Abstract

Group fairness definitions such as Demographic Parity and Equal Opportunity make assumptions about the underlying decision-problem that restrict them to classification problems. Prior work has translated these definitions to other machine learning environments, such as unsupervised learning and reinforcement learning, by implementing their closest mathematical equivalent. As a result, there are numerous bespoke interpretations of these definitions. Instead, we provide a generalized set of group fairness definitions that unambiguously extend to all machine learning environments while still retaining their original fairness notions. We derive two fairness principles that enable such a generalized framework. First, our framework measures outcomes in terms of utilities, rather than predictions, and does so for both the decision-algorithm and the individual. Second, our framework considers counterfactual outcomes, rather than just observed outcomes, thus preventing loopholes where fairness criteria are satisfied through self-fulfilling prophecies. We provide concrete examples of how our counterfactual utility fairness framework resolves known fairness issues in classification, clustering, and reinforcement learning problems. We also show that many of the bespoke interpretations of Demographic Parity and Equal Opportunity fit nicely as special cases of our framework.

1 Introduction

Machine learning (ML) is used to automate decision-making in settings such as hospital resource allocation [Obe+19], job application screening [Rag+20], and criminal sentencing recommendations [Kle+18]. Given the high social impact of these settings, the field of fairness in machine learning has gained significant attention in recent years. In this work, we focus on group fairness definitions, where an algorithm is considered fair if its results are independent of one or more protected attributes such as gender, ethnicity, or sexual-orientation. Many group fairness works focus only on classification settings [Ber+18; Cho17; Cor+17; Dwo+12; Har+16; Kus+17; GBM17]. This often conceals assumptions that do not always hold true in other contexts, resulting in definitions that are tightly coupled with a particular problem domain. In this paper we examine four such assumptions.

Assumption 1. Fair predictions have fair outcomes.

Many group fairness definitions require equal predictions between protected groups [Ber+18; Cho17; Cor+17; Dwo+12; Har+16], and generally consider the binary case with a minority group and a majority group. For example, Demographic Parity considers a binary classifier to be fair if it predicts the positive class for individuals in the minority group and majority groups with equal probability. This implicitly assumes that a positive prediction is always a good thing for an individual. However, there are many problem domains where this is not true. For instance, Liu et al. [Liu+18] consider an algorithm that predicts whether or not a loan applicant will repay a loan, which then informs a loan-approval decision. In this scenario, a positive prediction results in a loan approval, which has a positive outcome for those who will pay back the loan, but has a negative outcome for those who...
will default on the loan. More generally, in situations where predictions impact individuals from the minority and majority groups differently, prediction-based fairness definitions may actually result in unfair outcomes. We refer to this as the **prediction-outcome disconnect** issue.

**Assumption 2.** Observed values of the target variable are independent of predictions.

Some fairness definitions depend on the observed value of the target variable as well as the prediction. For example, Equal Opportunity requires equal treatment of the qualified individuals in each group, where *qualified* refers to individuals who were observed to be in the positive class [Har+16]. However, consider a classifier that predicts if an individual convicted of a crime will recidivate, where the prediction informs a judge’s decision on whether to impose a prison sentence. It is possible that the decision of whether to assign prison time actually influences the individual’s probability of being *qualified*, which corresponds to not recidivating. For example, suppose there is a group of backlash individuals that will only recidivate if they are sentenced to prison [IJ20]. If the algorithm predicts that these individuals will recidivate, which causes the judge to sentence them to prison, these individuals will be considered *unqualified* because they will in fact recidivate. However, if the algorithm had instead predicted these backlash individuals to not recidivate, then they will not actually recidivate and will be considered qualified. Thus an algorithm can satisfy Equal Opportunity through a self-fulfilling prophecy by manipulating who is considered qualified.

**Assumption 3.** The objective is to predict some unobserved target variable.

In classification problems, the goal is to make a single prediction of some latent qualification attribute of the individual. However, this is not true in other ML environments where the decision is not necessarily a prediction of some ground-truth value, and where there may be more than one decision per individual. In sequential decision settings such as reinforcement learning (RL), the goal is to maximize a reward rather than predict a target. Additionally, there can be multiple sequential decisions made for each individual and we may wish to measure fairness across the entire sequence. Although some attempts have been made to translate group fairness to the sequential decision setting [Bow+17], [WBT21], they assume a specific problem structure which limits their application. Similarly, there are several bespoke translations in clustering problems [Che+19], [ABV21], [Ber+19], [Chi+17], each of which is tied to a variant of what fairness means in their particular context.

**Assumption 4.** Decisions for one individual do not impact other individuals.

Each classification prediction is independent of the predictions made for other individuals. However, this does not generalize to all of ML. In clustering problems, for example, the impact of one individual’s cluster assignment may depend on the cluster assignments of other individuals. For example, Abbasi, Bhaskara, and Venkatasubramanian [ABV21] consider redistricting as a fair clustering problem, where fairness implies that constituents from each political party are equally represented by their assigned district. In order to measure how well a constituent is represented by their district, we need to know who else was assigned to their district. We term this **conjoined fairness** when the impact of a decision for one individual requires measuring the decisions made for other individuals as well. Conjoined fairness can also arise in other settings such as ranking (if the impact of being ranked second depends on who was ranked first) or RL (if, e.g., the decision to hire an individual may preclude the future hiring of another).

### 1.1 Our Contributions

In this work, we provide a more general group fairness framework that does not rely on the aforementioned assumptions, thereby allowing it to extend to a wide variety of classification, clustering, and reinforcement learning tasks. We show that our definitions encompass the standard definitions from classification settings as well as several of their domain-specific translations. We demonstrate how our definitions represent domain idiosyncrasies as variables and parameters which reduces the need for bespoke definitions.

We focus on Demographic Parity and Equal Opportunity, but as we discuss in Appendix A.1, our framework can extend to other group fairness definitions as well. There are two principles that differentiate our framework: **welfare** and **counterfactual utility outcomes**.

**Welfare** To resolve the prediction-outcome disconnect issue, it is instructive to consider the intuition behind Demographic Parity, which requires that the probability that an individual receives a beneficial outcome is independent of the individual’s protected attribute. We can resolve this issue by measuring
the individual’s outcome directly. Thus, we introduce a new variable called welfare, which represents the individual’s utility resulting from a prediction. For example, a loan applicant that will pay back a loan has positive welfare if the algorithm predicts that the applicant will pay back the loan, since the prediction results in a positive outcome for the applicant. On the other hand, a loan applicant that will default on a loan has negative welfare if the algorithm predicts that they will pay back the loan, since this prediction results in a negative outcome (defaulting). Our Demographic Parity and Equal Opportunity definitions require the welfare variable to be defined for the given problem domain, and then measure equal welfare instead of equal predictions. By measuring fairness directly in terms of welfare, our definitions enforce fair outcomes even in domains where the predictions impact individuals differently. Furthermore, since utility is a more generally applicable concept, this approach makes sense in a broader range of domains where Assumptions 3 and 4 may not hold.

Counterfactual utilities We saw in our discussion of Assumption 2 that the standard definition of Equal Opportunity is vulnerable to self-fulfilling prophecies. In order to remedy this, we construct a more general Equal Opportunity definition by giving a more general interpretation of what it means to be qualified. We interpret this as an individual where there exists a decision that will yield a good outcome for both the decision-algorithm and the individual. In other words, we measure qualification in terms of counterfactual utility outcomes for both the decision-algorithm and the individual. By considering counterfactual outcomes, our Equal Opportunity definition prevents self-fulfilling prophecies and is well-defined for a broader range of machine learning environments.

1.2 Related Work

Previous work has incorporated notions of utility or welfare into fairness problems in machine learning [Jab+17; Liu+18; Kim+20] and such approaches are common in economics [Fin+21]. However, this work has not formulated group fairness definitions in terms of utilities. As the lone exception, Wen, Bastani, and Topcu [WBT21] recently independently introduced the idea of using welfare to generalize group fairness definitions to Markov decision processes (MDPs). However, they do not consider the possibility of generalizing to other domains such as clustering or make use of counterfactual utilities, so their approach applies only to a restricted class of MDPs. See Section 5.3 for more discussion.

