Team Power and Hierarchy: Understanding Team Success

Abstract: Teamwork is cooperative, participative and power sharing. In science of science, few studies have looked at the impact of team collaboration from the perspective of team power and hierarchy. This research examines in depth the relationships between team power and team success in the field of Computer Science (CS) using the DBLP dataset. Team power and hierarchy are measured using academic age and team success is quantified by citation. By analyzing 4,106,995 CS teams, we find that high power teams with flat structure have the best performance. On the contrary, low-power teams with hierarchical structure is a facilitator of team performance. These results are consistent across different time periods and team sizes.

Keywords: Team Power; Power Hierarchy; Power level; Team Success; Scientific Collaboration; Artificial Intelligence

INTRODUCTION

To understand teamwork and its success, it is imperfect if we ignore the notion of power. As the prominent social scientist Bertrand Russell highlighted in his book that power is a fundamental concept in social science “in the same sense that energy is the fundamental concept in physics” (Russell, 1938, p.10). Power is manifested through cooperation (Blau, 1964, 1977). As long as more than one person works on a given task, power starts to influence every step of the process and the ultimate performance. Power is pervasive and often camouflaged in our society (French & Raven, 1959). But power is an essential, unavoidable, yet unrecognized element of collaboration (Galinsky et al., 2008).

Scientific teams have increasingly dominated the process of knowledge production (Wuchty et al., 2007). Individuals with different skills and diverse levels of
experience need to form a team to tackle complex problems and stay competitive (Becker & Murphy, 1992). When collaboration is increasingly common, power dynamics are consistently present in team activities (Dahl, 1957). Researchers are eager to find out the best way to form teams and improve team effectiveness in scientific settings (for review, Hall et al., 2018), but few pay attention to the role of power dynamics in scientific endeavors. John Heider once emphasized the importance of power in collaboration, saying, “Since all creation is a whole, separateness is an illusion. Like it or not, we are team players. Power comes through cooperation, independence through service, and a greater self through selflessness” (Heider 1997, p.77). For effective and successful scientific collaborations, all types of power should be recognized, acknowledged, and balanced to avoid power struggles and achieve optimal performance.

Greer et al. (2017) conceptualized team power as the combination of two variables: power hierarchy and power level. Hierarchy can help or hurt team effectiveness in different contexts and task types (Anderson & Brown, 2010; Bunderson et al., 2016). Hierarchy can improve cooperation, coordination, and role clarity, but it can also breed inequality and resentment. Greer and van Kleef (2010) found that power level moderates the effect of power hierarchy on team performance in their study of a single multinational financial company. When team power is at its lowest, some group members have substantially more power than others have, power hierarchy may facilitate conflict resolution by creating order and improving coordination. On the other hand, power hierarchy can create a perception of inequality and injustice between high-power individuals, heightening intragroup competition. Whether the findings on the complex relationships between team power and success from organizational science and behavioral science can be generalized to teams in science is still unknown.
This paper takes Computer Science (CS) as the test field to study the relationships between team power and team success. CS, especially data science and Artificial Intelligence (AI), has been widely applied in various domains, ranging from drug discovery (Gao et al., 2019), medical imaging diagnosis (Han et al, 2021), to fraud detection (Dunis et al., 2016). CS has been developed by teams of scientists, thus team power dynamics are inevitable. Power can play a crucial role to empower or disarm team members. Hierarchy can improve the coordination efficiency of a team, but it can also diminish the capability for solving conflicts, making the communication from bottom to top ineffective (Leavitt, 2003). Both highly flexible coordination and communication are key to building confidence when facing the uncertainty of CS research (Fountaine et al., 2019; Thamhain et al. 2004). Team power and hierarchy are highly sensitive to the size of a team, which is shaped by the tradeoff between benefits and risks (Fortunato et al., 2018). An interview with Andrew Ng, founder and CEO of Landing AI and former lead of the Google Brain AI research team, shows that a small team with AI experts and domain specialists to act quickly and fail fast is the good way to start (Insights Team, 2019). Fierce competition in CS also demands the quick turnover of tested experiments and requires adaptability to unknown future directions. However, big teams are more capable of solving “big problems.” For example, the breakthrough discovery of Higgs boson relied on CERN, the largest particle physics research center hosting thousands of scientists from all over the world. AI research is experiencing a rapid shift (Tang et al., 2020), reaching the stage of deep learning (Tang et al., 2020), and becomes more method-oriented (Frank et al., 2019b) and application-driven (Yuan et al., 2020). Thus, CS teams need to adapt to the changes of topics and directions over time.

