A Tight Analysis of Slim Heaps and Smooth Heaps

Corwin Sinnamon* Robert E. Tarjan*†

Abstract

The smooth heap and the closely related slim heap are recently invented self-adjusting implementations of the heap (priority queue) data structure. We analyze the efficiency of these data structures. We obtain the following amortized bounds on the time per operation: $O(1)$ for make-heap, insert, find-min, and meld; $O(\lg \lg n)$ for decrease-key; and $O(\lg n)$ for delete-min and delete, where $n$ is the current number of items in the heap. These bounds are tight not only for smooth and slim heaps but for any heap implementation in Iacono and Özkan’s pure heap model, intended to capture all possible “self-adjusting” heap implementations. Slim and smooth heaps are the first known data structures to match Iacono and Özkan’s lower bounds and to satisfy the constraints of their model. Our analysis builds on Pettie’s insights into the efficiency of pairing heaps, a classical self-adjusting heap implementation.

1 Introduction

A heap (sometimes called a priority queue) is a data structure consisting of a set of items, each with an associated real-valued key. Heaps support the following operations:

- **make-heap($h$)**: Create a new, empty heap $h$.
- **find-min($h$)**: Return an item of smallest key in heap $h$, or null if $h$ is empty.
- **insert($x$, $h$)**: Insert item $x$ with predefined key into heap $h$. Item $x$ must be in no other heap.
- **delete-min($h$)**: Delete from $h$ the item that would be returned by **find-min($h$)**.
- **meld($h$, $h'$)**: Meld item-disjoint heaps $h$ and $h'$.
- **decrease-key($x$, $k$, $h$)**: Decrease to $k$ the key of item $x$ in heap $h$, assuming that $x$ is an item in $h$ and $k$ is no larger than the current key of $x$. (Operation **decrease-key** is given a pointer to item $x$ in heap $h$, not just its key or some other identifier.)
- \textbf{delete}(x, h): Delete item \( x \) from heap \( h \), assuming that \( x \) is an item in heap \( h \). Again, \textit{delete} is given a pointer to \( x \) in \( h \).

Since a sequence of \( n \) insert operations followed by \( n \) delete-min operations will sort \( n \) numbers, the amortized time of either insert or delete-min must be \( \Omega(\log n) \) if the only allowed operations on keys are binary comparisons. One goal in designing a heap implementation is thus to restrict the required \( \Omega(\log n) \) overhead to as few kinds of heap operations as possible, while making the efficiency of the other operations as close to \( O(1) \) as possible. The Fibonacci heap achieves this goal [9]. It has amortized time bounds of \( O(\log n) \) per delete-min and delete, and \( O(1) \) for each of the other operations, where \( n \) is the number of items currently in the heap. In particular, Fibonacci heaps take \( O(1) \) time per decrease-key, making them an especially efficient way to implement Dijkstra’s shortest path algorithm.

Fibonacci heaps obtain their efficiency by maintaining an appropriate kind of balance in the trees representing the heap. To keep the trees balanced, the data structure stores \( \log \log n + O(1) \) bits of auxiliary information per node. A natural question is whether there is a “self-adjusting” heap that maintains no balance information but has the same amortized efficiency as the Fibonacci heap. The pairing heap [8] was devised as an answer to this question. It has an amortized time bound of \( O(\log n) \) per heap operation and was conjectured to have the same amortized efficiency as Fibonacci heaps. But Fredman [7] disproved this conjecture by showing that pairing heaps and similar data structures need \( \Omega(\log \log n) \) time per decrease-key operation. Whether pairing heaps achieve this bound remains an open question.

Two much-newer self-adjusting heaps are the smooth heap and the closely-related slim heap. Smooth heaps were introduced by Kozma and Saranurak [16] during their study of a duality between heaps and binary search trees, in which the insertion order of nodes in a heap corresponds to the key order of nodes in a binary search tree. Smooth heaps arise as a dual to the greedy algorithm for binary search trees [2, 6, 18, 19], an algorithm not practical to implement but known to be efficient in theory and highly adaptive. By duality, a smooth heap operating in sorting mode (\( n \) inserts followed by \( n \) delete-mins) takes \( O(n \log n) \) time sort \( n \) numbers. Unlike its dual, the smooth heap is simple and practical. Initial experimental studies of smooth and slim heaps [11, 12] show them to be competitive in practice with pairing heaps.

Kozma et al. [12] gave a self-contained description and analysis of smooth heaps. Their presentation avoids the use of duality, and their analysis applies to any sequence of heap operations, not just sorting mode. They also introduced the slim heap, a close variant of the smooth heap. They showed that with a simple implementation of decrease-key, slim and smooth heaps take \( O(1) \) amortized time per make-heap, insert, and meld, and \( O(\log n) \) per delete-min, decrease-key, and delete. They also gave a more complicated decrease-key implementation that runs in \( O(\log \log n) \) time, based on ideas Elmasry [3, 4, 5] applied to pairing heaps. This implementation requires extra machinery and does not satisfy the conditions of any known lower bounds on decrease-key.

In this paper, we show that on slim and smooth heaps the simple implementation of decrease-key actually takes \( O(\log \log n) \) amortized time, which is tight not only for these data structures but for any heap implementation in Iacono and Özkan’s “pure heap” model [14]. Our analysis builds on insights Pettie used to obtain his improved analysis of decrease-key on pairing heaps. We are optimistic that our approach will eventually yield a tight \( O(\log \log n) \) bound for decrease-key on pairing heaps.
In addition to this introduction, our paper contains seven sections. Section 2 presents a canonical framework for heap implementations, of which Fibonacci heaps, pairing heaps, slim heaps, and smooth heaps are instances. It reviews previous results directly related to our work, and introduces slim heaps and smooth heaps. The main novelty in these heaps is locally maximum linking. Section 3 describes this linking method and develops its properties. Section 4 gives an overview of our efficiency analysis, which we do first for slim heaps and then adapt to smooth heaps. Section 5 develops our scoring functions, which are the heart of the analysis. Section 6 uses the scoring functions to complete the analysis of slim heaps. Section 7 extends our analysis to smooth heaps. Section 8 contains final remarks, including a description of some variants of slim heaps and smooth heaps, and a hybrid with pairing heaps.

2 Canonical framework

Before and since the introduction of Fibonacci heaps, a vast amount of research has been conducted on efficient heap implementations. See [1, 10, 17] and references therein. We mention only the results directly relevant to our work. Fibonacci heaps and many other heap implementations, including the binomial queues on which Fibonacci heaps are based, use the following canonical framework:

A heap is a forest of rooted, ordered trees whose nodes are the items in the heap. The data structure is endogenous: the tree nodes are the items, rather than containing the items or containing pointers to the items. (One exception in which the heap is a set of exogenous trees is the hollow heap [10].) Each tree is (min-)heap ordered: the key of a child is no less than that of its parent.

The heap stores a list of its tree roots, accessed via a root of minimum key, the min-root. Each node stores a list of its children. We call a list of children a sibling list. In a root list or sibling list, we identify the front of the list with “left” and the back of the list with “right”, so that nodes early in the list are considered left of nodes later in the list. The first node on a list is leftmost, the last node rightmost.

Heap operations alter the forest by linking pairs of nodes on the root list. A link makes the node with smaller key (the winner of the link) the parent of the node of larger key (the loser of the link). The link is a left link if the loser was originally left of the winner, a right link if the loser was originally right of the winner. The loser becomes the new leftmost child of the winner. Thus the nodes on a sibling list are in decreasing order by link time (earliest rightmost, latest leftmost).

We use the word “link” to refer to the operation of creating a new parent-child pair in a heap, and also to the pair itself. Links are created during delete-min operations and cut (destroyed) during delete-min, decrease-key, and delete operations, as we shall describe. We denote by vw a link of v and w, with v the winner. A child of a node is either a left child or a right child, depending on whether it lost a left link or a right link to its parent.

The root list of a heap is singly-linked and circular. Circular linking supports melding in $O(1)$ time. Each list of children is doubly-linked and accessed via the leftmost child. This allows addition of a new leftmost child in $O(1)$ time. The leftmost child of a node has a pointer to its parent. Doubly linking the sibling lists and adding a pointer from each leftmost child to its parent allows a node $v$ (and its subtree) to be cut from its parent in $O(1)$ time by deleting $v$. 

3
from its sibling list.

Three pointers per node suffice to represent a heap. The first pointer of a node indicates its leftmost child, or is null if it has no children. The second pointer indicates the next root on the root list if the node is a root but not rightmost, the leftmost root on the root list if the node is the rightmost root, the next node on its sibling list if the node is a child but not rightmost on its sibling list, or is null if the node is a rightmost child. The third pointer of a node is non-null only if the node is a child. It indicates the previous sibling if the node is a child that is not leftmost on its sibling list, or its parent if the node is a leftmost child.