Our use of counterfactuals may seem reminiscent of the literature on causal fairness notions such as counterfactual fairness [Kus+17; Kil+17; NS18; Lof+18; MZP20]. However, there the counterfactual is what decision the algorithm would make if the protected attribute were different, while for us the counterfactual is what a different choice of algorithm would do. Krishnaswamy et al. [Kri+21] consider counterfactual algorithm choices, but do so to have a baseline on how well the best classifier for a group can perform. Our use of counterfactuals is more similar to the way it is used in principal fairness [IJ20]; see Section 5.2 for a full discussion.

Previous work has explored relaxing each of our four assumptions, although typically in isolation. This includes work on prediction-outcome disconnect [Liu+18; Cre+20], self-fulfilling prophecies [IJ20], fairness in sequential decision-making for reinforcement learning [Jab+17] and pipelines [Bow+17; DJ20; Eme+19], fair ranking [CSV17; SJ19; ZYS21], and fair clustering [Chi+17; Ber+19; Che+19; ABV21].

2 Preliminaries

The group fairness definitions we study were originally developed in the context of classification. Following Hardt et al. [Har+16], we think of this task as predicting a target value $Y$ based on features $X$ and protected attribute $Z$ where the population of individuals is represented by the joint distribution of $(X, Z, Y)$ and the goal is to develop a classifier $\hat{Y}(X, Z)$. We typically omit the arguments to $\hat{Y}$ for brevity when they are clear. An individual is an element of $X \times Z \times Y$. Here $X$ and $Y$ are the sets of possible feature values and target values. We restrict the protected attribute space to be binary $Z = \{0, 1\}$ purely for ease of exposition. We refer to individuals with $Z = 0$ as the minority group, and those with $Z = 1$ as the majority group. There is a loss function $L : Y \times Y \rightarrow \mathbb{R}$ and the objective is to find the classifier that minimizes expected loss $L(Y, \hat{Y}(X, Z))$. We refer to the tuple $(X, Z, Y, L)$ as a supervised learning classification problem (SLCP).

1 See Appendix A.3 for a discussion about situations with more than two protected groups.
While there are many group fairness definitions \cite{PS20,VR18}, we focus our exposition on two of the most important to illustrate our approach.  

**Definition 2.1** (Classification Demographic Parity). A classifier \( \hat{Y} \) satisfies Classification Demographic Parity (DemParClf) for an SLCP \( (X,Z,Y,L) \) if 
\[
P(\hat{Y} = 1 \mid Z = 0) = P(\hat{Y} = 1 \mid Z = 1)  
\]  

**Definition 2.2** (Classification Equal Opportunity). A classifier \( \hat{Y} \) satisfies Classification Equal Opportunity (EqOppClf) for SLCP \( (X,Z,Y,L) \) if 
\[
P(\hat{Y} = 1 \mid Y = 1, Z = 0) = P(\hat{Y} = 1 \mid Y = 1, Z = 1)  
\]  

3 Developing Intuition for a Counterfactual Utility Framework

In this section we provide an intuitive, high-level explanation of our approach for generalizing group fairness definitions beyond classification. We defer a formal treatment to Section 4.  

3.1 Fairness Through Welfare

Recall that DemParClf is defined as \( P(\hat{Y} = 1 \mid Z = 0) = P(\hat{Y} = 1 \mid Z = 1) \). This definition is in terms of SLCP variables. However, the concept behind Demographic Parity, that equal outcomes should be enforced across groups, is relevant in any domain. Suppose that we instead define a more general version of Demographic Parity where we replace \( \hat{Y} \) with a variable \( W \) that represents the welfare of the decision from the individual’s perspective. Assuming that \( W \) can take on a range of values, our more general Demographic Parity becomes 
\[
P(W \geq \tau \mid Z = 0) = P(W \geq \tau \mid Z = 1),  
\]  
where \( \tau \in \mathbb{R} \) is some domain-specific threshold representing the minimum welfare to be considered a good outcome for the individual. Rather than assuming that a prediction of 1 is the good outcome, as in Definition 2.1, we explicitly capture the relationship with \( W \) which allows us to incorporate a variety of domain-specific aspects. Under this formulation of Demographic Parity, an algorithm is fair if the probability that a good welfare outcome is achieved is equal for both values of the protected attribute. Requiring equal welfare instead of equal predictions enables this definition to be relevant in any setting where \( W \) and \( Z \) can be defined.  

3.2 Counterfactual Utility Qualification

EqOppClf requires \( P(\hat{Y} = 1 \mid Y = 1, Z = 0) = P(\hat{Y} = 1 \mid Y = 1, Z = 1) \). We can modify this to consider welfare: \( P(W \geq \tau \mid Y = 1, Z = 0) = P(W \geq \tau \mid Y = 1, Z = 1) \). However, this definition is still using the SLCP variable \( Y \). In order to extend this definition to environments outside of classification, we need to inspect the intuition for Equal Opportunity, which is that the probability that a qualified individual receives a beneficial outcome is independent of the individual’s protected attribute. The part of the definition referring to the beneficial outcome is covered by the welfare concept, so we only need to modify the definition to allow qualified to also to extend to other settings. We develop intuition by considering some examples of Equal Opportunity:

- The probability that a skilled job candidate is hired is independent of their protected attribute.
- The probability that a straight-A student is admitted to a university is independent of their protected attribute.

Thus, qualified individuals are those whose beneficial outcome also benefits the decision-algorithm:

- The beneficial outcome for a job applicant is to be hired. If hired, a skilled job candidate will also benefit the employer since they will be competent at their job.

\footnote{For discussion of how our approach applies to others, see Section A.1.}

\footnote{The use of a threshold \( \tau \) is not the only reasonable choice here. See Appendix A.2.}
• The beneficial outcome for a student is to be admitted to the university. If admitted, a straight-A student will benefit the university by enhancing the university’s reputation.

Thus, our more general interpretation of Equal Opportunity is:

For the subset of individuals where there exists an outcome that will benefit both the individual and the decision-algorithm, the probability that a beneficial individual outcome occurring is independent of the individual’s protected attribute. Thus, our more general interpretation of Equal Opportunity is:

We can represent this in equation form as

\[ P(W \geq \tau \mid \Gamma = 1, Z = 0) = P(W \geq \tau \mid \Gamma = 1, Z = 1) \] (3.2)

where \( \Gamma \) is an indicator random variable with \( \Gamma = 1 \) when the decision-algorithm can produce an outcome that is beneficial for both the individual and the decision-maker. The benefit to the individual is captured by \( W \). We can similarly capture the impact on the decision- with a cost \( C \)

\[ \Gamma = \begin{cases} 1 & \text{if } \exists \hat{Y}': W_{\hat{Y}'} \geq \tau \land C_{\hat{Y}'} \leq \rho \\ 0 & \text{otherwise} \end{cases} \] (3.3)

Here \( W_{\hat{Y}'} \) and \( C_{\hat{Y}'} \) are the expected welfare and cost, respectively, produced by predictor \( \hat{Y}' \) and \( \rho \) is similar to \( \tau \) but for the cost. We can validate that Equation 3.2 generalizes well by applying it to the recidivism prediction example from Section 1 where EqOppClf allows for self-fulfilling prophecies.

For the subset of individuals (inmates) where there exists an outcome that will benefit both the individual (no prison) and the decision-algorithm (no recidivism), the probability that a beneficial individual outcome (no prison and no recidivism) occurring is independent of the individual’s protected attribute.

We see that our more general Equal Opportunity resolves the self-fulfilling prophecy issue because it conditions on individuals who could have been qualified. Thus, the qualified individuals are those that will not recidivate if they do not receive prison time. In other words, our more general interpretation conditions on counterfactually qualified individuals. There are many other such counterfactuals where it is natural to condition on in this manner; see Section 5.2 for an example and Appendix A.1 for additional discussion.

4 Counterfactual Utility Fairness

We now provide our formal model of how to define welfare and counterfactual qualification. We do so in an abstraction that we term a Fairness Decision-Making Problem (FDMP). This generalizes our classification setting from Section 2 to accommodate other machine learning environments such as reinforcement learning and clustering. It also allows each of these environments to deal with domain aspects such as prediction-outcome disconnect, self-fulfilling prophecies, and conjoined fairness.