Practicing modern science requires an unprecedented level of teamwork (Bozeman & Youtie, 2017). This project is among the first to use large-scale datasets to study the dynamics of team power from millions of scientific teams. This paper aims to
understand the complex relationships between team power and success in the field of Computer Science from the following three perspectives: (1) power and hierarchy in teams, (2) power and hierarchy in teams of different sizes, and (3) power and hierarchy in different time stages of CS. This paper starts with the introduction and definition of team power. The literature review section outlines related work from behavioral science, management science, philosophy in science, and science of science. The methodology section details data collection and measures for team power and hierarchy. The result section illustrates patterns of combinations of team power and hierarchy, as well as their relationships with team success. The conclusion section summarizes the findings and highlights future directions.

**THE DEFINITION OF TEAM POWER**

Team power can be defined as whether one team member will obey/agree or resist/disagree with the thoughts/activities of others in the same team (Magee & Galinsky, 2008). There are three types of team power: power over, power with/to, and power for (Boulding, 1989). *Power over* is to control over resources for collaboration using force, coercion or threat, this is adversarial rather than collaborative. *Power over* is a tool to benefit the needs of a smaller group rather than the whole. *Power with/to* is to draw the collective capabilities of members to accomplish things together. It can be enacted by building and strengthening shared power for a team. *Power for* extends the collaborative membership to stakeholders who are not team members. It builds capacity for underpowered stakeholders. These three types of power exist in almost all collaborative endeavors which means that most collaborations use some force, some mutual exchange or negotiation, or some additional inclusion. There are two additional types of power that can affect team work: personal and positional (French & Raven, 1959). Personal power includes expertise (e.g., *expert power* when a person has knowledge or expertise which is valued by organizations or individuals),
referent authority (e.g., referent power when an individual can generate admiration and loyalty of others, such as charismatic leaders), and rights to access resources (e.g., informational power that a person has control and access to important resources, connections and information). Positional power (e.g., leaders) is acquired by a person through a position within an organization which can be used to punish or reward team members.

In team collaboration, there are two primary types of team power structures: team power hierarchy and team power level (Greer et al., 2017). Hierarchy is defined as an implicit or explicit rank order of individuals or groups with respect to a valued social dimension (Magee & Galinsky, 2008) or as vertical differences between team members in their possession of team resources and their levels of authority for decision making (Greer et al., 2018). Team power hierarchy can be hierarchical (e.g., top down or concentrated power) or flat (e.g., everyone holds similar levels of power). Power level is conceptualized as the average control of resources (e.g., important decision-making), average expertise level, or average position (Greer et al., 2011; Groysberg et al., 2011; Greer & Van Kleef, 2010). Team power level can be high (e.g., manager teams) or low (e.g., entry-level employee teams).

RELATED WORK

Power and Hierarchy in Teams

Despite strongly expressed beliefs in many societies that emphasize equality of opportunity, hierarchy is a persistent and possibly unavoidable part of social life (Bunderson et al., 2016). The extent to which hierarchy is beneficial or harmful for teams is an unsettled debate in current literature. The functionalist view (for reviews, see Anderson & Brown, 2010; Greer et al., 2018) highlights the functional benefits of hierarchy as: 1) creating a psychologically safe environment so that lower power
members have less responsibility; 2) motivating performance through hierarchy-related incentives (e.g., promotions, economic benefits, admiration); and 3) supporting division of labor and coordination (e.g., people with higher or lower powers work on different tasks). Meta-analytic evidence shows that through coordination-enabling processes, hierarchy can be beneficial to team performance.

For example, in a lab experiment, when members had collaborative planning, teams with a clear expertise hierarchy could integrate information more effectively to analyze problems in a terrorist plot (Woolley et al., 2008). Also, age-diverse teams were shown to have in-depth discussions and share task-relevant information when team need for cognition was high (Kearney et al., 2009).

However, these coordination-enabling results from controlled contexts do not necessarily exist in complex and dynamic real-world settings. The negative sides of the hierarchy are based on: 1) conflict theory, which argues that inequality over limited resources is more likely to trigger struggles in teams (for review, see Greer et al., 2017); and 2) the salience of power, which suggests that subordinates might not want to voice their opinions even though hierarchy can give people safety and certainty. Especially when leaders’ power over others is salient, members can be afraid to speak up and thus risk inhibiting the collective learning and information sharing needed to make adaptive changes (Edmondson, 2002). Indeed, equal and turn-taking communication can contribute to collective intelligence because people can take full advantage of their skills and knowledge (Woolley et al, 2010).