### 2.1 Heap operations

Heaps do the heap operations as follows:

- **make-heap** \((h)\): Create a new empty heap.
- **find-min** \((h)\): Return the min-root.
- **insert** \((v, h)\): Make \(v\) into a one-node tree, add \(v\) to the root list of \(h\), and update the min-root.
- **meld** \((h, h')\): Catenate the root lists of \(h\) and \(h'\) and update the min-root.
- **decrease-key** \((v, k, h)\): Change the key of \(v\) to \(k\). If \(v\) is not a root, cut the link between \(v\) and its parent, add \(v\) to the root list, and update the min-root. Node \(v\) retains its subtree.
- **delete** \((v, h)\): Decrease the key of \(v\) in \(h\) to \(-\infty\) and do a delete-min on \(h\).
- **delete-min** \((h)\): Cut the links between the min-root \(u\) and its children, and replace \(u\) on the root list by its list of children. These children, the new roots, precede any other roots, the old roots, on the root list. Repeatedly link roots on the root list until only one root is left. Make it the min-root. Return \(u\).

Different heaps differ mainly in the rule for doing links in delete-min operations. They also differ in possibly doing links during insert, meld, and decrease-key operations, and in not necessarily doing as many links as possible during a delete-min, thereby producing a set of trees rather than just a single tree. Some also differ in doing additional cuts and possibly links during decrease-key operations.

In binomial queues, Fibonacci heaps, hollow heaps, and other similar heaps, each node has a non-negative integer \(rank\), initially zero. Every link is between roots of equal rank, and every link increases the rank of the winner by one. Such balanced links make the data structure efficient, because they maintain a balance invariant: every subtree has size exponential in the rank of its root. The main novelty in Fibonacci heaps is to do extra cuts and rank decreases in each decrease-key operation in a way that maintains a weaker balance invariant: every subtree has size at least exponential in the rank of its root.
2.2 Pairing heaps

In spite of their theoretical efficiency, Fibonacci heaps are slower than other heap implementations in practice. This (and natural curiosity) motivated a search for a simpler implementation that would avoid the need to maintain ranks but still have the theoretical efficiency of Fibonacci heaps. The result of this search was the pairing heap [8]. Pairing heaps do not maintain ranks but do links based on the order of roots on the root list. They link only adjacent roots. After the min-root is deleted, the roots are linked in two passes. The first, the pairing pass, links the roots in adjacent pairs left-to-right, the first and second, the third and fourth, and so on. The second, the assembly pass, repeatedly links the rightmost two roots until only one root remains.

The original version of pairing heaps uses a one-tree representation: an insert links the new root with the existing one, a meld links the roots of the trees representing the two heaps, a decrease-key of a non-root node cuts the node whose key decreases and links it with the existing root. Fredman et al. [8] obtained an $O(\log n)$ amortized bound per heap operation for this version, and they conjectured that pairing heaps match the bounds of Fibonacci heaps. Fredman [7] disproved this conjecture, and proved more generally that any heap implementation, in a certain model based on the canonical framework, must store $\Omega(\log \log n)$ extra bits of information per node to attain an amortized bound of $O(1)$ per decrease-key operation, and that if no extra bits are maintained, the amortized time per decrease-key is $\Omega(\log \log n)$.

Both Fibonacci heaps and pairing heaps are subject to Fredman’s lower bound. Since ranks in Fibonacci heaps are logarithmic in heap size, they use $\lg \lg n + O(1)$ extra bits per node to store ranks, matching Fredman’s bound on the extra information needed to achieve $O(1)$ time per decrease-key. For pairing heaps, the question is whether or not the amortized time per decrease-key is $O(\log \log n)$, matching Fredman’s lower bound. This question remains open. The best currently known bounds for the original version of pairing heaps are $O(1)$ for insert and meld, $O(\log n)$ for decrease-key, delete-min, and delete [13]; and $O(4\sqrt{\log \log n})$ for insert, meld, and decrease-key, $O(\log n)$ for delete-min and delete [20].

A question more general than whether pairing heaps match Fredman’s bound is whether any heap implementation that does not store extra information matches Fredman’s bound. Elmasry [3, 4] provided a partial answer by modifying pairing heaps to use an insertion buffer, as suggested by Stasko and Vitter [21], modifying the implementation of decrease-key to also use a buffer and to do two cuts and a link, and sorting groups of roots by key to decide which roots to link. The insertion buffer reduces the amortized time per insert to $O(1)$; the other changes result in an amortized time of $O(\log \log n)$ for decrease-key and meld. Fredman’s model does not allow extra key comparisons when deciding which links to do, however, so Elmasry’s heap is not subject to his lower bound. Iacono and Özkan [14] proposed a different heap model, also based on the canonical framework, and also obtained an $\Omega(\log \log n)$ amortized lower bound for decrease-key. But Elmasry’s heap is not subject to their lower bound either. Until now, no heap implementation subject to either Fredman’s or Iacono and Özkan’s lower bound has been shown to have an $O(\log \log n)$ amortized time bound for decrease-key and an $O(\log n)$ bound for delete-min.
2.3 Slim heaps and smooth heaps

The smooth heap and the slim heap are recently introduced self-adjusting heap implementations. They use the canonical framework but add a couple of novelties. Slim heaps and smooth heaps both use *locally maximum linking*, which we describe in the next section, to decide which links to do in a delete-min. They differ only in how links change the data structure. Slim heaps do the classical one-sided links we have already described: the loser of a link becomes the new leftmost child of the winner. Smooth heaps do two-sided stable links: the loser of a link becomes the new leftmost or rightmost child of the winner if the link is a left link or a right link, respectively. To support two-sided linking, the sibling lists are circular (the second pointer of the rightmost node in a sibling list indicates the first node on the list rather than being null), and access to a sibling list is via the rightmost sibling rather than the leftmost (the first pointer of a node indicates its rightmost child rather than its leftmost). With these changes in the representation, a two-sided link takes $O(1)$ time.

In a slim heap, left and right children are in general intermixed on the sibling list containing them. The nodes on the list are in decreasing order by link time (earliest rightmost, latest leftmost). In a smooth heap, all left children precede all right children; left children are in decreasing order by link time, right children are in increasing order by link time.

Both slim and smooth heaps maintain the invariant that the min-root is leftmost on the root list.

![Diagram of linking in slim and smooth heaps](image)

Figure 1: Linking in slim and smooth heaps. The loser of a link is added as the leftmost child of the winner in a slim heap. The loser is added as the leftmost or rightmost child in a smooth heap, depending on whether the link is left or right.

Kozma et al. [12] proved amortized time bounds for slim heaps and smooth heaps of $O(1)$ for make-heap, insert, and meld, and $O(\log n)$ for decrease-key, delete-min, and delete. They also presented an Elmasry-style implementation of decrease-key that reduces its amortized time to $O(\log \log n)$. In this paper we prove that the simple canonical implementation of decrease-key has an amortized time bound of $O(\log \log n)$, with the delete-min time remaining $O(\log n)$.

Slim and smooth heaps conform to Iacono and Özkan’s pure heap model [14], and the bounds in this paper match their lower bound to within a constant factor for all operations except delete, which is not specifically addressed in their model. Kaplan, Zamir, and Zwick [15] obtained a lower bound on delete time for heaps that access keys via comparisons. They proved a trade-off among the amortized times of insert, find-min, and delete, and showed in particular that any comparison-based heap that takes $O(1)$ amortized time per insert and find-min must take $\Omega(\log n)$ amortized time per delete. Slim and smooth heaps are subject to this lower bound.
and match it. Our results provide the first truly simple self-adjusting heap implementation with efficiency that matches the lower bounds for every operation.

3 Locally Maximum Linking

Locally maximum linking does delete-min by choosing any node \( v \) on the root list whose key is greater than those of its left and right neighbors, linking \( v \) to the neighbor of larger key, and repeating until there is only one root. Each link removes the loser from the root list and leaves the winner in its original position. When comparing equal keys, the key of the node on the left is treated as smaller. As special cases, if the leftmost root has key greater than that of its right neighbor, these roots can be linked; if the rightmost root has key greater than that of its left neighbor, these roots can be linked. We can eliminate these special cases by adding dummy leftmost and rightmost nodes with keys of minus infinity, and doing locally maximum linking until there is only one non-dummy root.

An alternative way to break ties during key comparisons is by node identifier. Indeed, any tie-breaking rule with the following two properties will work: two comparisons between nodes during the same delete-min must have the same outcome, and the outcomes must not result in a cycle of nodes, each with key larger than the next.

Locally maximum linking uniquely determines the set of links done during a delete-min, although it does not uniquely determine their sequence. Doing leftmost locally maximum linking, in which the leftmost local maximum is linked to its neighbor of larger key, does uniquely determine the sequence of links and is a natural implementation, but any implementation will do. Leftmost locally maximum linking takes two comparisons per link: proceed leftward through the root list until finding a node \( w \) whose key is less than that of its left neighbor \( v \) (one comparison per node examined), link \( v \) with whichever of its neighbors has larger key (one comparison per link); continue from the winner of the link.

Doing locally maximum linking on a list of roots arranges them into a treap, a binary tree that is symmetrically ordered by root order on the list and heap-ordered by key. The treap is uniquely determined by the root order and the key order, assuming a fixed tie-breaking rule for key comparisons.