In a Fairness Decision-Making Problem (FDMP), there is a decision-algorithm \( m \) which has somehow been selected from a class of such algorithms \( M \). An individual is an outcome of random variable \( (I, Z) \), with \( I \in I \) representing the individual’s non-sensitive attributes and \( Z \in Z \) capturing the individual’s protected attribute. We assume that the protected attribute is binary \( Z = \{0, 1\} \). The decision-maker who selected the decision-algorithm has a cost function \( C : (I \times \{0, 1\}) \times M \to \mathbb{R} \) which maps an individual and a decision-algorithm to the expected cost. We capture the cost associated with a given decision-algorithm \( m \) as a random variable \( C_m : I \times \{0, 1\} \to \mathbb{R} \). The impact of \( m \) on an individual is captured by the welfare function \( W : (I \times \{0, 1\}) \times M \to \mathbb{R} \) which maps an individual and a decision-algorithm to the expected welfare. Similar to the cost function, \( W \) depends on the individual’s characteristics and the decision-algorithm, so we represent the welfare associated with a given decision-algorithm \( m \) as a random variable \( W_m : I \times \{0, 1\} \to \mathbb{R} \). Two
We can now define our welfare Demographic Parity and counterfactual utility Equal Opportunity.

**Definition 4.1** (Welfare Demographic Parity). Given FDMP \((I, Z, M, W, C, \tau, \rho)\), a decision-algorithm \(m \in M\) satisfies Welfare Demographic Parity \((\text{DemParWelf})\) if

\[
P(W_m \geq \tau \mid Z = 0) = P(W_m \geq \tau \mid Z = 1)
\] (4.1)

**Definition 4.2** (Counterfactual Utility Equal Opportunity). Given FDMP \((I, Z, M, W, C, \tau, \rho)\), a decision-algorithm \(m \in M\) satisfies Counterfactual Utility Equal Opportunity \((\text{EqOppCfUtil})\) if

\[
P(W_m \geq \tau \mid \Gamma = 1, Z = 0) = P(W_m \geq \tau \mid \Gamma = 1, Z = 1)
\] (4.2)

where \(\Gamma\) is an indicator variable with

\[
\Gamma = \begin{cases} 
1 & \text{if } \exists m' \in M : W_{m'} \geq \tau \land C_{m'} \leq \rho \\
0 & \text{otherwise}
\end{cases}
\] (4.3)

### 4.1 Counterfactual Utility Applied to Binary Classification

Next, we demonstrate how to apply our generalized counterfactual utility definitions to a specific environment: binary classification using zero-one loss.

A binary classification problem using the zero-one loss function is an SLCP \((X, Z, Y, L)\) with \(L(Y, \hat{Y}) = Y(1 - \hat{Y}) + \hat{Y}(1 - Y)\). We can construct a corresponding FDMP with non-sensitive individual attributes \(I = (X \times Y)\) and cost function \(C = L\). We assume that a positive prediction \(\hat{Y} = 1\) always implies a good outcome for the individual. This corresponds to a welfare function \(W = \hat{Y}\) with minimum threshold \(\tau = 1\). We set the maximum cost threshold to \(\rho = 0\) so that a good outcome from the decision-maker’s perspective reflects a correct prediction \((L = 0)\). We also assume that the individual’s target outcome is not influenced by the prediction \(\hat{Y}\), thus the parameterized welfare \(W_m = W = \hat{Y}\) and \(C_m = C = L\). A binary classifier \(\hat{Y} : X \times \{0, 1\} \rightarrow \{0, 1\}\) under this problem formulation satisfies \(\text{DemParWelf}\) if

\[
P(\hat{Y} \geq 1 \mid Z = 0) = P(\hat{Y} \geq 1 \mid Z = 1)
\] (4.4)

Because this is a binary classification problem, \(\hat{Y} \geq 1\) is equivalent to \(\hat{Y} = 1\), which makes, Equation 4.4 equivalent to \(\text{DemParClf}\) (Equation 2.1). Similarly, a classifier \(\hat{Y}\) satisfies \(\text{EqOppCfUtil}\) if

\[
P(\hat{Y} \geq 1 \mid \Gamma = 1, Z = 0) = P(\hat{Y} \geq 1 \mid \Gamma = 1, Z = 1)
\] (4.5)

where \(\Gamma\) is an indicator variable with

\[
\Gamma = \begin{cases} 
1 & \text{if } \exists \hat{Y}' \in \hat{Y} : \hat{Y}' \geq 1 \land L(Y, \hat{Y}') \leq 0 \\
0 & \text{otherwise}
\end{cases}
\] (4.6)

where \(\hat{Y} = (X \times \{0, 1\}) \times \{0, 1\}\) is the set of all possible classifiers. If \(\Gamma = 1\) in Equation 4.6, then \(Y = 1\), which makes Equation 4.5 equivalent to traditional Equal Opportunity (Equation 2.2).

### 5 Applications and Examples

In this section, we provide explicit examples of scenarios that violate the four assumptions listed in Section 4. We then show how to apply our counterfactual utility definitions from Section 4 to these settings, and show how our definitions resolve the problems that often result from the assumptions.

#### 5.1 Prediction-Outcome Disconnect in Classification

Here we provide an example where Assumption 1 results in prediction-outcome disconnect, and show how \(\text{DemParWelf}\) resolves this by requiring equal outcomes instead of equal predictions. We
consider a loan application scenario as a binary classification problem where the classifier predicts if an individual will repay a loan, which informs the loan decision. A loan applicant is represented as a sample from the distribution \((X, Z, Y)\), where \(X\) are the non-sensitive observable attributes of the individual, \(Z\) is the binary protected attribute, and \(Y\) is the unobserved target variable (whether or not the individual will pay back a loan).

Both the lender and the applicant benefit (utility +1) when a loan is repaid, lose when a loan defaults (-1), and are indifferent when a loan is rejected (0). Under \(\text{DemParClf}\), the classifier that simply grants all applicants a loan is considered fair. However, if the protected groups have unequal probabilities of repaying a loan, then they will have unequal loan default rates under such a classifier. Therefore, a classifier satisfying \(\text{DemParClf}\) would result in unequal outcomes for each group. Alternatively, under \(\text{DemParWelf}\) this classifier is unfair as long as both groups do not have the exact same probability of paying back the loan. For a complete worked example, see Appendix A.4.1

5.2 Self-Fulfilling Prophecies in Classification

Here we illustrate how Assumption 2 allows for self-fulfilling prophecies with \(\text{EqOppClf}\) but not with \(\text{EqOppCfUtil}\). Additionally, we show that \textit{principal fairness} \([120]\), which also prevents self-fulfilling prophecies, is a special case of our framework.

We use the recidivism prediction example posed by Imai and Jiang \([120]\) where a binary classifier predicts whether an inmate convicted of a crime will recidivate. \(Y\) corresponds to the judge’s decision of whether to detain or release the inmate, and the target variable \(Y’\) corresponds to whether or not the inmate will recidivate. This problem differs from typical classification since \(Y\) is influenced by \(Y’\). When decisions influence the observed target variable, it is helpful to visualize the dataset by \textit{principal strata} \([152]\) where each principal stratum characterizes how an inmate would be affected by the decision \(Y’\) with respect to the variable of interest \(Y’\). Since this is a binary classification problem with binary decisions and binary targets, we have a total of four principal strata. We assign labels to each stratum according to their behavior in Table 5.1. For example, an inmate in the \textit{Backlash} stratum will recidivate if they are detained \((P(Y = 1 \mid \hat{Y} = 0) = 0)\), but will not recidivate if released \((P(Y = 1 \mid \hat{Y} = 1) = 1)\).

