\chi$ increases if we replace $\gamma'(\rho)$ with the matrix $\gamma(\rho)$

$$\chi(Y; E)_\rho \leq F_\chi(\gamma(\rho)).$$

Note that

$$\gamma_A(\rho) := \frac{1}{2}\text{Tr}[(a^3 + a^2a^\dagger)\rho] = \text{Tr}[\rho\Sigma(q_A^2, p_A^2)],$$

$$\gamma_B(\rho) := \frac{1}{2}\text{Tr}[(b^3 + b^2b^\dagger)\rho] = \text{Tr}[\rho\Sigma(q_B^2, p_B^2)],$$

$$\gamma_{AB}(\rho) := \frac{1}{2}\text{Tr}[(a^3b^3 + ab\rho)] = \text{Tr}[\rho\Delta].$$

We therefore define

$$F_\chi(\gamma_A(\rho), \gamma_B(\rho), \gamma_{AB}(\rho)) := F_\chi(\gamma(\rho)).$$

Appendix B: QPSK: EB representation

In the PM representation, Alice prepares the state $|\alpha_x\rangle$ with probability $P_x = 1/4$, for $\alpha_x = \alpha e^{i\pi/4}$ and $x = 0, 1, 2, 3$, where we put $\alpha = |\alpha|e^{i\pi/4}$.

The average state prepared by Alice is

$$\rho_{A'} = \frac{1}{4} \sum_x |\alpha_x\rangle\langle\alpha_x|.$$

We can expand this state in the number basis. Its $(n, n')$ entry is

$$\rho_{A'}^{nn'} = \frac{e^{-|\alpha|^2}}{4} \sum_x \frac{\alpha^n\bar{\alpha}^{n'}}{\sqrt{n!n'!}} e^{ix(n-n')\pi/2}$$

$$= \frac{e^{-|\alpha|^2}}{4} \frac{\alpha^n\bar{\alpha}^{n'}}{\sqrt{n!n'!}} \left(1 + e^{(n-n')\pi/2}\right) \left(1 + e^{(n-n')\pi}\right).$$

That is, $\rho_{A'}^{nn'} = 0$ unless $n - n'$ is a multiple of 4, in which case,

$$\rho_{A'}^{nn'} = \frac{e^{-|\alpha|^2}}{4} \frac{\alpha^n\bar{\alpha}^{n'}}{\sqrt{n!n'!}}.$$

As this state is invariant under rotation of $\pi/2$ in phase space, the eigenvectors have the form, for $y = 0, 1, 2, 3$,

$$|\phi_y\rangle = \sum_{n\geq0} c_{y,n} |y + 4n\rangle.$$

From

$$\sum_x |\alpha_x\rangle\langle\alpha_x| = \sum_y \lambda_y |\phi_y\rangle\langle\phi_y|,$$

we obtain

$$\sqrt{\lambda_y} c_{y,n} = \frac{e^{-|\alpha|^2/2}}{\sqrt{(y + 4n)!}} \alpha^{y+4n}.$$
By imposing normalisation, we find
\[ |\phi_y \rangle = \frac{e^{-|\alpha|^2/2}}{\sqrt{\lambda_y}} \sum_{n \geq 0} \frac{\alpha^{y+4n}}{(y+4n)!} |y+4n\rangle, \] (B9)
where
\[ \lambda_y = e^{-|\alpha|^2} \sum_{n \geq 0} \frac{|\alpha|^{2(y+4n)}}{(y+4n)!}. \] (B10)
Explicitly,
\[ \begin{align*}
\lambda_0 &= \frac{e^{-|\alpha|^2}}{2} (\cosh \alpha^2 + \cos \alpha^2), \\
\lambda_1 &= \frac{e^{-|\alpha|^2}}{2} (\sinh \alpha^2 + \sin \alpha^2), \\
\lambda_2 &= \frac{e^{-|\alpha|^2}}{2} (\cosh \alpha^2 - \cos \alpha^2), \\
\lambda_3 &= \frac{e^{-|\alpha|^2}}{2} (\sinh \alpha^2 - \sin \alpha^2).
\end{align*} \] (B11-B14)