Whether hierarchy is beneficial to team performance depends, in part, on task type. Greer et al. (2018) reviewed three aspects of team tasks which would influence the function of hierarchy: task ambiguity, task complexity, and task interdependence.

When tasks are more predictable, routine, and stable, teams prefer hierarchical structures (Anderson & Brown, 2010). In contrast, if tasks are ambiguous, requiring
more flexibility and creativity, flatter structures are better. Ronay et al. (2012) showed that hierarchy can improve team performance if team members deal with interdependent tasks (e.g., basketball), but can decrease team performance if team members perform independent tasks (e.g., baseball). Compared with baseball (Simmons, 2012), basketball requires more coordination and cooperation among team members. In professional basketball teams from the NBA, differentiation of players’ pay and participation (e.g., playing time and starting lineup), a proxy of power hierarchy, can increase team performance by enhancing team processes (Halevy et al., 2012).

Whether developing a new algorithm, or applying existing algorithms to a specific domain, scientific research is non-routine and complex, and it requires demonstrating novelty by advancing the state of the art. In such scientific tasks, member voice and participation are critical, and power dispersion could be flat to allow members with complementary skills to work together. But, the situation is not fully true in academia because power hierarchy is pervasive in academic activities. Merton (1973) claimed that scientific community is controlled by gerontocracy, where the elderly sets the rules in scientific domains. As scientists become more senior, their positions in the hierarchy tends to rise, they gain access to more resources, and thus can increase their productivity and impact, following the principles of the Matthew effect (Merton, 1973). Researchers of different ages have different roles in the division of labor, with younger scholars often making more “technical” contributions while senior ones focus on “conceptual” tasks (Larivière et al., 2016). In some scientific fields, junior researchers appear in the first position whereas veteran or highly ranked ones tend to appear in the last, usually playing the supervisory roles (Costas & Bordons, 2011).

Another key to reconciling the two different perspectives on the effect of power hierarchy is power level. By considering power level and power hierarchy together,
Greer and Van Kleef (2010) found that hierarchy was useful for teams with low power, but problematic for teams with high power. In the low-power teams, individuals are more likely to accept hierarchy because clear roles could help them better know what to do. For low-power individuals, a lack of hierarchy creates a power vacuum that gives rise to conflicts and power struggles. However, in high-power teams, members prefer balanced power without hierarchy because members with high power are more prone to be competitive, aggressive, jealous, and sensitive when power differences exist within the team (Greer et al., 2011). For example, in science, if a senior full-time professor is paired with several junior students, then the paper is more likely to be in the high-impact publications (Bales et al., 2014), which stresses the importance of mentorship. Mentoring in academia is dominated by the intergenerational relationship that mentor and mentee are from different generations with a wide age gap (Satterly et al., 2018). In the organizational behavior field, Greer et al. (2011) did field studies within a financial company to test the effect of power level on team performance. They found that a team made up of high power people (e.g., a management team), performs worse than a team consisting of low position power people (e.g., secretarial teams) while collaborating in a logic puzzle game. This is because, when people with high power work together, they are more likely to have intragroup conflicts. For lower power level teams, like aircrews or rifle squads, a highly hierarchical setting with military leaders and commands is necessary (Goodwin et al., 2018). To avoid the disadvantages of power centralization, they design effective training interventions to improve coordination and performance across units (Salas et al., 1995).

*Power and Hierarchy in Large Teams and Small Teams*

Team size plays an important role in team performance. As a parameter in a model for the assembly of creative teams, team size could determine team outcomes (Guimera et al., 2015). As team size becomes larger (Wuchty et al., 2007), there is a trade-off
between solving big problems and having practical burdens (Fortunato et al., 2018). Large teams enable clear division of labor and specialization in complex tasks particularly when there is a high degree of certainty about the tasks to be accomplished (Meyer & Schroeder, 2015; Whitley, 2000). Small teams are more agile, which can lead to more effective communication and adaptability (Katzenback & Smith, 1993). Large teams tend to have more citations (Wuchty et al., 2007; Larivière et al., 2014), earn prestigious awards, and receive more funding (Adams et al., 2005). Even though large teams may receive more attention, Wu et al. (2019) showed that innovation does not scale up with large teams. Hall et al., (2018) reviewed that the ideal team size is six to nine members, which is a manageable size.