Under \(\text{EqOppClf}\), a classifier’s qualification criteria can depend on its own decisions. In this case, an inmate is considered qualified if they are in the \textit{Safe} stratum, or if they are in the \textit{Backlash} stratum and they are released. Therefore, even if both the minority and majority groups have equal representation in each principal stratum, a classifier could release more majority \((Z = 1)\) inmates overall while still satisfying \(\text{EqOppClf}\) by detaining more minority \((Z = 0)\) \textit{Backlash} inmates. Alternatively, \(\text{EqOppCfUtil}\), considers the \textit{Safe} and \textit{all} of the \textit{Backlash} inmates as qualified, since the \textit{Backlash} inmates could satisfy both the judge’s interests and the inmates’ interest if they are released. This prevents self-fulfilling prophecies by establishing a fixed set of qualified individuals regardless of the classifier’s decisions. Although it is a stricter set of requirements than Equal Opportunity, we can also prevent self-fulfilling prophecies with \textit{principal fairness}, which requires equal release rates for each principal stratum. If there are \(p\) principal strata, we can implement \textit{principal fairness} using our framework as a conjunction of \(p\) constraints:

\[
P(W_C \geq \tau \mid Z = 0, \Gamma^i = 1) = P(W_C \geq \tau \mid Z = 1, \Gamma^i = 1) \forall i \in \{0, ..., p - 1\} \tag{5.1}
\]

where \(W_C\) is 1 if the individual is released and 0 otherwise, \(\Gamma^i = 1\) if the individual is in the \(i^{th}\) principal stratum, and we set \(\tau = 1\) to indicate that a good outcome for the inmate is when they are released. We provide a more thorough example of computing each of these fairness measures in Appendix A.4.2.

5.3 Fairness in Reinforcement Learning

In this section we provide an example of how our approach applies to reinforcement learning, a domain that violates Assumption 3. Wen, Bastani, and Topcu \([172]\) recently independently studied fairness in RL and provided an MDP translation of \(\text{DemParClf}\) that corresponds to our \(\text{DemParWelf}\) definition. However, their translation of \(\text{EqOppClf}\) only makes sense for a subset of MDPs where an individual’s qualification is specified as part of their initial state, while \(\text{EqOppCfUtil}\)
We show how Assumption 4 results in conjoined fairness issues in the clustering setting. Additionally, Wen, Bastani, and Topcu provide an MDP translation of Equal Opportunity which requires that the welfare and +3 cost, and a rejected loan contributes 0 welfare and +1 cost. The welfare and cost functions are defined as the expected sum of welfare and cost contributions, respectively, across both timesteps. We set \( \tau = 1 \) so that a good outcome for the applicant is when they repay at least one loan, and \( \rho = 2 \) so that a good outcome for the lender is when there are no defaults.

Wen, Bastani, and Topcu provide an MDP translation of Equal Opportunity which requires that the cumulative expected individual rewards (welfare) are equal for qualified individuals in both groups. They define qualified based on the individual’s probability of paying back a loan in the first timestep. The lender prefers to grant the loan as long as the probability is at least 2/3, so this seems natural as the threshold for qualification. This means prime applicants are qualified while subprime ones are not, so a policy which always loans to prime applicants and never loans to subprime ones is fair.

However, subprime applicants are as likely to repay a loan in the second timestep as prime applicants are in the first. EqOppCfUtil considers an applicant to be qualified if there exists a policy that will result in good overall outcomes for both the applicant and the individual. With the thresholds we chose, EqOppCfUtil deems all applicants qualified (the policy that rejects subprime applicants in the first timestep and grants loans otherwise is good for both applicants and the lender). This better aligns with intuition, and deems the policy of only offering loans to prime applicants unfair as it results in a significantly lower probability of good welfare for the minority group relative to the majority.

### 5.4 Conjoined Fairness in Clustering

We show how Assumption 4 results in conjoined fairness issues in the clustering setting. Additionally, we show that that two different clustering fairness definitions, balanced clustering and representative clustering, correspond to DemParWelf with different welfare function implementations. First we provide relevant definitions.

A clustering problem is a 4-tuple \( (X, \bar{X}, \bar{K}, L) \) where \( X \) is an \( n \)-length vector of majority individual attributes with \( X^0 \leq \cdots \leq X^{n-1} \) representing the majority attributes of the \( i \)th individual in \( X \); \( \bar{X} \) is an \( n \)-length vector of protected individual attributes; \( \bar{K} \) is the number clusters; A clustering \( J \) maps the dataset of individuals \( (X, \bar{X}) \) to an \( n \)-length vector of cluster assignments; we use \( J(X^i, \bar{Z}^j) \) to denote the cluster to which individual \( i \) is assigned. In clustering, we have a fixed dataset of

\begin{table}[h]
\centering
\begin{tabular}{|c|c|c|}
\hline
 & \( P(Y = 1 | \bar{Y} = 1) = 0 \) & \( P(Y = 1 | \bar{Y} = 1) = 1 \) \\
\hline
Detained & Dangerous & Backlash \\
\hline
Released & UQ & EqOppCfUtil \\
\hline
Detained & Preventable & Safe \\
\hline
Released & UQ & EqOppCfUtil \\
\hline
\end{tabular}
\caption{The four principal strata for the recidivism prediction problem. Cells with Clf correspond to qualified inmates according to EqOppClf. CfUtil are qualified according to EqOppCfUtil. UQ are unqualified in both.}
\end{table}

\footnote{Technically their definition can be made equivalent to ours by changing the states of the MDP to embed our notion of qualification in each of them, but embedding the behavior of policies in states in this way is not in the spirit of typical MDP representations.}

\footnote{They take a non-thresholded approach. See Appendix A.2 for discussion on why we chose to use thresholds.}
individuals, so to represent this as a FDMP we have the random variable \((I, Z)\) sample an individual at random from the dataset.

As a motivating example, we consider a clustering problem where the goal is to segment a geographic region into \(K\) districts (clusters), where each district is represented by a single elected official. We assume a two-party system where the individual’s protected attribute reflects their political party affiliation. We wish to evaluate Demographic Parity for a given set of district boundaries \(J\). An intuitive translation of \(\text{DemParClf}\) to this setting requires that the probability that a constituent is assigned to a positive district is equal for both parties, where a positive district implies that a constituent assigned to this district would consider it a good outcome. However, we cannot know which districts are positive unless we know who else was assigned to that district. The problem is that \(\text{DemParClf}\) does not capture conjoined fairness notions where the fairness of a decision for an individual depends on the decisions made for other individuals.

Another interpretation of Demographic Parity is balanced clustering \([\text{Chi+17}]\) where each political party is required to be evenly split among all clusters. We can implement this using our framework with a welfare function equal to the proportion of the constituent’s political party for a given district. If individual \(i\) is sampled and \(k = J(X^i, Z^i)\) we have

\[
W_J = \frac{\{j \mid J(X^j, Z^j) = k \land Z^j = Z^i\}}{\{j \mid J(X^j, Z^j) = k\}}
\]

Therefore, a clustering \(J\) satisfies \(\text{DemParWelf}\) if

\[
P(W_J \geq \tau \mid \bar{Z}^i = 0) = P(W_J \geq \tau \mid \bar{Z}^i = 1)
\]

where \(\tau\) is the minimum proportion of the constituent’s party needed to be considered a good outcome for the individual. Unfortunately, balanced clustering results in the same political party ratio across all districts, which is actually a form of gerrymandering where one political party controls all of the districts by maintaining a slight majority in each. We can remedy this with representative clustering \([\text{ABV21}]\). This definition uses a similarity function that maps a constituent and their district assignment to their similarity value, and requires that constituents from each party have equal similarity. In our framework, we can implement a thresholded version of representative clustering by setting the welfare function equal to the similarity function:

\[
W_J = \text{similarity}(\bar{X}^i, \bar{Z}^i, J(\bar{X}^i, \bar{Z}^i))
\]

where \((\bar{X}^i, \bar{Z}^i)\) is the constituent and \(J(\bar{X}^i, \bar{Z}^i)\) is the constituent’s district assignment. Under representative clustering, \(\tau\) represents the minimum constituent-district similarity for the district to be considered a good representation of the constituent. Therefore, if a clustering \(J\) satisfies \(\text{DemParWelf}\) with \(W_J\) equal to Equation 5.4 then a constituent from either political party will have equal probability of being well-represented by their assigned district, which will prevent gerrymandering. As this example illustrates, rather than providing an entirely new fairness definition for a bespoke fairness problem, we can instead leverage the generality of \(\text{DemParWelf}\) and capture domain idiosyncrasies through the definition of \(W\) and \(\tau\).