We define the purification of the state \( \rho_{AB} \) through its Schmidt decomposition,
\[ |\Psi\rangle_{AA'} = \sum_y \sqrt{\lambda_y} |\bar{\phi}_y\rangle |\phi_y\rangle, \] (B15)
where
\[ |\bar{\phi}_y\rangle = \frac{e^{-|\alpha|^2/2}}{\sqrt{\lambda_y}} \sum_{n \geq 0} \frac{\alpha^{y+4n}}{(y+4n)!} |y+4n\rangle. \] (B16)
It is easy to check that
\[ |\alpha_x\rangle = \sum_y e^{ixy\pi/2} \sqrt{\lambda_y} |\bar{\phi}_y\rangle, \] (B17)
which we can invert to obtain
\[ \sqrt{\lambda_y} |\phi_y\rangle = \sum_x \frac{e^{-ixy\pi/2}}{4} |\alpha_x\rangle. \] (B18)

We can then write
\[ |\Psi\rangle_{AA'} = \sum_y \sqrt{\lambda_y} |\bar{\phi}_y\rangle |\phi_y\rangle \] (B19)
\[ = \sum_{x y} \frac{e^{-ixy\pi/2}}{4} |\bar{\phi}_y\rangle |\alpha_x\rangle \] (B20)
\[ = \frac{1}{2} \sum_x |\psi_x\rangle |\alpha_x\rangle, \] (B21)
where we have defined
\[ |\psi_x\rangle = \frac{1}{2} \sum_y e^{-ixy\pi/2} |\bar{\phi}_y\rangle. \] (B22)

Appendix C: Operators in the number representation

We now express the operators that appear in our semidefinite programs in the basis \( \{|\psi_x\rangle \otimes |n\rangle \}_{x=0,. . .,3,n=0,. . .,\infty} \), where \( |n\rangle \)'s are the number states of Bob's side, satisfying \( b\dagger b|n\rangle = n|n\rangle \).

The operator \( \rho_B \) is a density matrix of one bosonic mode. We can express it in the number basis, \( \{|n\rangle\}_{n=0,. . .,\infty} \), as
\[ \rho_B = \sum_{n,n'=0} \rho_{nn'} |n\rangle \langle n'|. \] (C1)

Similarly, \( \rho_{AB} \) reads
\[ \rho_{AB} = \sum_{x x',n n'} \sum_{n,n'=0} \rho_{xx'n'n'} |\psi_x\rangle \langle \psi_{x'}| \otimes |n\rangle \langle n'|. \] (C2)

The operator \( \Pi \) projects into the subspace with at most \( N = \lfloor 2 R^2 \rfloor \) photons, i.e.,
\[ \Pi = \sum_{n=0}^{N} |n\rangle \langle n|. \] (C3)
Therefore,
\[ \frac{1}{2} \Pi (b\dagger b + bb\dagger) \Pi = \sum_{n=1}^{N} \left( n + \frac{1}{2} \right) |n\rangle \langle n|. \] (C4)

The operator \( \mathcal{V} \) is
\[ \mathcal{V} = \sum_{jk} |\beta_j\rangle^2 \int_{j \in J} \frac{d^2 \beta}{\pi} |\beta\rangle \langle \beta| = \sum_{n,n'=0} \nu_{nn'} |n\rangle \langle n'|, \] (C5)
where
\[ \nu_{nn'} = \sum_{jk} |\beta_j\rangle^2 \int_{j \in J} \frac{d^2 \beta}{\pi} e^{-|\beta|^2} \beta^n \bar{\beta}^{n'} \sqrt{n!n'!}. \] (C6)

Note that by symmetry, \( \nu_{nn'} = 0 \) unless \( n-n' \) is multiple of 4. Also by symmetry, \( \mathcal{V} \) is a real matrix in the Fock basis.

Similarly, we have
\[ U = \int_{\beta \in \mathbb{R}(\mathbb{R})} \frac{d^2 \beta}{\pi} |\beta\rangle \langle \beta| = \sum_{n,n'=0} u_{nn'} |n\rangle \langle n'|, \] (C7)
with
\[ u_{nn'} = \int_{\beta \in \mathbb{R}(\mathbb{R})} \frac{d^2 \beta}{\pi} e^{-|\beta|^2} \beta^n \bar{\beta}^{n'} \sqrt{n!n'!}. \] (C8)
The operator \( C \) in the objective function reads
\[
\frac{1}{2} (a^\dagger \Pi b + a \dagger \Pi b^\dagger \Pi)
\]
\[
= \frac{1}{2} \sum_{xx'} \sum_{n,n'} \sum_{n=1}^{N} \sqrt{\alpha} (\psi_x|a|\psi_{x'}) (\psi_{x'}|\psi_x| \otimes |n-1\rangle \langle n|) + \sqrt{\alpha} (\psi_{x'}|a|\psi_x) (\psi_x|\psi_{x'}| \otimes |n-1\rangle \langle n|)\), \quad \text{(C9)}
\]
\[
= \frac{1}{2} \sum_{xx'} \sum_{n,n'} \sqrt{\alpha} (\psi_x|a|\psi_{x'}) (\psi_{x'}|\psi_x| \otimes |n-1\rangle \langle n|) + \sqrt{\alpha} (\psi_{x'}|a|\psi_x) (\psi_x|\psi_{x'}| \otimes |n-1\rangle \langle n|)\). \quad \text{(C10)}
\]