Locally maximum linking has two crucial properties. The first was proved in [16] and [12]. We include a proof for completeness.

**Lemma 1.** During a delete-min, a node wins at most one left link and at most one right link. Hence during a delete-min each node acquires at most one new left child and at most one new right child.

**Proof.** Consider a link of a locally maximum node \( v \) during a delete-min. Node \( v \) links with either its left neighbor \( u \) or its right neighbor \( w \). Suppose it links with with \( u \). Then this link is a right link won by \( u \), and \( u \) has key greater than that of its new right neighbor \( w \). The new right neighbor of \( u \) can change, but when it does the key of the new right neighbor is smaller than that of the old one. Thus \( u \) cannot win another right link. If \( v \) links with \( w \), the proof is symmetric except for the tie-breaking rule in key comparisons, which does not affect the validity of the proof. \( \square \)
The second crucial property of locally maximum linking needs some definitions for its description. Let \( v \) and \( w \) be adjacent roots on the root list just after the min-root is removed in a delete-min, with \( w \) right of \( v \). The boundary between \( v \) and \( w \) is the partition of the roots into two parts, the left side, containing \( v \) and the roots to its left, and the right side, containing \( w \) and the roots to its right. A link crosses a boundary if one of its vertices is on each side.

**Lemma 2.** Consider a delete-min. Fix a boundary. Among links done during the delete-min that cross this boundary, let \( vw \) and \( v'w' \) be two consecutive ones, with \( vw \) done first. Then (i) \( v \) is a descendant of \( w' \) after the delete-min; (ii) \( v \) and \( w' \) are on the same side of the boundary, as are \( w \) and \( v' \); and (iii) if \( v \) and \( w' \) are left of the boundary, \( w' = v \) or \( w' \) is left of \( v \), and \( v' \) is right of \( w' \); if \( v \) and \( w' \) are right of the boundary, \( w' = v \) or \( w' \) is right of \( v \), and \( v' \) is left of \( w \).

**Proof.** Without loss of generality suppose \( v \) is on the left side of the boundary: the proof is symmetric if it is on the right side, except for the tie-breaking rule for key comparisons, which does not affect the validity of the proof. During the delete-min, let \( y \) and \( z \) be the rightmost and leftmost roots on the left and right sides of the boundary, respectively. Nodes \( y \) and \( z \) can change as links occur, but only in three ways: \( y \) can lose a link to its left neighbor, which replaces \( y \) by this neighbor; \( z \) can lose a link to its right neighbor, which replaces \( z \) by this neighbor, or \( y \) and \( z \) can be linked, which replaces \( y \) by its left neighbor if \( y \) is the loser, or \( z \) by its right neighbor if \( z \) is the loser. A link only crosses the boundary if it links the current \( y \) and \( z \), since all links are between adjacent roots. Thus when \( v \) and \( w \) are linked, \( y = v \) and \( z = w \). After the link, the new \( z \), the old right neighbor of \( z \), has key less than that of \( v = y \), since linking is locally maximum. When \( z \) changes because of a link not crossing the boundary, its key decreases. When \( y \) changes because of a link not crossing the boundary, its key decreases but remains greater than that of \( z \): otherwise \( y \) would have linked to \( z \), because the linking is locally maximum. Furthermore, \( v \) is a descendant of the new \( y \). Thus in the next link crossing the boundary, that of \( v' \) with \( w' \), \( y = w' \) loses and \( z = v' \) wins, making all three parts of the lemma true.

**Corollary 3.** Consider a delete-min. Fix a boundary. After the delete-min, all the winners and losers of the links crossing the boundary are on a single path in the tree. Along this path, consecutive links crossing the boundary alternate between left and right links.

**Proof.** The Corollary follows from Lemma 2 by induction on the number of links done during the delete-min that cross the boundary.

**Corollary 4.** Consider a delete-min. Fix two boundaries. Consider all the links done during the delete-min that cross the first boundary. Along the path in the data structure that contains these links after the delete-min, proceeding from bottom to top (leaf to root), the links that cross the first but not the second boundary precede all those that cross both boundaries. Those that cross the first but not the second boundary alternate between left and right links.

**Proof.** By Corollary 3, all the links that cross the first boundary are on one path in the data structure after the delete-min, and they alternate between left and right links. Assume the left side of the first boundary is contained within the left side of the second; the argument is symmetric if not, since then the right side of the first boundary is contained within the right side of the second. Let \( vw \) be a link that crosses both boundaries. Suppose \( w \) is on the left side
of both boundaries and \( v \) is on the right side of both; the argument is symmetric if \( w \) is on the right side of both and \( v \) is on the left side of both. By part (iii) of Lemma 2, the next link \( v'w' \) crossing the first boundary has \( v = w' \) or \( w' \) right of \( v \), and \( v' \) is left of \( w \). Hence \( v'w' \) crosses both boundaries. It follows by induction on the number of links crossing the first boundary that all those crossing the first boundary but not the second precede all those crossing both, from bottom to top along the path.

4 Analysis Overview

We consider a sequence of heap operations beginning with no heaps. We denote by \( n \) the current number of nodes in the heap or heaps involved in an operation. We denote by \( \lg x \) the function \( \max\{0, \log_2 x\} \). When stating time bounds we ignore \( O(1) \) time per operation. In particular, our amortized bounds of \( O(\lg n) \) for delete-min and delete, and \( O(\lg \lg n) \) for decrease-key, hold for \( n \geq 4 \); for \( n < 4 \) the true bounds are \( O(1) \). As a shorthand for stating bounds, we use “\( O(\lg n) \) per delete-min” to denote the sum over the delete-min operations of the logarithm of \( n \), where \( n \) is the number of items in the heap at the time of the delete-min, and similarly for “\( O(\lg \lg n) \) per decrease-key.”

Each make-heap, find-min, insert, meld, and decrease-key takes \( O(1) \) time worst-case. Each link in a delete-min and cut of a link in a decrease-key or delete-min takes \( O(1) \) time. The time for a delete-min is at most \( O(1) \) plus a constant times the number of links. The total time for a sequence of heap operations starting with empty heaps is thus at most a constant times the number of operations plus the number of links. Ignoring \( O(1) \) time per operation, we estimate this by the number of links. We shall prove a bound on the amortized number of links of \( O(1) \)
per insert, $O(\lg n)$ per delete-min, and $O(\lg \lg n)$ per decrease-key. The bound for melds is zero. Since a delete consists of a decrease-key followed by a delete-min, an amortized bound of $O(\lg n)$ for delete follows.

### 4.1 The potential method

In our efficiency analysis we use the potential method [22]. We assign to each state of the data structure a real-valued potential. We define the amortized cost of an operation to be its actual cost plus the potential of the data structure after the operation minus the potential before it. That is, the amortized cost is the actual cost plus the net increase in potential caused by the operation. If we sum the amortized costs of the operations in a sequence, the sum of the potential differences telescopes: the sum of the actual costs of the operations equals the sum of their amortized costs, plus the final potential (after the last operation), minus the initial potential (before the first operation). If the initial potential is zero (corresponding to an empty data structure) and the final potential is non-negative, then the sum of the amortized costs of the operations is an upper bound on the sum of the actual costs of the operations. This is true even if the potential is temporarily negative in the middle of the sequence.

There is a more general way to use a potential function to bound the total cost of a sequence of operations. If the potential is zero initially and non-negative finally, then the sum of the increases in the potential is an upper bound on the sum of the magnitudes (absolute values) of the decreases. Hence if we can obtain an upper bound on the sum of the increases and show that each operation produces a decrease in the potential at least equal to its cost, the upper bound on the sum of the increases is an upper bound on the total cost. Furthermore, twice the sum of the increases in the potential is a bound on the sum of the magnitudes of all the potential changes, positive and negative.

### 4.2 Node and link types

During a delete-min, a node is new if it is in a subtree rooted at a new root just after deletion of the min-root, old otherwise. A node remains new or old until the end of the delete-min. A tree is mixed if it contains an old node and a new node. Immediately after deletion of the min-root, all descendants of a new root are new, and all descendants of an old root are old, so there are no mixed trees. A link between a new root and an old root produces a mixed tree, but there is never more than one such tree:

**Lemma 5.** During a delete-min, at most one tree is mixed, the tree rooted at the rightmost new root or the tree rooted at the leftmost old root.

**Proof.** Just after deletion of the min-root, no trees are mixed. A link of an old root and a new root creates a mixed tree rooted at the winner. Suppose link $vw$ is the first to create a mixed tree. Assume $v$ is new; the argument is symmetric if $v$ is old. Then $v$ is the rightmost new root, and the tree rooted at $v$ is the only mixed tree. Since $v$ has won a right link, it cannot win another one later. If $v$ wins a left link, it remains the only root of a mixed tree. If $v$ loses a right link, the winner becomes the rightmost new root and the only root of a mixed tree. This root cannot win another right link. Hence the rightmost new root remains the only root of a mixed tree until it loses a left link to the leftmost old root, which makes the leftmost old root
the only root of a mixed tree. The symmetric argument applies to this root. The lemma follows by induction on the number of links during the delete-min.