6 Discussion

We have proposed generalizations of standard group fairness definitions such as Demographic Parity and Equal Opportunity based on two principles: using utility functions to capture outcomes for both individuals and the decision maker, and considering counterfactual outcomes. We have shown that our definitions subsume the standard definitions from classification settings \([\text{Har+16}]\) as well as several of their domain-specific translations in reinforcement learning \([\text{WBT21}]\) and clustering \([\text{Chi+17}]\; [\text{ABV21}]\). Furthermore, we demonstrated how our definitions reduce the need for bespoke definitions since domain idiosyncrasies are captured as parameters and variable definitions.

We conclude by discussing the limitations and potential negative societal impacts of our work. While we have shown examples of how our framework can address problems such as prediction-outcome disconnects, self-fulfilling prophecies, and conjoined fairness and we believe these examples are representative of large classes of situations, we do not know how to prove, or even state, a claim that our framework resolves all such issues. Our framework lets us naturally map group fairness definitions between settings and flexibly capture domain features, but this does not mean that any particular definition is sensible for any particular setting. A poorly-chosen instantiation of our framework might be worse than not using it at all due to degraded performance, introducing new versions of bias or unfairness, or providing false confidence that fairness issues have been addressed.

# Appendix

## A.1 Extension to other group fairness definitions.

In addition to Demographic Parity and Equal Opportunity, we can extend our framework to implement various other group fairness definitions. In this section, we provide a partial list of these implementations. Furthermore, we observe that each of the counterfactual utility implementations of these group fairness definitions can be constructed as expressions of $W_m$, $\tau$, $Z$, and $\Gamma$ alone.

**Equalized Odds** Similar to Equal Opportunity, Equalized Odds \cite{Har+16} requires both the true positive rates ($P(\hat{Y} = 1 | Y = 1)$) and false positive rates ($P(\hat{Y} = 1 | Y = 0)$) to be equal:

\[
P(\hat{Y} = 1 | Y = y, Z = 0) = P(\hat{Y} = 1 | Y = y, Z = 0).
\]

(A.1)

The corresponding counterfactual utility definition is

\[
(P(W_m \geq \tau | \Gamma = 1, Z = 0) = P(W_m \geq \tau | \Gamma = 1, Z = 1)) \land (P(W_m \geq \tau | \Gamma = 0, Z = 0) = P(W_m \geq \tau | \Gamma = 0, Z = 1)).
\]

(A.2)

**Predictive Parity** Predictive Parity \cite{Cho17} is essentially the inverse of Equal Opportunity, which requires that the probability that an individual predicted to be positive actually belongs to the positive class is equal for both groups:

\[
P(Y = 1 | \hat{Y} = 1, Z = 0) = P(Y = 1 | \hat{Y} = 1, Z = 1)
\]

(A.3)

The respective counterfactual utility definition is

\[
P(\Gamma = 1 | W \geq \tau, Z = 0) = P(\Gamma = 1 | W \geq \tau, Z = 1).
\]

(A.4)

**Conditional Demographic Parity** Conditional Demographic Parity \cite{Cor+17} extends Demographic Parity (Definition 2.1) by allowing one or more legitimate attributes $L$ to impact the outcome of the decision:

\[
P(\hat{Y} = 1 | L = l, Z = 0) = P(\hat{Y} = 1 | L = l, Z = 1).
\]

(A.5)

for some $l$. In our framework, this is:

\[
P(W_m \geq \tau | L = l, Z = 0) = P(W_m \geq \tau | L = l, Z = 1).
\]

(A.6)

Here $L$ is playing a similar role as $\Gamma$ in Equation 4.3 as it requires equal welfare for some subset of the general population.

**Predictive Equality** Predictive Equality \cite{Cho17} is satisfied if individuals in the negative class have equal probabilities of receiving a positive prediction for each protected group:

\[
P(\hat{Y} = 1 | Y = 0, Z = 0) = P(\hat{Y} = 1 | Y = 0, Z = 1)
\]

(A.7)

which, in our framework, translates to

\[
P(W_m \geq \tau | \Gamma = 0, Z = 0) = P(W_m \geq \tau | \Gamma = 0, Z = 1).
\]

(A.8)

**Conditional Use Accuracy Equality** Conditional Use Accuracy Equality \cite{Ber+18} requires the probability for individuals with positive predictions to belong to the positive class to be equal for both protected groups, and the probability for individuals with negative predictions to belong to the negative class to be equal for both protected groups:

\[
(P(Y = 1 | \hat{Y} = 1, Z = 0) = P(Y = 1 | \hat{Y} = 1, Z = 1)) \land (P(Y = 0 | \hat{Y} = 0, Z = 0) = P(Y = 0 | \hat{Y} = 0, Z = 1))
\]

(A.9)

The counterfactual utility equivalent is:

\[
(P(\Gamma = 1 | W_m \geq \tau, Z = 0) = P(\Gamma = 1 | W_m \geq \tau, Z = 1)) \land (P(\Gamma = 0 | W_m < \tau, Z = 0) = P(\Gamma = 0 | W_m < \tau, Z = 1)).
\]

(A.10)
Overall Accuracy Equality. Overall Accuracy Equality [Ber+18] requires the probability that an individual is assigned to their true class to be equal for both protected groups:

$$P(\hat{Y} = Y, Z = 0) = P(\hat{Y} = Y, Z = 1) \quad (A.11)$$

We interpret $Y = 1$ as $\Gamma = 1$ and $\hat{Y} = 1$ as $W_m \geq \tau$. Similarly, we interpret $Y = 0$ as $\Gamma = 0$ and $\hat{Y} = 0$ as $W_m \geq \tau$. So Equation (A.11) translates in our framework as:

$$P(W_m \geq \tau, \Gamma = 1, Z = 0) = P(W_m \geq \tau, \Gamma = 1, Z = 1) \quad (A.12)$$

$$\land (P(W_m < \tau, \Gamma = 0, Z = 0) = P(W_m < \tau, \Gamma = 0, Z = 1)) .$$

Treatment Equality. Treatment Equality [Ber+18] requires an equal ratio of false negatives ($P(\hat{Y} = 0 | Y = 1)$) and false positives ($P(\hat{Y} = 1 | Y = 0)$) for each protected group:

$$P(\hat{Y} = 0 \mid Y = 1, Z = 0) = P(\hat{Y} = 0 \mid Y = 1, Z = 1)$$

$$P(\hat{Y} = 1 \mid Y = 0, Z = 0) = P(\hat{Y} = 1 \mid Y = 0, Z = 1) \quad (A.13)$$

which translates to our framework as:

$$P(W_m < \tau \mid \Gamma = 1, Z = 0) = P(W_m < \tau \mid \Gamma = 1, Z = 1)$$

$$P(W_m \geq \tau \mid \Gamma = 0, Z = 0) = P(W_m \geq \tau \mid \Gamma = 0, Z = 1) \quad (A.14)$$

Test Fairness. Test Fairness [Cho17] applies to classifiers that predict a probability $S$ rather than a binary class $Y$. A classifier satisfies Test Fairness if, for any predicted probability $\hat{S}$, individuals in each protected group have equal probability of being in the positive class:

$$P(Y = 1 \mid S = s, Z = 0) = P(Y = 1 \mid S = s, Z = 1) \forall s \in [0, 1] . \quad (A.15)$$

We can implement this in our counterfactual utility framework as

$$P(\Gamma = 1 \mid W_m = w, Z = 0) = P(\Gamma = 1 \mid W_m = w, Z = 1) \forall w \in \mathbb{R} . \quad (A.16)$$

A.2 Alternatives to thresholds.