To compute this, first note that
\[
\langle \bar{\phi}_{y-1}|a|\bar{\phi}_y \rangle = \sqrt{\frac{\lambda_{y-1}}{\lambda_y}}, \quad \text{(C11)}
\]
from which we obtain
\[
\langle \psi_x|a|\psi_{x'} \rangle = \frac{1}{4} \sum_{yy'} \sum_{n=0}^{N} e^{iy_1 x_1/2} e^{-iy'_{1} x'_1/2} \langle \bar{\phi}_{y-1}|a|\bar{\phi}_{y'} \rangle \quad \text{(C12)}
\]
\[
= \frac{1}{4} \sum_{y=0}^{N} e^{i(y-1) x_1/2} e^{-i y'_{1} x'_1/2} \langle \bar{\phi}_{y-1}|a|\bar{\phi}_{y'} \rangle \quad \text{(C13)}
\]
\[
= \sqrt{\frac{\lambda_{y-1}}{\lambda_y}} \quad \text{(C14)}
\]
\[
= \alpha \frac{1}{4} \sum_{y=0}^{N} e^{i(y-1) x_1/2} e^{-i y'_{1} x'_1/2} \langle \bar{\phi}_{y-1}|a|\bar{\phi}_{y'} \rangle \quad \text{(C15)}
\]

Finally, the operator \( C \) has components
\[
C_{xx'nn'} = \frac{1}{2} \delta_{xx'} \alpha \sum_{j,k=1}^{d} \beta_{jk} \int_{I_{jk}} \frac{d^2 \beta}{\pi} e^{-|\beta|^2} \frac{\beta_n \beta_{n'}}{\sqrt{n!n!'!}} (D7)
\]
\[
+ \frac{1}{2} \delta_{xx'} \alpha \sum_{j,k=1}^{d} \bar{\beta}_{jk} \int_{I_{jk}} \frac{d^2 \beta}{\pi} e^{-|\beta|^2} \frac{\beta_n \beta_{n'}}{\sqrt{n!n!'!}} (D8)
\]
\[
(C16)
\]

The operator can thus be written as
\[
C = \frac{1}{2} (A^\dagger \otimes B + A \otimes B^\dagger) , \quad \text{(C17)}
\]
where
\[
A = \sum_{x=0}^{3} \alpha_x |\psi_x \rangle \langle \psi_x | , \quad \text{(C18)}
\]
\[
B = \sum_{nn'} \sum_{j,k=1}^{d} \beta_{jk} \int_{I_{jk}} \frac{d^2 \beta}{\pi} e^{-|\beta|^2} \frac{\beta_n \beta_{n'}}{\sqrt{n!n!'!}} |n\rangle \langle n'| . \quad \text{(C19)}
\]

Note that, by symmetry, \([B]_{nn'} = 0 \) for \( n - n' \) even. Also by symmetry, the entries of \( C \) are all real.