A link can be cut by a delete-min, by a decrease-key, or not at all. We call a link phantom if it is eventually cut by a decrease-key, real otherwise. A child is phantom if its link to its parent is phantom, real otherwise. We shall treat phantom links almost as if they never existed. There is at most one phantom link per decrease-key, so it suffices to count real links, although our analysis also counts phantom links. A link is new if both the winner and the loser are new roots when the link is performed, old otherwise. An old or new link can be either real or phantom. Corollary 4 gives us an important property of new links:

Lemma 6. Consider a delete-min. Fix a boundary between two new roots. The new links done during the delete-min that cross this boundary are on a single path in the data structure after the delete-min, and along this path they alternate between left and right links.

Proof. Let the given boundary be the first boundary, and let the second boundary be between the leftmost new root and the rightmost old root. Then the new links crossing the first boundary are exactly the links crossing the first boundary but not the second. The lemma follows from Corollary 4.

4.3 Old links

As a first, simple example of the potential method, we use it bound the total number of old links. The idea is not new: see e.g. [9].

Theorem 7. The number of old links is at most three per insert and three per decrease-key.

Proof. We define the potential of an old root to be three, and that of a set of heaps to be the sum of the potentials of its old roots. We define the cost of an operation to be the number of old links it does. The potential is initially zero and always non-negative. An insert or decrease-key increases the potential by at most three and does no links, so it has amortized cost at most three. A meld has amortized cost zero. Consider the effect of a delete-min. During the delete-min, each old root wins at most two links and loses at most one. Each old root except possibly one (the root remaining after the delete-min) is a child at the end of the delete-min, so its potential decreases by three, at least equal to the number of links it won or lost. The min-root deleted by the delete-min had potential three, more than the number of links won by the root remaining after the deletion. We conclude that the amortized cost of a delete-min is non-positive. The theorem follows by the potential method.

4.4 New links

The heart of the matter is to count new links. Consider a new link vw done during a delete-min that deletes min-root u. The delete-min begins by cutting the links won by u, including uv and uw, both real. We shall define a potential that decreases as a result of linking u and v, later cutting uw, and still later linking v and w. This decrease in potential helps pay for the one or two links won by v in the delete-min that links v and w.
This argument uses past decreases in the potential to pay for links in the present. Equivalently, it uses current decreases in the potential to pay for links in the future.

We do the rest of the analysis for slim heaps first, and then adapt it to smooth heaps.

5 Scores

Our potential has two parts, node scores and link scores, which we define and study in turn.

5.1 Node scores

The first part of the potential is the node score. We define the real subtree of a node \( v \) to be the subtree of \( v \) whose nodes are connected to \( v \) by a path of real links. We use dot notation for some functions in order to reduce the number of parentheses in expressions. We define the size \( v.s \) of \( v \) to be the number of nodes in its real subtree, unless \( v \) is a new root, in which case its size is the number of new nodes in its real subtree. New roots and new nodes exist only in the middle of a delete-min operation, so at other times every node has size equal to the number of nodes in its real subtree. By Lemma 5 at most one new root, the rightmost, has size less than the number of nodes in its real subtree. When this node loses a link, its size increases by the number of old nodes in its subtree. We treat this increase as a distinct event happening just after completion of the link, so we can account for it separately. This is just for the convenience of the analysis.

We define the mass \( v.m \) of a node \( v \) as follows: If \( v \) is an old root or a phantom child, its mass is its size. If \( v \) is a new root, its mass is the sum of its size and those of the new roots to its right on the root list, plus the number of new nodes in the real subtree rooted at the leftmost old root, if any. Equivalently, the mass of \( v \) is the number of new nodes in its real subtree and in those rooted at nodes to its right on the root list. If \( v \) is a real child, its mass is the sum of its size and those of the real children to its right on its sibling list, excluding its right neighbor, whether real or phantom.

We define the score \( v.r \) of a node \( v \) to be \( \lg \lg (v.m/v.s) \). Since \( 1 \leq v.s \leq v.m \leq n \), \( v.r \) is well-defined. Since we have defined the \( \lg \) function to be non-negative, \( 0 \leq v.r \leq \lg \lg n \). Any node \( v \) such that \( v.m = v.s \) has score zero. This includes all old roots, the rightmost new root.
during a delete-min, and all phantom children. The node score of a set of heaps is the sum of the scores of their nodes.

We use the size, mass, and score of a node only in the analysis; the data structure does not maintain them.

The definitions of size and mass include three exceptions needed to make the analysis work. The first is the omission of phantom links from the definitions of size and mass: if we include them, a cut during a decrease-key can decrease the mass and size of all the proper ancestors of the node whose key changes. This can increase the sum of their node scores by $\Theta(\log n)$, which exceeds our target bound for decrease-key.

The second exception is the size and mass of new roots: if the size of a new root includes old nodes in its real subtree, then a link lost by an old root to a new root can increase the mass of all the new roots; if the mass of a new root does not include new nodes in the real subtree of an old root, then a link lost by a new root to an old root can decrease the mass of all the new roots. Our definitions of size and mass prevent such instabilities. Excluding old nodes from the sizes of new roots can result in the size of a new root increasing when it loses a link, because its size now counts the old nodes in its subtree. But then its mass now also counts these nodes. We treat this increase in size and mass as a distinct event happening just after the link. Increasing the size and mass of a node by the same amount cannot increase its node score. Hence we can ignore such changes when considering events that increase node scores.

The third exception is the mass of real children. In the mass of a real child $v$, we exclude the size of its right neighbor in order to allow $v$ to win a left link and a right link in either order during a delete-min. If $v$ wins two links during a delete-min, after each link the loser has mass at most its size plus the size of the winner at the start of the delete-min, no matter in which order the links are won. If we were to include the size of all siblings right of $v$ in the mass of $v$, then if $v$ wins a left link followed by a right link, our bound on the increase in the score of $v$ caused by the right link would not hold.

It is possible to modify the implementations of slim and smooth heaps to eliminate the need for the second and third exceptions, but this violates a key principle of data structure design: keep the data structure simple, even if this complicates the analysis. We discuss this more in Section 8.

An important property of node scores is that in a delete-min the number of new roots whose score is bounded by a constant is $O(\lg n)$:

**Lemma 8.** At any given time during a delete-min, the number of new roots with node score less than $\lg c$ for any fixed positive $c > 2$ is $O(\lg n)$, where the constant in the big “$O$” depends on $c$.

**Proof.** Consider some time during a delete-min. Let $v$ be a new root other than the rightmost. Suppose $\lg \lg (v.m/v.s) < \lg c$. Then $v.m/v.s < 2^c$. Hence $v.m/(v.m - v.s) > 2^c/(2^c - 1)$. Since $v.m - v.s$ is the mass of the root to the right of $v$, the mass of $v$ is at least $2^c/(2^c - 1)$ times the mass of any new root to its right. The mass of a new root is at least one and at most $n$. Hence the number of new roots with score less than $\lg c$ is $O((\lg n) \lg (2^c/(2^c - 1)))$. \(\square\)

If the sum of node scores is to be a potential, we need to bound the sum of increases in node scores. To do this, we study changes in sizes and masses resulting from links and cuts. The size of a node is initially one and is non-decreasing until it is deleted; its size increases only when it
wins a real link, or when it is the rightmost new root and it loses a link. The mass of a node is also initially one, but it can increase or decrease as the result of a link or cut.

When the rightmost new root loses a link during a delete-min, its size increases by at least as much as its mass, which cannot increase its node score, as we have already observed. We treat this change in size, mass, and score as occurring just after the link is done, and hence we treat changes resulting from links and cuts as distinct from this kind of change.

Cutting a phantom link changes no mass or size and thus changes no node score. Doing a phantom link changes no sizes and does not increase any masses, but it can decrease the masses of new roots if the loser is a new root or the leftmost old root. We conclude that phantom links and cuts of phantom links do not increase any node score.

Cuts of real links occur when the min-root $u$ is removed during a delete-min operation: each child $v$ of $u$ becomes a new root, and its mass and hence its score change accordingly; the score of the removed min-root becomes zero. Cutting $uw$ increases the mass of $v$ by the size of its right neighbor on the root list after $u$ is removed, unless $v$ is the rightmost new root. The following lemma bounds these increases:

**Lemma 9.** The total increase in node score caused by removing the min-root in a delete-min is at most $2 \lg n + \lg \lg n$.

**Proof.** Let $u, v, w$ be three consecutive new roots just after the min-root is removed in a delete-min, in left-to-right order. We claim that the increase in the node score of $u$ when the min-root was removed is at most $2 \lg v.m - 2 \lg w.m$. Summing over this bound over the new roots will give the lemma.

To prove this claim we use the fact that $\lg \lg x - \lg \lg y \leq 2 \lg x - 2 \lg y$ for $x \geq y > 0$. This holds because the derivative of $2 \lg x$ is at least that of $\lg \lg x$ at every point. Furthermore, $\lg x - \lg y \leq \log_2 x - \log_2 y$ for $x \geq y > 0$, so $\lg \lg x - \lg \lg y \leq 2 \log_2 x - 2 \log_2 y$.