Large teams have extra cognitive resources because they can be more diverse in skills and knowledge than small teams (Bantel & Jackson, 1989). However, large teams likely produce additional affective conflicts (Amason & Sapienza, 1997) and process conflicts (Behfar et al., 2011) due to increased communication costs (Staats et al., 2012) and decreased relational support (Mueller, 2012). Conflicts and struggles mediate the interactive effects of team power level and hierarchy on team performance (Greer & Van Kleef, 2010). Therefore, we need to exclude the effect of team size to study the relationship between hierarchy and team performance. For example, Woolley et al. (2010) found that collective intelligence is strongly correlated with equity rather than hierarchy in their experiments. They also replicated the same result in teams consisting of two to five people. Similarly, when examining the role of team power and hierarchy amidst team conflicts, Greer et al. (2011) and Bunderson et al. (2016) controlled team size. Team performance might be influenced by other factors besides the team power indicators proposed in this paper, and here we control team size as a possible influential factor of papers’ citations.

Power and Hierarchy over Time
According to Yin & Wang (2017), time helps us understand paradigm shifts, identify breakthroughs and sleeping beauties, understand resource allocation, and predict future citation impact. In the AI field, by analyzing AI research from arXiv between 1993 and 2019, Tang et al. (2020) observed the pace of AI innovations from four stages: embryo, stable, machine-learning and deep-learning stage. Before 1980, AI research typically made references not only to computer science, mathematics, but also to social sciences, including philosophy, geography and arts. However, after that time, AI has relied more heavily on mathematics and computer science, indicating more emphasis on developing methods. Other social science disciplines find that it is difficult to track AI papers that are increasingly published in highly specialized outlets (Frank et al., 2019b). Therefore, we need to consider the temporality of CS teams, i.e., how teams evolve over time.

As McGrath et al. argued, “Rather than static, groups are inherently dynamic systems, operating via processes that unfold over time”. (McGrath et al., 2000, p.98). Accordingly, a holistic and longitudinal design may best capture group process and performance. As time goes by, the effect of surface-level diversity (e.g., demographic variables) on team outcomes would diminish compared with deep-level diversity (e.g., psychological variables) (Harrison et al., 2002). Since we measure team power and hierarchy via career age, we need to consider how this demographic characteristic affects team performance over time. Laboratory studies have several constraints, which are different from “real-world” team processes over time. Even though researchers design games to illustrate how equal or hierarchical team power influences the process of cooperation in lab experiments (Woolley et al., 2008; Greer et al., 2011), limited time is available to observe their long-term performance. However, time might influence the performance of power hierarchy on team function (Martínez-Córcoles et al., 2021). At an early stage, teams might need a hierarchical structure, like a powerful leader, for close guidance. But the process is gradual, since
team members need some time to adapt to each other. In later stages, members could be involved naturally in communication, sharing decision-making under the guidance of a leader. Therefore, a long-term experiment observation could provide us more fine-grained metadata about user behaviors and far more valid results. In the regression analyses, we overcome time effects to capture more accurate associations between team power indicators and team success.

**Team Success in Computer Science**

Many studies have examined the success of Computer Science teams from the perspective of the individual, publication, and institution (Fiala & Tutoky, 2017). Yuan et al. (2020) found that CS, especially AI, is experiencing a shift from theory-oriented to application-driven. Also, distinguished CS scientists have high mobility in job positions which spark their productivity in publications after changing institutions. In addition to talents, Tang et al. (2020) analyzed the rapid pace of AI innovation using another two indicators: AI publication number and publication updates. Firstly, as more newcomers join the AI community, they breed more innovative ideas. Secondly, the number of AI preprints in arXiv has increased dramatically over time. Thirdly, the acceleration of refining, improving, and updating processes suggests that AI researchers have frequent trial-and-error lifecycles. Frank et al. (2019b) calculated the Gini coefficient of AI papers, authors, and citations across institutions. They found that the diversity of AI research decreases based on these metrics. This reflects the power concentration of AI, which is caused by preferential attachment between privileged institutions and conferences. The CS field is becoming exceedingly hierarchical and is dominated by a few organizations.