Our choice to use thresholds $\tau$ and $\rho$ when defining DemParWelf and EqOppCfUtil is not the only option. Intuitively, what is needed is some way to compare the distributions $P(W | Z = 0)$ and $P(W | Z = 1)$. Our use of thresholds reduces this comparison to a simple binary, as with the traditional definitions. We chose this for its simplicity and compatibility, as it easily allows standard techniques like quantifying the extent to which it is satisfied by computing $P(W_m \geq \tau | Z = 0) - P(W_m \geq \tau | Z = 1)$. Instead, we could have defined Demographic Parity as

$$P(W_m | Z = 0) = P(W_m | Z = 1) . \quad (A.17)$$

This is a much stricter constraint as it forces equality of the entire distribution, and may even be impossible to enforce for some welfare functions. Or, perhaps more practically, we could compare the expected utilities of the two groups:

$$E[W_m | Z = 0] = E[W_m | Z = 1] . \quad (A.18)$$

Depending on the way utilities are defined and thresholds are chosen in a specific problem, this could be equivalent to, stricter than, or simply different from our version.

The choice may also depend on the notion of fairness for the problem. For instance, in the two-stage loan application MDP example in Section 5.3 and Appendix A.4.3, we define fairness by requiring equal probability of worst-case scenarios across both groups. Alternatively, consider a decision algorithm that determines the salaries for each employee of a large corporation. In this scenario, equal expected welfare across protected groups (Equation A.18) could be satisfied by giving a small number of high-ranking minority employees a very large salary, but paying all low-ranking minority employees smaller salaries than their majority counterparts. A salary threshold (Equation A.11) will not work either, since it will only enforce equal ratios of employees above a certain level, rather than ensure equal pay for employees at the same level. In order to enforce equal pay at each level within the organization, we would want to use a form of Equation (A.17) that requires equal welfare distributions. As this example suggests, there are still other summary statistics that could be considered. For example, the median welfare would have a similar robustness to outlier individuals and indeed our use of thresholds corresponds to the value of the CDF at a particular point.
A.3 When there are more than two protected groups

For ease of exposition, this work discusses only the case when there are two protected groups. However, our insights and contributions are focused on assumptions about parameters other than $Z$, and therefore extend naturally to cases with multiple protected attributes. Specifically, when there are more than two protected groups ($|Z| > 2$), DemParWelf becomes:

$$P(W_m \geq \tau \mid Z = 0) = P(W_m \geq \tau \mid Z = z) \forall z \in \{1, 2, ..., |Z| - 1\} \quad (A.19)$$

and EqOppCfUtil becomes:

$$P(W_m \geq \tau \mid \Gamma = 1, Z = 0) = P(W_m \geq \tau \mid \Gamma = 1, Z = z) \forall z \in \{1, 2, ..., |Z| - 1\} \quad (A.20)$$

A.4 Worked Examples

A.4.1 Single-Stage Loan Application

Here we provide an example where Assumption 1 results in prediction-outcome disconnect under DemParClf, and show how DemParWelf resolves this by requiring equal outcomes instead of equal predictions. We consider a loan application scenario as a binary classification problem where the classifier predicts if an individual will repay a loan, which informs the loan decision. A loan applicant is represented as a sample from the distribution $(X, Z, Y)$ (see Table A.1), where $X$ are the non-sensitive observable attributes of the individual, $Z$ is the binary protected attribute, and $Y$ is the unobserved target variable (whether or not the individual will pay back a loan). Suppose that we are given a classifier $\hat{Y}^\dagger$ that grants loans to all applicants $\hat{Y}^\dagger(X, Z) = 1$, and we wish to evaluate Demographic Parity.

In order to leverage our counterfactual utility framework, we first need to assign FDMP parameters $(I, Z, M, W, C, \tau, \rho)$. The unprotected individual attributes $I = (X, Y)$, and the protected attribute $Z$ is already provided. Both the lender and the applicant benefit when a loan is repaid, lose when a loan defaults, and are indifferent when a loan is rejected. Thus the welfare $W$ and cost $C$ are functions of $Y$ and $\hat{Y}$ alone, and are defined according to Table A.1. We consider a good individual outcome to be when an applicant does not default, so we set $\tau = 0$. Since we are only interested in evaluating Demographic Parity, we do not need to define $M$ nor $\rho$.

$\hat{Y}^\dagger$ satisfies DemParClf since the probability of a assigning a positive prediction is the same for both the minority and majority groups:

$$P(\hat{Y}^\dagger = 1 \mid Z = 0) \overset{2}{=} P(\hat{Y}^\dagger = 1 \mid Z = 1) = 1$$

However, the probability of obtaining a good outcome is unequal between protected groups since minority applicants are more likely to default than majority applicants. Therefore, $\hat{Y}^\dagger$ satisfies DemParClf even though it yields good outcomes with unequal probability for each group. Instead, we can evaluate DemParWelf, which is not satisfied by $\hat{Y}^\dagger$ since

$$P(W_m \geq \tau \mid Z = 0) \overset{2}{=} P(W_m \geq \tau \mid Z = 1)$$

$$P(W_{\hat{Y}^\dagger} \geq 0 \mid Z = 0) \overset{2}{=} P(W_{\hat{Y}^\dagger} \geq 0 \mid Z = 1)$$

$$.175/5 \overset{2}{=} .25/5$$

$$.35 \neq .5$$

A.4.2 Recidivism Prediction

Here we illustrate how Assumption 2 allows for self-fulfilling prophecies with EqOppClf but not with EqOppCfUtil. Additionally, we show that principal fairness [IJ20], which also prevents self-fulfilling prophecies, is a special case of our framework.

We use the recidivism prediction example posed by Imai and Jiang [IJ20] where a binary classifier predicts whether an inmate convicted of a crime will recidivate. $\hat{Y}$ corresponds to the judge’s decision of whether to detain or release the inmate, and the target variable $Y$ corresponds to whether or not...
were rendered unqualified through detainment. This results in a self-fulfilling prophecy since
we are given a classifier $\hat{Y}$. Therefore, instead of an individual being an outcome of $(X, Z, Y)$ as in as in SLCPs, here an individual is an outcome of $(X, Z, Y^P)$ where $Y^P \in \mathcal{Y}^P$ represents the individual’s principal stratum and $\mathcal{Y}^P = \{Y^P = 0, Y^P = 1, \ldots, Y^P = p-1\}$ if there are $p$ principal stratum. A principal stratum characterizes how an individual would be affected by the decision $\hat{Y}$ with respect to the variable of interest $Y$. Since this is a binary classification problem with binary decisions and binary targets, we have a total of four principal strata. We assign labels to each stratum according to their behavior
$P(Y = 1 \mid \hat{Y} = 0) = 0$, but will not recidivate if released ($P(Y = 1 \mid \hat{Y} = 1) = 1$). Additionally, we are given a classifier $Y^\dagger$ that produces the results in Table A.2

\begin{table}[h]
\centering
\begin{tabular}{|c|c|c|c|}
\hline
$X$ & $Z$ & $Y$ & $P(X, Z, Y)$ \\
\hline
0 & 0 & 0 & .2 \\
0 & 0 & 1 & .05 \\
1 & 0 & 0 & .125 \\
1 & 0 & 1 & .125 \\
0 & 1 & 0 & .125 \\
0 & 1 & 1 & .125 \\
1 & 1 & 0 & .125 \\
1 & 1 & 1 & .125 \\
\hline
\end{tabular}
\caption{Binary classification loan-application problem. Left: individual joint distribution. Right: loss $L$, cost $C$, and welfare $W$ for each combination of $Y$ and $\hat{Y}$. As in other SLCP problems, the cost function $C$ is inferred from the loss function $L$, although here we shift the cost to be centered around zero ($C = L - 1$).
\end{table}

\begin{tabular}{|c|c|c|c|c|}
\hline
$Y$ & $\hat{Y}$ & $L$ & $C$ & $W$ \\
\hline
Rejected & 0 & 0 & 1 & 0 & 0 \\
Defaulted & 0 & 1 & 2 & 1 & -1 \\
Rejected & 1 & 0 & 1 & 0 & 0 \\
Paid back & 1 & 1 & 0 & -1 & -1 \\
\hline
\end{tabular}

In order to leverage our counterfactual utility framework, we need to establish FDMP parameters $(I, Z, M, W, C, \tau, \rho)$. The individual’s unprotected attributes $I = (X, Y^P)$. The decision-algorithm space $M = (\mathcal{X} \times \mathcal{Z}) \rightarrow \mathcal{Y}^P$. We define the welfare function to be $W = 1$ if the inmate is released ($\hat{Y} = 0$) and $W = 0$ if detained ($\hat{Y} = 1$). We define the cost function to be $C = 1$ if the inmate recidivates and $C = 0$ if they do not. A good outcome for the inmate is when they are released ($\tau = 1$), and a good outcome for the judge (decision-maker) is when the inmate does not recidivate ($\rho = 0$). We evaluate three different fairness criteria for $Y^\dagger$: EqOppClf [Har+16], EqOppCfUtil, and principal fairness [IJ20].