Let variables take their values just after deletion of the min-root. The increase in the score of $u$ is $\lg \lg (u.m/u.s) - \lg \lg ((u.m - v.s)/u.s) \leq 2 \log_2 (u.m/u.s) - 2 \log_2 ((u.m - v.s)/u.s) = 2 \log_2 (u.m/(u.m - v.s))$. Since $u.m = u.s + v.m = u.s + v.s + w.m$, this bound on the increase equals $2 \log_2 ((u.s+v.m)/(u.s+w.m))$. Subtracting $u.s$ from both the numerator and denominator can only increase the bound, yielding $2 \log_2 (v.m/w.m) = 2 \lg v.m - 2 \lg w.m$.

This bound on the score increase applies to every new root $u$ except the last two, which do not have new roots $v$ and $w$ to their right. The sum of this bound over all new roots except the last two telescopes to at most $2 \lg n$. The next-to-last new root has score at most $\lg \lg n$, and the last has score zero, so the lemma holds.

It remains to bound the effect of real links on node scores. Let $vw$ be such a link. This link can only change the scores and masses of $v$ and $w$. In particular, if $v$ is new and left of $w$, the link does not change the mass of $v$, nor of any root left of $v$, by our definitions of the size and mass of new roots; if $v$ is new and right of $w$, the new mass of $v$ is the sum of its old mass and the size of $w$, and the link does not change the mass of any root left of $w$.

We show by a case analysis that link $vw$ cannot increase the score of $v$. If $v$ is old, its size and mass are the same both before and after the link, so its score is zero at both times. If $v$ is new and the link is right, the link does not change the mass of $v$ and does not decrease its size. If $v$ is new and the link is left, the link increases both the size and mass of $v$ by the size of $w$. In neither case does the link increase the score of $v$.
Link $vw$ can only increase the score of $w$ if the link is old or it is a new right link. If $vw$ is a new left link, then the mass of $w$ before the link is its size plus the mass of $v$, and its mass after the link is at most its size plus the size of $v$. Hence the link cannot increase the score of $w$.

We bound the increase in the scores of losers of real links in three lemmas.

**Lemma 10.** The sum of increases in node scores of losers of real links won by old roots is at most $2 \log \log (2n)$ per decrease-key and delete-min.

*Proof.* We use the potential method. We give each old root $v$ a root potential of $2 \log \log (2v.s)$. We define the root potential of a collection of heaps to be the sum of the root potentials. We define the cost of a link won by an old root to be the increase in the node score of the loser. Each insert creates an old root, but this root has a root potential of zero, making the amortized cost of an insert zero. Each decrease-key also creates an old root, increasing the root potential by at most $2 \log \log (2n)$ and making the amortized cost of the decrease-key $2 \log \log (2n)$.

Consider a delete-min. Each old root except possibly one (the min-root after the delete-min) becomes a child during the delete-min. The potentials of all the old roots are available to cover the cost of the links they win, if we add at most $2 \log \log (2n)$ potential to cover the increase in the potential of the min-root after the delete-min.

Suppose an old root $v$ wins a real link $vw$ during a delete-min. Denote by unprimed and primed variables the values they take just before and just after the link, respectively. Then $w.r' < \log \log ((v.s + w.s)/w.s)$. If $v.s \leq w.s$, $w.r' = 0$, so the link does not increase the node score of $w$. If $v.s > w.s$, $w.r' < \log \log (2v.s)$. Since $v$ wins at most two such links during a delete-min, the increase in the node score of the losers of these links is at most the decrease in the root potential of $v$ by the end of the delete-min. Hence the amortized cost of a delete-min is at most $2 \log \log (2n)$. The lemma follows by the potential method.

**Lemma 11.** Consider a delete-min. Fix a boundary. The sum of increases in node scores caused by real links that cross the boundary is at most $\log n$.

*Proof.* By Corollary 3, all the losers of the links that cross the boundary are on one path in the data structure after the delete-min. We bound the sum of the scores of the losers, which bounds the sum of their score increases. Let $w$ and $w'$ be two consecutive losers along the path, with $w$ a descendant of $w'$. Let variables take their values just after the delete-min. Then $w.x = \log \log (w'.m/w'.s) \leq \log \log (w'.m/w.m) \leq \log (w'.m/w.m) = \log w'.m - \log w.m$. Summing this bound over all the pairs of consecutive losers, the sum telescopes and is at most $\log n$.

**Corollary 12.** The sum of increases in node scores caused by real links lost by old roots to new roots is at most $\log n$ per delete-min.

*Proof.* Consider a delete-min. Choose the boundary between the rightmost new root and the leftmost old root. Every real link lost by an old root to a new root crosses this boundary. Apply Lemma 11.

It remains to bound the sum of increases in node scores of losers of new right links. See Figure 4

**Lemma 13.** The sum of increases in node scores caused by real new right links is at most $2 \log n$ per delete-min.
Figure 4: A new link between new roots $v$ and $w$ in a slim heap. Whether $vw$ is a left or right link, $w$ becomes the leftmost child of $v$.

**Proof.** Consider a delete-min. We claim that if $vw$ is a real new right link done during the delete-min, then the node score of $w$ increases by at most $2 \log_2(v.m_0/(v.m_0 - v.s_0))$, where $v.s_0$ and $v.m_0$ are the size and mass of $v$ at the beginning of the delete-min, just after $v$ becomes a new root. Summing this bound over the real new right links done during the delete-min will give us the lemma.

To prove the claim, let unprimed and primed variables take their values just before and just after the link, respectively. During the delete-min, $v$ wins at most one link before it wins $vw$. The size of the loser of that link, if there is one, is not counted in the mass of $w$ after the link $vw$, since the mass of a child node does not include the size of its right sibling. Hence $w.m' < v.s_0 + w.s$. Also, $v.m_0 - v.s_0 = v.m - v.s = w.m$, since if $v$ wins a left link its size and mass increase by the same amount. The link $vw$ increases the node score of $w$ by at most $\log_2((v.s_0 + w.s)/w.s) - \log_2(w.m/w.s)$. Observe that $w.m = v.m_0 - v.s_0$ and $v.s_0 + w.s \leq v.s_0 + w.m = v.m_0$, so the increase is at most $\log_2(v.m_0/w.s) - \log_2((v.m_0 - v.s_0)/w.s)$. Recall that $\log_2 x - \log_2 y \leq 2 \log_2 x - 2 \log_2 y$ whenever $x \geq y > 0$; this inequality was used in the proof of Lemma 9. Hence the increase is at most $2 \log_2(v.m_0/w.s) - 2 \log_2((v.m_0 - v.s_0)/w.s) = 2\log_2(v.m_0/(v.m_0 - v.s_0))$, which proves the claim.

We finish the proof by using the claim. Let $v_1, v_2, ..., v_k$ be the new roots just after deletion of the min-root. Each $v_i$ with $i < k$ can win at most one real new right link during the delete-min. If it does, the node score increases by at most $2 \log_2 v_i.m_0 - 2 \log(v_i.m_0 - v_i.s_0)$ by the claim. This bound is $2 \log v_i.m_0 - 2 \log v_{i+1}.m_0$. Summing over all $v_i$ for $i < k$, including those that do not win a real new right link, we find that the sum telescopes, totaling $2 \log v_1.m_0 - 2 \log v_k.m_0 \leq 2 \log n$. □

Combining Lemmas 9 and 10, Corollary 12, and Lemma 13 gives the following theorem:

**Theorem 14.** The sum of the increases in node scores is $O(\log \log n)$ per decrease-key plus $O(\log n)$ per delete-min.

**Corollary 15.** The sum of the magnitudes of the changes in node scores is $O(\log \log n)$ per decrease-key plus $O(\log n)$ per delete-min.
Proof. Since the sum of the node scores is initially zero and always non-negative, the sum of increases in node scores is at least the sum of the magnitudes of the decreases. Hence the sum of the magnitudes of all the node score changes, positive and negative, is at most twice the sum of the increases. The corollary follows from Theorem 14.

Theorem 14 shows that we can use the node score as a potential to help obtain our target amortized bounds, and Corollary 15 shows that we can also use the sum of the magnitudes of the changes in node scores. We shall use both in our analysis.

5.2 Link scores

The second part of the potential is the link score. To introduce it, we need a bit of additional notation. We denote by $v.r_w$ and $v.r'_w$, respectively, the node score of $v$ just before and just after it is linked with $w$. If the link between $v$ and $w$ is cut and $v$ and $w$ are later linked, the subscript refers to the most recent link between $v$ and $w$. We shall omit the subscript when ambiguity does not result.

Each link $vw$ has a link score $vw.r = w.r_v - v.r'_w$, the node score of the loser just before the link minus the node score of the winner just after the link. The link score of a set of heaps is the sum of the scores of their links.

Lemma 16. The score of an old link is zero. The score of a real new link is non-negative.