CS is a knowledge intensive field and is fully driven by innovations (Zhai et al., 2021). AI is one critical subfield of CS. AI teams focus on AI+X, where X is a domain or an application which AI will be applied to. AI teams typically contain data scientists,
data engineers, and applied scientists; sometimes even product managers and end users are included (Insights Team, 2019). How to incorporate these members with diverse skills and backgrounds into CS teams deserves our attention. Previous research focuses on the patterns of scientific collaboration in computer science teams from different perspectives. For example, Bu et al. (2018a) concluded that heterogeneous teams (e.g., diverse career age) benefit more from persistent collaboration than homogenous teams. By tracing the entire career stage of researchers in the field of computer science, Bu et al. (2018b) concluded that young scholars could maximize their success if they can accumulate some experience before working with ‘giants’. The most famous AI scientists are clustered in the same community in a cooperation network (Yuan et al., 2020). Meanwhile, collaboration between industry and academia in teams is becoming more frequent (Frank et al., 2019b).

For CS teams in tech companies, the working environment is shifting towards self-driven and self-managed rather than a traditional hierarchical team structure. Thamhain et al. (2004) surveyed 80 teams in 27 technology companies over five years. These teams were made up of managers, scientists, engineers, and technicians. They found that team structure, like power sharing among team members, is important to team effectiveness. The authors suggest that workers in tech teams prefer autonomy and freedom compared with the formal command, control and managerial power (Thamhain et al., 2003). CS teams should have the test-and-learn mentality that can turn mistakes into new discoveries. Therefore, CS teams should be agile and ready to fail (Fountaine et al., 2019). Adaptability and flexibility of teams would enable CS teams, especially AI teams, to possess a competitive edge. Just as we have summarized in the section Power and Hierarchy in Teams, researchers have conducted experiments, surveys, and observations to unpack the complex relationships between team power and success in science, sports, healthcare, organizations, and the military.
However, the patterns of team power and hierarchy for successful CS teams are not yet explored using a large-scale quantitative lens.

**METHODS**

*Data*

We use DBLP April 2020 version (https://dblp.org/), which contains journal and conference papers in computer science (Tang et al., 2008). The citation data is extracted by Tang et al. (2008) from DBLP, ACM, and MAG (i.e., Microsoft Academic Graph). First, Tang et al. (2012) disambiguated the author names in the DBLP dataset, reaching a precision rate of 83.01%. Given there still exists limitations in the name disambiguation, we delete those papers with authors’ career age above 80 based on the fact that individual scientists do not have active careers longer than most people’s lifespan. Then, we choose papers with complete information, including 4,894,063 unique paper IDs, 4,398,138 unique author IDs, and 82,226,114 total citations ranging from 1800 to 2020. Finally, by excluding solo-authored papers, we get a final dataset, providing 4,106,995 co-authored papers, 4,099,577 unique authors, 68,965,173 citations from 1800 to 2020.

*Measures*

**The Conceptualization of Power and Hierarchy**

Power can be conceptualized as job position, expertise, age, wealth, gender, race or ethnicity, ability, physical stature, and perceived intelligence (Greer & Van Kleef, 2010; Groysberg et al., 2011; Piercy, 2019). Although power can be rooted in various sources, this paper primarily focuses on age differences as a demonstration of power hierarchy in academia. Age has been historically emphasized as the basis of hierarchical power (Linton, 1936, p.118). Members may be presumably conferred
power based on age (Piercy, 2019). When people of different ages work together, old people would be given higher power or status in the hierarchy because they might have more experience, knowledge and wisdom (Harrison & Klein, 2007; Gingras et al. 2008). The gap between mentor and mentee in academia can be further enlarged by the personal power of mentors, such as knowledge, expertise, collaboration networks, access to resources, and reputation/authority (Anderson et al., 2011).

Harrison and Klein (2007) suggested that the variable age distributed within a unit, might indicate different diversities in different contexts. Prior research on age effects has considered either variety-based or separation-based diversity, but it has ignored disparity diversity. For example, age-diverse teams consist of team members who can exchange and integrate diverse task-relevant information, knowledge, or experience to enhance performance (Kearney et al., 2009). In this case, they categorize participants into different age groups and measure diversity using Blau’s (1977) index of heterogeneity. However, the isolation of some age groups from others might discourage the exchange of information and cause conflicts (Bayazit & Mannix, 2003). The separation of opinions regarding a particular event is thus measured as the standard deviation. Compared with variety-based or separation-based diversity, disparity diversity (hierarchy) emphasizes more vertical differences, which means higher-level people might have more influence on lower-level ones.