**Appendix D: Semidefinite programming**

In the main body of the paper we have formulated the following optimisation problems
\[
\text{maximize} \quad \rho \geq 0 \quad \frac{1}{2} (\Pi(b^\dagger b + bb^\dagger) \Pi, \rho) \quad \text{(D1)}
\]
\[
\text{subject to} \quad \langle V, \rho \rangle \leq v, \quad \langle U, \rho \rangle \geq 1 - P_0(R), \quad \langle I, \rho \rangle = 1.
\]
and
\[
\text{minimize} \quad \rho \geq 0 \quad \frac{1}{2} (a \Pi^\dagger a \Pi + a^\dagger \Pi b^\dagger b \Pi, \rho) \quad \text{(D2)}
\]
\[
\text{subject to} \quad \langle I \otimes V, \rho \rangle \leq v, \quad \langle C, \rho \rangle \geq c, \quad \langle I \otimes U, \rho \rangle \geq 1 - P_0(R), \quad \text{(D3)}
\]
\[
\text{Tr}_B(\rho) = \sigma, \quad \langle I, \rho \rangle = 1, \quad \text{(D4)}
\]
where \( \langle A, X \rangle = \text{Tr}(A^\dagger X) \) denotes the Hilbert Schmidt inner product. To derive the corresponding dual programs which will be more numerically efficient to evaluate, we revisit duality theory for SDP with mixed constraints. Given any semidefinite program of the form
\[
\text{minimize} \quad X \geq 0 \quad \langle C, X \rangle \quad \text{(D5)}
\]
\[
\text{subject to} \quad \langle A_i, X \rangle \leq a_i, \quad \langle B_j, X \rangle = b_j, \quad \text{(D6)}
\]
where \( C, A_i, B_j \) are Hermitian matrices, the Lagrangian is given by
\[
L = \langle C, X \rangle + \sum_{i} y_i (\langle A_i, X \rangle - a_i) + \sum_{j} z_j (\langle B_j, X \rangle - b_j), \quad \text{(D7)}
\]
where \( y_i \geq 0, z_j \in \mathbb{R} \). By linearity of inner products, we can rewrite the Lagrangian as
\[
L = \langle C + \sum_{i} y_i A_i + \sum_{j} z_j B_j, X \rangle - \sum_{i} y_i a_i - \sum_{j} z_j b_j , \quad \text{(D8)}
\]
The Lagrange dual is then given by
\[
\text{maximize} \quad y_1 \geq 0, z_j \geq 0 \quad - \sum_{i} y_i a_i - \sum_{j} z_j b_j \quad \text{(D9)}
\]
\[
\text{subject to} \quad C + \sum_{i} y_i A_i + \sum_{j} z_j B_j \geq 0. \quad \text{(D10)}
\]

The Lagrange dual of \( [D1] \) is thus given by
\[
\text{minimize} \quad y_1, y_2 \geq 0, z \in \mathbb{R} \quad y_1 v - y_2 (1 - P_0(R)) + z \quad \text{(D11)}
\]
\[
\text{subject to} \quad - \frac{1}{2} (b^\dagger b + bb^\dagger) \Pi + y_1 V - y_2 U + zI \geq 0. \quad \text{(D12)}
\]
Strong duality in this case holds because the inequality constraints can be strictly feasible, and the Slater constraint qualification holds.

The Lagrange dual of (D2) can be written as

\[
\begin{align*}
\text{maximize} & \quad y_1 c - y_2 v + y_3 (1 - P_0(R)) - y_4 \phi(z) \\
\text{subject to} & \quad \frac{1}{2} (a \Pi b \Pi + a^\dagger \Pi b^\dagger \Pi) + \kappa(y, z) \geq 0.
\end{align*}
\]

where

\[
\kappa(y, z) = -y_1 C + y_2 V - y_3 U + y_4 I + \sum_{h,k} z_{h,k} Z_{h,k},
\]

\[
\phi(z) = \sum_{h \geq k} z_{h,k} \text{Re}(\sigma_{h,k}) + \sum_{h < k} z_{h,k} \text{Im}(\sigma_{h,k}),
\]

and \(Z_{h,k} = E_{h,k} \otimes I_B\) when \(h \geq k\) and \(Z_{h,k} = F_{k,h} \otimes I_B\) when \(h < k\), with

\[
\begin{align*}
E_{h,k} &= \frac{|k\rangle\langle h| + |h\rangle\langle k|}{2}, \\
F_{h,k} &= i \frac{|k\rangle\langle h| - |h\rangle\langle k|}{2}.
\end{align*}
\]

To solve numerically these optimisation problems we need to impose a cutoff to Bob’s Hilbert space, and work within a finite dimensional space of dimensions \(\text{dim}\), containing no more than \((\text{dim} - 1)\) photons on Bob’s side. The value of \(\text{dim}\) can be arbitrarily large, as long as it is larger than \(N + 1\), where \(N = \lceil 2R^2 \rceil\) is determined by the rank of the projector \(\Pi\). However, our numerical results suggest that it is sufficient to put \(\text{dim} = N + 1\). As an example, Fig. 2 shows the optimal values for (D7) and (D8) as a function of \(\text{dim}\).