Proof. Let $vw$ be a link. If $w$ is old, its node score is zero before the link. If $v$ is also old, its node score after the link is zero, making the link score zero. If $v$ is new, its size and mass are equal after the link, since its new right neighbor cannot have any new nodes in its real subtree. Hence the score of $v$ after the link is zero, again making the link score zero.

Suppose $w$ is new and $v$ is old. The node score of $v$ after the link is zero. Furthermore, since $v$ wins a left link with $w$, it cannot have won a previous left link during the current delete-min, so its tree contains no new nodes. Hence the size and mass of $w$ are equal before the link, making its node score before the link zero and making the link score zero as well.

Suppose $vw$ is new and real. Its link score is $w.r - v.r' = \lg \frac{w.m}{w.s} - \lg \frac{v.m'}{v.s'}$, where unprimed and primed variables take their values just before and just after the link, respectively. If the link is left, $v.m' = w.m$ and $v.s' = v.s + w.s > w.s$, so $v.m'/v.s' \leq w.m/w.s$, making the link score non-negative. If the link is right, $v.m' = v.m = w.m + v.s$ and $v.s' = v.s + w.s \leq v.s + w.m$, so $v.m'/v.s' \leq w.m/w.s$, again making the link score non-negative.

Phantom new links can have negative scores, but all phantom links are cut before the end of the operation sequence, leaving the final link score non-negative. Cutting a real link does not increase the total link score, but cutting a phantom link can increase the total link score.

We shall use decreases in link score to help pay for new links. This use is indirect, however, and requires time-shifting. Let $v$ be a new root in a delete-min that deletes $u$. We shall show that if $v$ wins a new link $vw$ during this delete-min, then there is in effect a decrease in the link score of the heap at least equal to the score of real link $uv$. We use this decrease to help pay for the new link or links that $v$ wins during the delete-min that deletes $u$. 

17
Remark 17. We do not obtain any decrease in link score if \( v \) does not win a new link in the delete-min that deletes \( u \). On the other hand, we can obtain a decrease of twice the score of \( uv \) if \( v \) wins two new links in this delete-min. But this gives us only a factor of two, which we ignore.

Rather than plunge directly into the proof of this result, we shall work into it gradually. Suppose \( vw \) is a new link done during the delete-min that deletes min-root \( u \). The delete-min cuts link \( uw \). Let us play a bit fast and loose with the notation, and let \( x.r \) be the node score of \( x \) at some unspecified time. Then link \( uw \) and link \( vw \) have scores \( w.r - u.r \) and \( w.r - v.r \) respectively. Subtracting the former from the latter, the difference is at most \( u.r - v.r \), which is the negative of the score of link \( uv \). That is, the drop in score caused by cutting \( uw \) and linking \( w \) to \( v \) equals the score of \( uv \), which is what we want. This calculation is not correct of course, because the node scores must be evaluated at different times. But we can correct for these differences by using Corollary 15 to shift node scores from one time to another.

Let us do the calculation accurately, including the time shifts.

\[
vw.r - uw.r = w.r_v - v.r'_w - w.r_u + u.r'_w
\]

The fourth term in the final expression is the negative of the link score of \( uv \). The first three terms shift the node scores of \( w, v, \) and \( u \), respectively, to their correct times.

The time intervals over which the shifts of \( w.r \) occur are from just before \( w \) loses a link to just before its next loss. For a given \( w \), these time intervals are disjoint. Hence the sum of these terms over all nodes and over all delete-min operations is at most the sum of the magnitudes of the increases and decreases in the score of \( w \). Corollary 15 bounds this quantity.

The time intervals over which the shifts of \( v.r \) occur are from just before \( v \) loses a link to just after \( v \) wins a link during the delete-min that cuts the link that \( v \) previously lost. During a delete-min, a node wins at most two links. Thus if we partition the time intervals over which the node score of \( v \) is shifted into those ending at a first win by \( v \) in a delete-min and those ending at a second win by \( v \) in a delete-min, the intervals in each part of the partition are disjoint. Hence the sum of these terms over all nodes and all delete-min operations is at most twice the bound in Corollary 15.

The third term, \( u.r'_w - u.r'_v \) is more problematic, because the time shifts for \( u \) can overlap for many of the new roots, of which \( v \) and \( w \) are only two. We can only use Corollary 15 to bound shifts with at most constant overlap. Lemma 6 comes to our rescue. We call \( u.r'_w - u.r'_v \) the shift of link \( vw \).

Lemma 18. The sum of the shifts of the new links done during a delete-min that deletes root \( u \) is at most the sum of the magnitudes of the changes in the node score of \( u \) from the time it was inserted until it is deleted.

Proof. Let \( v_1, v_2, \ldots, v_k \) in left-to-right order be the new roots just after the removal of \( u \). For \( i < k \) let \( \Delta_i = u.r'_{v_i} - u.r'_{v_{i+1}} \). We claim that the sum of the shifts of the new links done during the delete-min is at most \( \sum_{i=1}^{k-1} |\Delta_i| \).

To prove the claim, for each \( i < k \) and for each new link \( vw \) done during the delete-min that crosses the boundary between \( v_i \) and \( v_{i+1} \), allocate to the loser \( w \) an amount \( \Delta_i \) if \( vw \) is a left link (\( w \) is on the left side of the boundary), or \(-\Delta_i \) if \( vw \) is a right link (\( w \) is on the right side.
of the boundary). By Lemma 6, the new links crossing the boundary alternate left and right, so the numbers of left and right links crossing the boundary differ by zero or one. Hence the sum of the allocations for a given \( i \) over all links crossing the boundary between \( v_i \) and \( v_{i+1} \) is either 0, \( \Delta_i \), or \( -\Delta_i \), hence at most \( |\Delta_i| \). The sum of the allocations over all \( i < k \) is thus at most \( \sum_{i=1}^{k-1} |\Delta_i| \).

To finish proving the claim, we show that the sum of the shifts of the new links done during the delete-min equals the sum of the allocations. Let \( vw \) be a new link done during the delete-min. If \( w \) is left of \( v \), \( w \) receives an allocation of \( \Delta_i \) for each \( i \) such that \( v_i \) is \( w \) or between \( w \) and \( v \). The sum of these allocations telescopes and equals the shift of \( vw \). Symmetrically, if \( w \) is right of \( v \), \( w \) receives an allocation of \( -\Delta_i \) for each \( i \) such that \( v_i \) is \( v \) or between \( v \) and \( w \). The sum of these allocations also telescopes and equals the shift of \( vw \).

The \( v_i \) are on the root list in decreasing order by the time they were linked to \( u \). Thus the time intervals from just after the link of \( v_{i+1} \) to \( u \) to just after the link of \( v_i \) to \( u \) are disjoint. Hence \( \sum_{i=1}^{k-1} |\Delta_i| \) is at most the sum of the magnitudes of the changes in the score of \( u \) over its entire history. The lemma follows from the claim.

Now we put the pieces together.

**Theorem 19.** The sum of the link scores of all real links \( uv \) such that \( v \) wins a new link \( vw \) during the delete-min that deletes \( u \) and \( uw \) was new is \( O(\lg \lg n) \) per decrease-key plus \( O(\lg n) \) per delete-min.

**Proof.** If \( v \) wins a new link \( vw \) during a delete-min that deletes \( u \), we define the cost of link \( vw \) to be \( uv.r \). Any other link has cost 0. We use the link score of the heap as a potential to bound the total cost. Only new links and cuts of new links change the link score of the heap and only new links have non-zero cost. Cutting a phantom new link during a decrease-key increases the total link score by the negative of the score of the link. This is at most \( \lg \lg n \), making the amortized cost of a decrease-key at most \( \lg \lg n \).

The remaining new links and cuts of new links are among the cuts of real links and the new links done during delete-min operations. Consider a delete-min that deletes \( u \). For each new link \( vw \) done during this delete-min, we pair the cut of link \( uw \) with the link \( vw \). Link \( uw \) may be either new or old; if it is old, we pair it with \( vw \) anyway, even though its link score is zero. Each new root except at most one loses one link during the delete-min. Thus at most one cut of a link is unpaired. This cut does not increase the link score, since the link is real.

Let \( vw \) be a new link done during the delete-min. The cost of \( vw \) is \( uv.r \). Thus the amortized cost of cutting \( uw \) and linking \( w \) to \( v \) is \( uv.r - uw.r + vw.r \). By our calculation earlier in this section, this is at most \( (w.r_v - w.r_u) + (v.r_u - v.r'_w) + (u.r'_w - u.r'_v) \). As discussed earlier in the section, the sum of the first two terms over all such links \( vw \) is at most three times the sum of the magnitudes of the changes in node score. By Corollary 15, this is \( O(\lg n) \) per decrease-key plus \( O(\lg n) \) per delete-min. The third term is the shift of \( vw \). By Lemma 18 and Corollary 15, the sum of the shifts over all such links \( vw \) is also \( O(\lg n) \) per decrease-key plus \( O(\lg n) \) per delete-min. Hence the sum of the amortized costs of all operations has the bound in the theorem. The theorem follows by the potential method.
6 Counting New Links

Finally we are ready to bound the number of new links. Suppose \( v \) wins a new link during the delete-min that deletes root \( u \). Let \( uv \) be the first such link. By Theorem 19 and the potential method, the link score of \( uv \) is available to pay for the one or two links won by \( v \) during the delete-min that deletes \( u \). Link \( uv \) is a real link since it is cut during a delete-min. If the score of \( uv \) is at least 1/2, it covers the cost of the links won by \( v \). If not, we shall show that when \( v \) was linked to \( u \), the node score of \( v \) decreases by enough to pay for the links won by \( v \), with certain exceptions that we pay for by other means. The complete analysis consists of the following seven cases. Each case assumes that none of the previous cases applies.