In science, we focus more on career age rather than chronological age (Amjad et al., 2017; Bu et al., 2018b). On the one hand, it is easier to measure scientists’ career age in the large-scale publication datasets compared to asking their ages directly. On the other hand, compared with physical age, career age is a better indicator for seniority since the age of earning a terminal degree varies significantly by field and by personal circumstances. In this research, we conceptualize career age differences as evidence of a power hierarchy and examine how seniority-based hierarchy affects team success.
The Operationalization of Power, Hierarchy and Team Success

Hierarchy also has other synonyms, such as disparity, dispersion, inequality, centralization, steepness, inequality, and asymmetry. Even though all of these concepts concern vertical differences within teams, the operationalization is quite different (Bunderson et al., 2016). The most common approach measuring hierarchy is centralization, which views hierarchy as the concentration of valued social assets or sources in a small group. Harrison and Klein (2007) suggested that power hierarchy belongs to disparity and should be operationalized with the Gini coefficient (Gini, 1936) or the coefficient of variation (Bedeian & Mossholder, 2000) to represent the concentration degree and vertical differences. He and Huang (2011) used the Gini coefficient to represent age inequality. The second common approach is steepness. Steepness is referred to as separation by Harrison and Klein (2007), which represents horizontal differences in positions or opinions. For example, Greer and Van Kleef (2010) measured power dispersion with the standard deviation of members’ positions in the organizational hierarchy. The difference between these two measures is that centralization focuses on the concentration of valued assets in a few members, whereas steepness is the difference aggregated across all members (Anderson & Brown, 2010). Based on the definition of hierarchy (Bunderson et al., 2016; Harrison & Klein, 2007), hierarchy not only stresses vertical difference but also the control of resources in the minority relative to the majority. Therefore, we choose to operationalize hierarchy with the Gini coefficient since this measure meets these two requirements.

In sum, we use career age (from the researcher’s first paper until the focal one) to represent his or her power in a team. The average career age of team members can serve as a proxy to measure team power. The power hierarchy is quantified by the Gini coefficient of career age of team members. Team performance is measured by the
average citations per year since the paper was published, which is a normalization of citations based on time (Abbasi & Jaafari, 2013; Zhang et al., 2019). The descriptive statistics of these variables are shown in Table 1.

RESULTS

Team Power, Hierarchy and Team Success

Figure 1 presents the average number of citations per year for a paper conditional on the combinations of its power level and hierarchy of team members. Since 26.16% of papers do not have any citation, we consider all papers including those without citations (Figure 1A) and papers with citations (Figure 1B) separately. The horizontal axis in Figure 1A-B shows 2×2 categories indicating the paper’s power level (i.e., whether this paper’s mean career age of authors is higher or lower than the median value for all papers’ mean career age) and power hierarchy (i.e., whether this paper’s Gini coefficient of career ages of its authors is higher or lower than the median value
for all papers’ Gini coefficient). Figure 1 shows that teams with high power level outperform those with low power level. The average annual citations of higher power teams (blue and orange) are larger than those of lower power ones (green and red). In Figure 1, when team power is high (blue and orange), power hierarchy is negatively associated with citations, which indicates that teams with high hierarchy will get lower citations than those with low hierarchy given all teams have high team power. The differences between mean citations are statistically significant through the independent-sample t-test for two groups in Figure 1A ($t = 35.34, p < 0.001$) and Figure 1B ($t = 30.12, p < 0.001$). The absolute value of t score represents the difference between two groups (the larger, the more difference). A positive t-score indicates the mean value of the first team is larger than that of the second team, and p value tells how significant the difference between two groups is. It indicates that power equity is a better facilitator in high-level teams. When the team power level is low (green and red), power hierarchy is positively associated with citations. The citation number of low hierarchy teams is significantly smaller than that of high hierarchy teams given all teams have low team power. The differences of mean citations are statistically significant through t-test results in Figure 1A ($t = -42.23, p < 0.001$) and Figure 1B ($t = -25.95, p < 0.001$). Since Figure 1 A and B have no significant difference, we choose all paper (i.e., papers having zero or more citations) as our dataset for the following experiments.
Note. * P < 0.05; ** P < 0.01; *** P < 0.001.