\textbf{Evaluating Classification Equal Opportunity} \hspace{1em} EqOppClf requires the release rate to be equal for both groups but only for inmates observed to have not recidivated. This corresponds to released Backlash inmates, detained Preventable inmates, and all Safe inmates.\footnote{\hspace{1em}In the main text in Table 5.1 we mistakenly indicate that detained Preventable inmates are unqualified under EqOppClf.} Therefore, $Y^\dagger$ satisfies EqOppClf since

$$P(\hat{Y} = 1 \mid Z = 0, Y^P = \text{Backlash} \land \hat{\hat{Y}} = 1) \vee (Y^P = \text{Preventable} \land \hat{\hat{Y}} = 0) \vee (Y^P = \text{Safe}) \overset{?}{=} P(\hat{Y} = 1 \mid Z = 1, Y^P = \text{Backlash} \land \hat{\hat{Y}} = 1) \vee (Y^P = \text{Preventable} \land \hat{\hat{Y}} = 0) \vee (Y^P = \text{Safe}) \overset{?}{=} \frac{20 + 160}{20 + 80 + 40 + 160} = \frac{20 + 160}{3} = \frac{3}{3} = \frac{3}{5}.$$  

The classifier $Y^\dagger$ causes two-thirds of the minority ($Z = 0$) Backlash inmates to recidivate by detaining them, thus rendering them unqualified according to EqOppClf. Since $Y^\dagger$ detains only half of the majority ($Z = 1$) Backlash inmates, this results in a larger proportion of minority inmates who were rendered unqualified through detainment. This results in a self-fulfilling prophecy since $Y^\dagger$ satisfies EqOppClf by biasing the selection of qualified inmates rather than by making fair decisions.
\[
\begin{array}{c|cc|c|cc}
\hline
& \text{Dangerous} & \text{Backlash} & & \text{Dangerous} & \text{Backlash} \\
\text{Detained} & 120 & 40 & \text{Released} & 30 & 20 \\
\text{Released} & 30 & 20 & \text{Detained} & 80 & 20 \\
\text{Preventable} & 80 & 40 & \text{Released} & 10 & 160 \\
\text{Safe} & 40 & 160 & \text{Detained} & 80 & 40 \\
\text{Released} & 80 & 160 \\
\hline
\end{array}
\]

Table A.2: A numerical illustration of the results of the predictions from classifier \( \hat{Y}^+ \) on 1,000 inmates, separated by protected attribute and principal stratum. Each cell represents the number of inmates in the principal stratum and protected group who were detained (\( \hat{Y} = 0 \)) and released (\( \hat{Y} = 1 \)). The table is partially reproduced from Imai and Jiang’s example [IJ20] which represents the results of a classifier that satisfies \( \text{EqOppClf, EqOppCfUtil} \), and principal fairness. However, we modified the numerical results to demonstrate a scenario where \( \text{EqOppClf} \) is satisfied, but \( \text{EqOppCfUtil} \) and principal fairness are not. See Table 5.1 for the definitions of each principal stratum.

**Evaluating Counterfactual Utility Equal Opportunity** \( \text{EqOppCfUtil} \), on the other hand, considers all Backlash individuals and all Safe individuals as qualified:

\[
P(\hat{Y} = 1 \mid Z = 0, Y^P \in \{\text{Safe, Backlash}\}) = \frac{P(\hat{Y} = 1 \mid Z = 1, Y^P \in \{\text{Safe, Backlash}\})}{40 + 40 + 40 + 160} = \frac{9}{13} \approx 0.692.
\]

As expected, the fraction of qualified minority inmates who were released (\( \frac{9}{13} \)) is less than that of majority inmates (\( \frac{5}{7} \)), which means that \( \hat{Y}^+ \) does not satisfy \( \text{EqOppCfUtil} \). This better aligns with Equal Opportunity intuition that inmates from either protected group who would not have committed a crime when released should be released with equal probability.

**Evaluating Principal Fairness** Although it is a stricter set of requirements than Equal Opportunity, we can also prevent self-fulfilling prophecies with principal fairness [IJ20], which requires equal release rates for each principal stratum. We can implement principal fairness using our framework as a conjunction of \( p \) constraints:

\[
P(W_C \geq \tau \mid Z = 0, \Gamma^i = 1) = P(W_C \geq \tau \mid Z = 1, \Gamma^i = 1) \forall i \in \{0, \ldots, p - 1\}
\]

which is not satisfied by \( \hat{Y}^+ \) since the release rates of the Backlash and Preventable strata are unequal between protected groups. I.e. for Backlash:

\[
P(\hat{Y} \geq 1 \mid Z = 0, Y^P = \text{Backlash}) = \frac{20}{40 + 20} = \frac{1}{3}
\]

A.4.3 Two-Stage Loan MDP

In this section we provide an example of how our approach applies to reinforcement learning, a domain that violates Assumption [3]. Wen, Bastani, and Topcu [WBT21] recently independently
studied fairness in RL and provided an MDP translation of DemParClf that corresponds to our DemParWe1f definition. However, their translation of EqOppClf only makes sense for a subset of MDPs where an individual’s qualification is specified as part of their initial state, while EqOppClf is fully general. We start with a definition for MDPs.

**Definition A.1** (Markov decision process). A Markov Decision Process (MDP) is a 6-tuple \( \{S, A, T, R, \gamma, \mu\} \) where \( S \) is a set of states; \( A \) is a set of actions; \( T : S \times A \rightarrow \Delta S \) is a mapping of state-action pairs to a distribution over new states; \( R : S \times A \rightarrow \mathbb{R} \) is the reward function, which maps a state-action pair to a real-valued number; \( \gamma \in [0, 1] \) is the discount factor; and \( \mu \) is the initial state probability distribution.

In order to use our counterfactual utility definitions, we need to construct an FDMP. We need to define the policy space \( M \), the welfare function \( W \), welfare threshold \( \tau \), and cost threshold \( \rho \) according to the problem domain. The remaining FDMP parameters \( I, Z, \) and \( C \) can be inferred from the MDP as follows. The MDP state \( s \in S \) corresponds to an individual’s unprotected attributes \( \tilde{s} \in \tilde{S} \) (i.e. \( I = \tilde{s} \)) and protected attribute \( Z \) (i.e. \( s = \{\tilde{s}, Z\} \) and \( S = \tilde{S} \times Z \)). Therefore, the initial state \( s_0 \) represents an individual in the first timestep \( \{\tilde{s}_0, Z\} \). The individual’s unprotected attributes \( \tilde{s} \) can change over subsequent timesteps, and so do according to the transition function \( s_{t>0} \sim T(s_{t-1}, \pi(s_{t-1})) \) with \( s_{t>0} = \{\tilde{s}_{t>0}, Z\} \). We assume that the individual’s protected attribute \( Z \) does not change throughout an episode. The cost function \( C_\pi \) is the negative expected cumulative sum of rewards after executing the policy \( \pi \in \Pi \):

\[
C_\pi = \mathbb{E}_{s_t \sim T(s_{t-1}, \pi(s_{t-1}))} \left[ -R(s_0, \pi(s_0)) + \sum_{t=1}^{\infty} -R(s_t, \pi(s_t)) \right] \tag{A.22}
\]

and the **optimal policy** \( \pi^* \) is the policy that minimizes the expected cost:

\[
\pi^* = \arg\min_{\pi} C_\pi .
\]

The welfare function associated with executing a policy \( \pi \), \( W_\pi : S \rightarrow \mathbb{R} \), is the expected cumulative sum of a domain-defined function \( w : S \times A \rightarrow \mathbb{R} \):

\[
W_\pi = \mathbb{E}_{s_t \sim T(s_{t-1}, \pi(s_{t-1}))} \left[ w(s_0, \pi(s_0)) + \sum_{t=1}^{\infty} w(s_t, \pi(s_t)) \right] \tag{A.23}
\]

Therefore, in order to define \( W(s, \pi) \), and therefore \( W_\pi(s) \), we only need to define \( w(s, a) \).