Case 1: Link \( uv \) is an old link. We charge any links won by \( v \) to \( uv \). At most two links are charged to \( uv \) this way. By Theorem 7, the total charge over all such cases in all delete-min operations is at most six per insert and six per decrease-key.

Case 2: The link score of \( uv \) is at least 1/2. We charge the link or links won by \( v \) to four times the link score of \( uv \). By Theorem 19, the total charge over all such cases in all delete-min operations is \( O(\lg \lg n) \) per decrease-key plus \( O(\lg n) \) per delete-min.

Let \( x \) be the root deleted during the delete-min that most recently linked \( u \) and \( v \).

Case 3: The node score of \( v \) just after the removal of \( x \) is less than 3/2. We charge the links won by \( v \) to the delete-min that deletes \( y \). By Lemma 8, the charge for Case 3 is \( O(\lg n) \) per delete-min.

Case 4: The node score of \( v \) just after the removal of \( x \) is less than \( \lg(2/(2 - \sqrt{2})) \). As in Case 3, we charge the links won by \( v \) to the delete-min that deletes \( x \). Since a given \( u \) can win up to two links during the delete-min that deletes \( x \), the charge to the delete-min is at most four per node of score less than \( \lg(2/(2 - \sqrt{2})) \). By Lemma 8, the charge for Case 4 is \( O(\lg n) \) per delete-min.

Case 5: The node score of \( u \) is less than one just before the link of \( u \) and \( v \). Since Case 3 does not apply, the node score of \( v \) decreases by at least 1/2 from just after the deletion of \( y \) to just before the link of \( u \) and \( v \). We charge the link or links won by \( v \) to four times this decrease. By Theorem 14, the total charge over all such cases in all delete-min operations is \( O(\lg \lg n) \) per decrease-key plus \( O(\lg n) \) per delete-min.

In the remaining two cases, we show there is at least a positive constant decrease in the node score of \( v \) due to the link \( uv \). Let unprimed and primed variables take their values just before and just after the link of \( u \) and \( v \). Since the Cases 2 and 5 do not apply, \( uv.r = v.r - u.r' < 1/2 \) and \( v.r \geq 1 \), so \( u.r' > 1/2 \). If \( v.r' = 0 \), the node score of \( v \) drops by at least one as a result of link \( uv \). Hence we can assume \( v.r' > 0 \).

Case 6: Link \( uv \) is a left link. The drop in the node score of \( v \) caused by the link is

\[
v.r - v.r' \geq \log_2 \log_2(v.m/v.s) - \log_2 \log_2((u.s + v.s)/v.s)
= \log_2 \log_2(v.m/v.s) - \log_2 \log_2(v.m/v.s) - \log_2(v.m/(u.s + v.s))
= \log_2 2^{v.r} - \log_2 (2^{v.r} - 2^{u.r'}) = \log_2 \left(1/(1 - 1/2^{v.r - u.r'})\right)
\]

Since \( v.r - u.r' \) is the link score of \( uv \), which is less than 1, the drop in the node score of \( v \) is at least \( \log_2(1/(1/2)) = 1 \). We charge the one or two links won by \( v \) to twice this drop. By
Theorem 14, the total charge over all such cases in all delete-min operations is is $O(\lg \lg n)$ per decrease-key plus $O(\lg n)$ per delete-min.

**Case 7:** Link $uv$ is a right link. Let subscript zero denote values of variables just after $y$ is removed. The drop in the node score of $v$ caused by the link is greater than
\[
v.r - v.r' \geq \log_2 \log_2 (v.m/v.s) - \log_2 \log_2 ((u.s_0 + v.s)/v.s)
= \log_2 \log_2 (v.m/v.s) - \log_2 (\log_2 (v.m/v.s) - \log_2 (u.m_0/(u.s_0 + v.s)) + \log_2 (u.m_0/v.m))
= \log_2 2^{v.r} - \log_2 (2^{v.r} - 2^{u.r'}) + \log_2 (u.m_0/(u.m_0 - u.s_0))
= \log_2 \left(\frac{1}{\left(1 - 1/2^{v.r-u.r'} + \lg (u.m_0/(u.m_0 - u.s_0))/2^{v.r}\right)}\right)
\]
Since $v.r - u.r' < 1$, $1/2^{v.r-u.r'} > 1/2$. Since Case 4 does not apply, $\lg (u.m_0/u.s_0) = 2^{u.r_0} \geq 2/(2 - \sqrt{2}) > 3$, so $u.m_0 > 8u.s_0$. Hence $\lg (u.m_0/(u.m_0 - u.s_0)) \leq 1/4$. The link causes the node score of $v$ to drop by at least $\lg (1/(1 - 1/2 + 1/4) = \lg (4/3)$. We charge the link or links won by $v$ to $2/\lg (4/3)$ times the drop in the node score of $v$ caused by the link. By Theorem 14, the total charge over all such cases in all delete-min operations is is $O(\lg \lg n)$ per decrease-key plus $O(\lg n)$ per delete-min.

This covers all the cases, giving us the desired result:

**Theorem 20.** The total number of new links is $O(1)$ per insert plus $O(\lg \lg n)$ per decrease-key plus $O(\lg n)$ per delete-min.

Combining Theorems 7 and 20 with the discussion in Section 4 gives us the desired bound for slim heaps:

**Theorem 21.** The total time of a sequence of heap operations on a slim heap is $O(1)$ per make-heap, find-min, or insert, $O(\lg \lg n)$ per decrease-key, and $O(\lg n)$ per delete-min or delete.

## 7 Analysis of Smooth Heaps

In this section we adapt our analysis to smooth heaps. To do so, we need to treat left and right children somewhat separately, since the order of right children in a smooth heap is the reverse of their order in a slim heap, and in a slim heap left and right children are intermixed, whereas in a smooth heap all the left children precede all the right children. We extend the definition of “left” and “right” to new roots. A new root is a **left root** if it was a left child just before it became a new root, a **right root** otherwise.

To a large extent, the analysis of new roots in slim heaps applies directly to the left roots in smooth heaps and symmetrically to the right roots. We also have to deal with links between left and right roots, and between right roots and old roots, which complicates the analysis. On the other hand, the analysis for links between left roots and links between right roots is slightly simpler because a node can only win one left link and one right link during a delete-min, and the resulting sibling order is independent of the order of these links. In a slim heap, a node can win a left link first and then a right link, or vice versa, and the order of linking determines the sibling order. As discussed in Section 5.2, our definition of mass in slim heaps allowed for either link order by omitting the size of the right sibling of a child. For smooth heaps we do not need to do this.
On the other hand, in slim heaps we had to avoid counting old nodes in the size of new roots, but in smooth heaps we also have to avoid counting descendants of right roots in the sizes of left roots, and vice-versa. Accordingly, during a delete-min, we call a node old, left, or right if, just after removal of the min-root, it was a descendant of an old, left, or right root, respectively. This definition is independent of that of left and right children: a left or right child can be an old, left, or right node.

We redefine the size of a node to be the number of nodes in its real subtree if it is a child or an old root, the number of old and right nodes in its subtree if it is a right root, or the number of left nodes in its subtree if it is a left root. We redefine the mass of a node to be its size if it is an old root or a phantom child, the number of left nodes in its real subtree and in those of the roots to its right on the root list if it is a left root, the number of right and old nodes in its subtree and in those of the roots to its left in the root list if it is a right root, its size plus those of the left children to its right on its sibling list if it is a left child, or its size plus those of the right children to its left if it is a right child.

There is at most one root whose size is not equal to the size of its real subtree. It is either the rightmost left root, because its tree contains a right or old node, or the leftmost right root, because its tree contains a left node. When a link between a left node and a right node occurs, the loser’s size and mass can increase: if the loser is the left node, they increase by the number of right and old descendants; if it is the right node, they increase by the number of left descendants. We treat these size and mass increases as a separate event happening just after the node loses the link, so we do not need to consider these changes when studying the effect of links and cuts on node and link scores, just as in the analysis of smooth heaps. Increasing the size and mass of a node by the same amount does not increase its node score.

We proceed to describe in detail how the analysis changes.

As in slim heaps, the size of a node is initially one and is non-decreasing until it is deleted; its size increases only when it wins a real link, or when it loses a real link between a left root and a right root. The mass of a node is also initially one, but it can increase or decrease as the result of a link or a cut.