Figure 1. Team power level and hierarchy and their relationships with team success

In Figure 1, we divide high/low team power and hierarchy using the 50\textsuperscript{th} percentile. In Figure 2, we show the cutoff for high and low at different percentiles of all papers’ mean career age and Gini index: the 20\textsuperscript{th}, 40\textsuperscript{th}, 60\textsuperscript{th}, 80\textsuperscript{th}, and 100\textsuperscript{th}. As the power level increases and the hierarchy decreases, the surface becomes dark red and the average annual citation number becomes larger. As the power level decreases and the hierarchy decreases, the surface becomes dark blue and the average annual citation number becomes smaller. Therefore, hierarchy empowers low power teams but disarms high power teams. These patterns suggest that the association is not sensitive to the percentile of cutoff.

Figure 2. The relationship between team success and power according to different percentile cutoffs

Results Considering Control Variables: Time and Team Size
Further analyses verify the universality of these associations for scientific teams across different time periods and team sizes. We bin the time periods with 10-year windows and merge the scientific papers before 1990 since these papers only occupy 1.96% of all papers. Figure 3 indicates that the results in Figure 1 still exist across all time periods. The citation of high power low hierarchy group is significantly higher than that of high power high hierarchy group at four stages using t-test, before 1990 ($t = 3.57, p < 0.001$), 1990-2000 ($t = 9.55, p < 0.001$), 2000-2010 ($t = 19.55, p < 0.001$), 2010-2020 ($t = 26.25, p < 0.001$). By contrast, the citation of low power low hierarchy teams is significantly lower than that of low power high hierarchy teams in four different time periods using t-test, before 1990 ($t = -8.86, p < 0.001$), 1990-2000 ($t = -13.57, p < 0.001$), 2000-2010 ($t = -24.25, p < 0.001$), 2010-2020 ($t = -32.59, p < 0.001$). We can see that the absolute value of $t$ becomes larger with time, which suggests that hierarchy brings larger differences to teams’ citations over time. Especially when CS enters the 2010s, hierarchical structure produces dramatic increases of citations for low power teams, whereas flat structure leads to the highest citations for high power teams.

Note. * $P < 0.05$; ** $P < 0.01$; *** $P < 0.001$.

Figure 3. The relationship between team success and power across time periods
Regardless of the team size, the findings in Figure 1 are consistent in Figure 4 as well. For papers with more than seven authors (2.38% of all papers), we merge them into one category. The impact of high power low hierarchy group is significantly higher than that of high power high hierarchy group across different team sizes: two members \( (t = 26.50, p < 0.001) \), three members \( (t = 20.69, p < 0.001) \), four members \( (t = 19.40, p < 0.001) \), five members \( (t = 16.12, p < 0.001) \), six members \( (t = 9.52, p < 0.001) \), seven members \( (t = 5.91, p < 0.001) \), and more than eight members \( (t = 4.38, p < 0.001) \). On the contrary, the impact of low power low hierarchy teams is significantly lower than that of low power high hierarchy teams in both small and large teams: two members \( (t = -16.81, p < 0.001) \), three members \( (t = -19.82, p < 0.001) \), four members \( (t = -18.17, p < 0.001) \), five members \( (t = -13.97, p < 0.001) \), six members \( (t = -8.93, p < 0.001) \), seven members \( (t = -5.53, p < 0.001) \), and more than eight members \( (t = -7.89, p < 0.001) \). We can see that as the size of the team grows, the t score becomes smaller for teams with high power. The results show that teams consisting of two members most need equal communication and teams with three to four scholars especially need hierarchy in order to achieve success.

**Note.** * P < 0.05; ** P < 0.01; *** P < 0.001.

**Figure 4. The relationship between team success and power across different team sizes**
In the previous analysis, we consider each variable: percentile cutoffs, time, and team size separately. To check the robustness of our results, we run a regression model with all variables considered in Table 2. Power level (t = 0.11, p < 0.001) and hierarchy (t = 0.51, p < 0.001) are positively related to team success. When we do not consider the cutoff of power level and hierarchy, the coefficient of the interaction effect between these two variables is significant (t = -0.13, p < 0.001). The negative coefficient suggests that in teams with relatively high power, hierarchy is negatively related to citation, whereas in teams with low power, hierarchy is positively related to citation. The effects of hierarchy on team success is contingent on the level of team power. Larger teams have more citations (t = 0.23, p < 0.001). Even when we include fixed effects regarding year, the results are consistent with those previously reported.