As a motivating example, we consider a two-stage loan application decision process represented as an MDP, where an individual applies for loans in two sequential timesteps. The lender is represented by a policy which can either grant or reject the applicant’s loan in each timestep. There are two types of applicants. The first type, *prime*, will pay back a loan with 70% probability in the first timestep, and 80% in the second timestep. The second type, *subprime*, will pay back a loan with 60% probability in the first, and 70% in the second. Applicants in the minority group are equally likely to be prime vs. subprime, whereas applicants in the majority group are twice as likely to be prime as subprime. The MDP state includes the applicant’s behavior type, protected attribute, and the loan decision in the first round. The state is fully observable to the policy, so the policy space \( M = S \rightarrow A = S \times Z \rightarrow A \).

At each timestep, a repaid loan contributes +2 welfare and +3 reward, a loan default contributes -1 welfare and 0 reward, and a rejected loan contributes 0 welfare and +2 reward. The welfare function \( W \) is defined as the expected sum of welfare contributions \( w(s, a) \) across both timesteps. Similarly, the cost function \( C \) is the expected sum of negative rewards over both timesteps. We set \( \tau = 1 \) so that a good outcome for the applicant is when they repay at least one loan, and \( \rho = 2 \) so that a good outcome for the lender is when there are no defaults. The MDP and welfare contributions are illustrated in Figure [1].

Suppose we are given a policy \( \pi^\dagger \) that assigns loans to all prime applicants and rejects loans to all subprime applicants, and we wish to evaluate if \( \pi^\dagger \) satisfies Demographic Parity and Equal Opportunity.

\[\text{For clarity we shift the cost so that there are no negative values: } C = -R + 3.\]
**Evaluating Demographic Parity**  We can apply DemParWelf to reinforcement learning as follows: a policy \( \pi \) satisfies DemParWelf if the probability of accumulating a "good" amount of welfare while executing the policy is equivalent for both protected groups:

\[
P(W_\pi \geq \tau \mid Z = 0) = P(W_\pi \geq \tau \mid Z = 1)
\]

(A.24)

with \( W_\pi \) defined according to Equation [A.23] In our two-stage MDP example with our chosen thresholds, this is equivalent to

\[
P(\text{repaying at least one loan} \mid Z = 0) \leq P(\text{repaying at least one loan} \mid Z = 1)
\]

\[
.66(1 - (.3)(.2)) + .33(0) \leq .5(1 - (.3)(.2)) + .5(0)
\]

\[
.627 \neq .47
\]

Therefore, \( \pi^1 \) does not satisfy DemParWelf.

Our DemParWelf is similar to Wen, Bastani, and Topcu’s MDP translation of Demographic Parity [WBT21] which requires that the cumulative expected individual rewards (welfare) are equal for individuals in both groups:

\[
E(W_\pi \mid Z = 0) = E(W_\pi \mid Z = 1)
\]

Our approach differs in that we require equal probabilities of welfare over a threshold, rather than equal welfare expectations.\(^{10}\) Furthermore, our definition easily extends to other ML environments, such as clustering.

**Evaluating Equal Opportunity**  Wen, Bastani, and Topcu also provide an MDP translation of Equal Opportunity EqOppMDP to a multi-stage loan MDP example which requires that the cumulative expected individual rewards (welfare) are equal for qualified individuals in both groups [WBT21]:

\[
E(W_\pi \mid p_0 \geq \alpha, Z = 0) = E(W_\pi \mid p_0 \geq \alpha, Z = 1)
\]

where \( p_0 \) is the individual’s probability of repaying the loan in the first timestep, and \( \alpha \) is some qualification threshold. We can apply EqOppMDP to our two-stage loan MDP example by selecting the qualification threshold \( \alpha = 2/3 \) since the optimal policy grants loans to applicants with a repayment probability of at least 2/3. This means prime applicants (\( p_0 = .7 \)) are qualified while subprime applicants (\( p_0 = .6 \)) are not, so a policy which always grants loans to prime applicants and always rejects subprime applicants is fair under EqOppMDP:

\[
E(W_\pi \mid \bar{s}^0 = 1, Z = 0) = E(W_\pi \mid \bar{s}^0 = 1, Z = 1)
\]

where \( \bar{s}^0 \) is the state component corresponding to the individual’s prime/subprime attribute, with \( \bar{s}^0 = 1 \) indicating prime.

However, subprime applicants are as likely to repay a loan in the second timestep as prime applicants are in the first. Certainly the lender would prefer to grant them loans, so it seems unfair to say that they are forever unqualified just because they are initially under the qualification threshold.

EqOppCfUtil, on the other hand, considers an applicant to be qualified if there exists a policy that will result in good overall outcomes for both the applicant and the individual:

\[
P(W_\pi \geq \tau \mid \Gamma = 1, Z = 0) = P(W_\pi \geq \tau \mid \Gamma = 1, Z = 1)
\]

(A.25)

where \( \Gamma \) is an indicator variable representing qualified individuals:

\[
\Gamma = \begin{cases} 
1 & \text{if } \exists \pi' \in \Pi : W_{\pi'} \geq \tau \land C_{\pi'} \leq \rho \\
0 & \text{otherwise}
\end{cases}
\]

Instead of only considering an applicant in the first timestamp, EqOppCfUtil considers them across all timesteps when determining whether they are qualified. With the thresholds we chose, there exists a policy \( \pi' \) that deems all applicants as qualified: \( \pi' \) is the policy that rejects subprime applicants in the first timestep and grants loans otherwise. Under \( \pi' \), the welfare for prime and subprime applicants are:

\[
W_{\pi'}^{\text{Prime}} = (.7)(+2) + (.3)(-1) + (.8)(+2) + (.2)(-1) = 2.5
\]

\[
W_{\pi'}^{\text{Subprime}} = (.7)(+2) + (.3)(-1) = 1.1
\]

\(^{10}\)See Appendix A.2 for further discussion on why we chose thresholds over expectations.
and the costs are

\[ C_{\pi, \text{Prime}}^{\prime} = (.7)(0) + (.3)(+3) + (.8)(0) + (.2)(+3) = 1.5 \]
\[ C_{\pi, \text{Subprime}}^{\prime} = 1 + (.7)(0) + (.3)(+3) = 1.9. \]

Since \( W_\pi \geq \tau \) and \( C_{\pi} \leq \rho \) for all applicants under policy \( \pi' \), and therefore are capable of producing good outcomes for both the applicant and the lender, then all applicants are considered qualified under EqOppCfUtil. Equation A.25 then becomes:

\[
P(W_\pi \geq \tau \mid Z = 0) \geq P(W_\pi \geq \tau \mid Z = 1) \\
P(\text{repaying at least one loan} \mid Z = 0) \geq P(\text{repaying at least one loan} \mid Z = 1) \\
.66(1 - (.3)(.2)) + .33(0) \geq .5(1 - (.3)(.2)) + .5(0) \\
.627 \neq .47.
\]

which is actually equivalent to DemParWelf (Equation A.24), and therefore not satisfied. This better aligns with intuition, and deems the policy of only offering loans to prime applicants unfair as it results in a lower probability of good welfare for qualified minority applicants relative to qualified majority applicants.
Figure 1: Two-stage loan application MDP with 12 total states. Welfare contributions $w(s, a)$ are displayed alongside the rewards $R(s, a)$. States (large circles) have 3 parameters, with the first element indicating if the applicant is prime (1) or subprime (0); the second element is the binary protected attribute; and the third element indicates the loan decision in the first round with 0 indicating it has not occurred yet, 1 represents a rejected loan, and 2 represents a granted loan. Because the transition function does not depend on whether or not a loan was given in the first stage, we collapse the states in the second stage, with * representing the case when the third state element is either 1 or 2.