Phantom links behave just as in slim heaps. Cutting a phantom link changes no mass or size and thus changes no node score. Doing a phantom link changes no sizes and does not increase any masses, but as in a slim heap it can decrease the masses of new roots if the loser is a new root or the leftmost old root. We conclude that phantom links and cuts of phantom links do not increase any node score.

Because of the redefinition of the masses of children, removing the min-root at the beginning of a delete-min changes no sizes or masses of the remaining nodes, so we do not need Lemma 9. That is, cuts do not change any link scores except that of the removed min-root, whose score becomes zero.

As in slim heaps, a real link can change only the scores of the winner and loser, and cannot increase the score of the winner. To verify this we must consider two extra kinds of links, those between a right root and an old root and between a left root and a right root. A real link between a right root and an old root increases the size and mass of the winner by the same amount, which does not increase its score, and in addition changes only the mass of the loser. A real link between a left root and a right root changes neither the size nor mass of the winner, and in addition changes only the size and mass of the loser.

Lemma 10 holds as stated, as do Lemma 11 and Corollary 12. Lemma 11 also gives us a
bound on the increases in node scores caused by links between left and right roots:

**Lemma 22.** The sum of increases in node scores caused by links between left and right roots is at most \(\lg n\) per delete-min.

**Proof.** Consider a delete-min. Choose the boundary between the rightmost left root and the leftmost right root. Every link between a left root and a right root crosses this boundary. Apply Lemma 11.

The proof of Lemma 13 applies separately to right links between left roots and symmetrically to left links between right roots. We incur a constant factor of two. Theorem 14 and Corollary 15 hold as stated.

We define the link score exactly as in slim heaps. We need to consider the effect on links scores of links between left and right roots, and between right and old roots.

**Lemma 23.** A real link between a left root and a right root has non-negative link score.

**Proof.** Let \(vw\) be a link between a left link and a right link. Assume \(v\) is a left root; the argument is symmetric if \(v\) is a right root. If the tree rooted at \(v\) contains a right node, the size and mass of \(v\) are equal both before and after the link, so the link score is non-negative. If the tree rooted at \(v\) does not contain a right node, then the score of \(w\) before the link and the score of \(v\) after the link are both zero, making the link score zero.

Phantom links can have negative scores, and so can real links lost by old roots to right roots. A real link lost by a right root to an old root has link score zero, because the old root has score zero before the link, and it cannot yet have won a left link during the delete-min, so the right link has size and mass equal before the link, making its score and the link score zero. Although phantom links are cut before the end of the sequence of heap operations, this need not be true of real links lost by old roots to new roots. But we can bound the contribution of these links to the total link score by applying Lemma 2 and doing some time-shifting:

**Lemma 24.** The negative of the total link score at the end of a sequence of heap operations is \(O(\lg \lg n)\) per decrease-key plus \(O(\lg n)\) per delete-min.

**Proof.** The only real links with negative score are those between right roots and old roots. Consider the set of links done between a right root and an old root during a single delete-min. They all cross the boundary between the rightmost right root and the leftmost old root, so they are all on a single path in the data structure after the delete-min. We bound the sum of the scores of the winners of the links by \(\lg n\), which gives the lemma.

Let \(v_1, v_2, ..., v_k\) be the winners of these links, bottom-up along the path, and let \(w_1, w_2, ..., w_k\) be the corresponding losers. Let variables take their values at the end of the delete-min. For \(i < k\), \(v_i.m \leq w_i.s \leq v_{i+1}.s\). Hence \(v_{i+1}.r = \lg (v_{i+1}.m/v_i.m) \leq \log_2(v_{i+1}.m/v_i.m) = \log_2 v_{i+1}.m - \log_2 v_i.m\). Summing this bound over all \(i < k\), the sum telescopes and is at most \(\lg n\). We conclude that the sum of the node scores of the winners at the end of the delete-min is at most \(\lg n\).

What we want is a bound on the sum of the scores of the winners just after the links they won. This requires shifting the score of each winner backward in time from the end of the delete-min to just after it won the link. The time intervals over which the shifts occur are disjoint for all such links. The lemma follows from Corollary 15.
Lemma 18 holds without change. Theorem 19 also holds: the only change needed in the proof is to observe that the negative of the final link score, which must be added to the sum of the amortized costs to get an upper bound on the total cost, is $O(\lg \lg n)$ per decrease-key plus $O(\lg n)$ per delete-min by lemma 24.

In the analysis of Section 6, Cases 1, 2, and 5 apply as stated. We apply Cases 3, 4, 6 and 7 separately to left roots $v$ and symmetrically to right roots $v$, incurring a constant factor of two. We need to consider an additional possibility: link $uv$ is between a left root and a right root. Assume $u$ is left: the argument is symmetric if $u$ is right. Node $u$ has not won a right link in the delete-min before it wins $uv$, so its tree contains only left nodes. Hence the size and mass of $v$ are the same just before the link, making its score zero. Then Case 3 or Case 5 applies, validating the analysis in Section 6 for smooth heaps and giving us Theorem 21 for these heaps.

8 Remarks

We have proved that slim and smooth heaps have amortized efficiency matching Iacono and Özkan’s lower bounds for heaps that conform to their pure heap model, intended to include all possible “self-adjusting” heap implementations. We are optimistic that our ideas will extend to give the same bounds for pairing heaps, but so far giving a tight analysis of these heaps remains an open problem.

Our analysis includes a couple of complications needed to obtain the desired bounds for the canonical versions of slim and smooth heaps. By slightly changing the implementations, one can simplify the analysis, although as we mentioned in Section 5.1 this violates the goal designing simple data structures. Nevertheless, we describe how to do so, because it is straightforward and might be useful in another setting.

In a slim heap, we can avoid the need to exclude the size of its right sibling in defining the mass of a child by making sure that if a node wins two links during a delete-min, it wins the right one first. One way to do this is to do the links right-to-left: find the rightmost local maximum, say $v$ with left neighbor $u$ and right neighbor $w$, and link $v$ to its neighbor of larger key. If this is $u$, $u$ wins a right link before it wins a left link. If this is $w$, $w$ wins a left link but both its neighbors have smaller key than that of $w$: if its right neighbor had larger key, $v$ would not be the rightmost local maximum. Node $w$ continues to have larger key than those of both its neighbors until it loses a link. This linking order is what one would obtain naturally by implementing locally maximum linking recursively. An alternative is to do the links in arbitrary locally maximum order, but mark a node if it wins a left link; and, if it wins a right link later in the same delete-min, insert the new child right of the old leftmost child, not left of it. Then the sibling order is the same as if the right link occurred first.

In both slim and smooth heaps, links that involve nodes of different types (old and new in the case of slim heaps, left, right, and old in the case of slim heaps) complicate the analysis. We can eliminate links between old and new roots by doing delete-min in two passes. We eliminate the min-root and do linking in find-min instead of delete-min: To do a find-min, link all the roots on the root list using locally maximum linking and return the resulting root. To do a delete-min, do a find-min, delete the root, and do another find-min. The first find-min in a delete-min links only old roots, the second links only new roots. We call this the two-pass version of a slim or smooth heap. In a smooth heap, we must still consider links between left and right roots in the
analysis. We can eliminate even these by linking left and right roots separately and then linking the final winner of the links of left roots with the final winner of the links of right roots.

More interesting is whether our analysis extends to variants of slim and smooth heaps not designed to make the analysis simpler. We mention two such variants: the eager version and the lazy version. Neither maintains the min-root.

The eager version maintains the forest as a single tree, as in the original version of pairing heaps: it does an insert by linking the newly created root with the existing root, melds two heaps by linking the roots of their trees, and does a decrease-key of a non-root node by changing its key, cutting it from its parent, and linking it with the existing root. A find-min returns the root of the tree.

The lazy version maintains a list of trees. It does insert and meld as in the original version. It does find-min by linking all the existing roots using locally maximum linking and returning the one remaining root. It does delete-min by doing a find-min and deleting and returning the root. (Delete-min does only one find-min, not two).

We conjecture that both versions of both slim and smooth heaps have the efficiency stated in Theorem 21. For the eager versions, our analysis extends to give $O(lg lgn)$ time per insert, meld, and decrease-key, and $O(lg n)$ per delete-min and delete. But we think the tight bound for insert and meld is $O(1)$. For the lazy variant, we think the desired bounds are provable but have not yet worked out the details.

There is also a hybrid of a pairing heap and a slim heap or smooth heap for which Theorem 21 is true: after deleting the min-root in a delete min, do one pairing pass, linking the first and second roots, the third and fourth, and so on. Then do locally maximum linking of the remaining roots. We call the resulting data structure the hybrid heap. It does 3/2 comparisons per link, whereas pairing heaps do one, and slim and smooth heaps do two.

In all these data structures, scrambling the old roots before doing the linking in a delete-min has no effect on the analysis, but scrambling the new roots is fatal. The efficiency of these structures depends on keeping sibling order consistent with linking order. In particular, the analysis applies to the original presentation of smooth heaps [16], which maintains a consistent left-to-right order of nodes by insertion time, only perturbed somewhat by decrease-key and meld operations.