DISCUSSION AND CONCLUSION

Science is no longer an individual endeavor. Countless scientific adventures and breakthroughs have been achieved by teams of scientists. Power is pervasive in all kinds of team collaboration and is absolutely critical for effective collaboration. Even
though team power has developed a rich literature in other domains, such as healthcare (Arslanian-Engoren, 1995; Lockhart-Wood, 2000), sports (Halevy et al., 2012; Ronay et al., 2012), the military (Goodwin et al., 2018; Salas et al., 1995), and business management (Greer et al., 2011, 2017, 2018), understanding team power dynamics in team collaboration is relatively new in science of science, especially on the side of scientific collaboration (Chi & Glänzel, 2017; Wagner et al., 2011; Wang & Wei, 2016; Zhang et al., 2018). Power in scientific teams can be manifested by seniority, scientific status, and scholarly impact. The imbalance in power is an intrinsic feature of scientific teams. The dispersion of team power forms hierarchies, which can be viewed as vertical differences between team members in their possession of team resources and their levels of authority for decision making. Hierarchy in science is prevalent given the pervasiveness of mentoring in our education systems. Supervisors (e.g., faculty) and subordinates (e.g., graduate students) have significant differences in personal power in academia (Green and Bauer, 1995). Even though a growing literature focuses on power differences from the single dyadic relationship between mentor and mentee, it does not take the whole team into account, like the average team power level and power hierarchy within teams. In this paper, we clarify these concepts of team power and hierarchy with authors’ career age. This paper can help us understand the characteristics of team power in scientific teams and provide guidance for building successful teams.

There are two different accounts about the effects of power hierarchy: the conflict (Anderson & Brown, 2010) and functional perspectives (Greer et al., 2017). Hierarchy provides the mechanism to facilitate team member interactions by clarifying expectations, roles, and members’ placement in the ranks as well as by guiding resource allocation. However, it can also create a negative pathway to team effectiveness by heightening conflict-enabling states, such as highlighting differences between members, opposing interests among leadership, and provoking contests and
conflicts within the pecking order of the team. This paper is among the first to use a large-scale dataset to reconcile these two opposing lines of thoughts from millions of scientific teams. The rapid rise of Computer Science has been heavily driven by research teams in academia and industry. How to form effective AI teams is now one of the most critical questions that executives, administrators, and leaders need urgent answers. Therefore, it is critical to understand the recipe of success for Computer Science teams, especially AI teams, from the power perspective. We unpack the complex relationships between team power and success by introducing power-level as the key moderator that determines whether hierarchy enhances or inhibits team outcomes, inspired by Greer & Van Kleef (2010). They show that power level moderates the effect of power dispersion on conflict resolution in business management. In low-power groups, members accept hierarchy, thereby reducing power struggles. When multiple high-power team members share similar resources, egos and power competition can create conflicts and harm team function (Greer et al., 2011). Prior research primarily relies on survey or experimental methods to explore team hierarchy and performance. As a result, the sample size, space and time are often limited. It is also problematic to rely on these methods since it is difficult to simulate real-life task settings. With millions of CS papers in the DBLP dataset, we find that power hierarchy is a two-sided sword. In different power-level teams, hierarchy plays different roles. Compared with low-level teams, power equity is a better facilitator in high-level teams. Our findings are consistent with the results from the study conducted by Greer and van Kleef (2010), whose results were based on only one international company. We also test the universality of these results in small and large teams and in different time spans. The results tell us that a team consisting of young students especially needs a powerful supervisor to lead to success. However, in the teams with all-star researchers, they would need equal cooperation relationships. These findings suggest important consequences of hierarchy in academia and point out directions of future CS collaboration.
There are several limitations in this research. First, career age is a simple proxy of power in scientific teams. We must admit there are few cases that people who are young in the academia are more senior than the elderly in terms of knowledge and creativity. As we have reviewed in the conceptualization of power, power can be represented with position, expertise, ability, and perceived intelligence (Greer & Van Kleef, 2010; Groysberg et al., 2011; Piercy, 2019). In the operationalization part, we can consider using other variables, like h-index (Egghe & Rousseau, 2008) to measure team power level and hierarchy. All other alternative measures could provide a baseline for the power measurement based on career age. Second, the measure of citation is just one dimension to evaluate scientific success. It would be interesting to measure success using disruptive innovation (e.g., new knowledge overshadowing past ideas) (Wu et al., 2019) or combinational novelty (e.g., atypical combination of pre-existing knowledge components) (Uzzi et al., 2013; Liu et al., 2020). Thirdly, we only discuss the power dynamics in CS teams. In the future, we would test the relationship between team power and success in other domains in order to see whether this pattern is still consistent in different disciplines.
