Abstract

For the problem of task-agnostic reinforcement learning (RL), an agent first collects samples from an unknown environment without the supervision of reward signals, then is revealed with a reward and is asked to compute a corresponding near-optimal policy. Existing approaches mainly concern the worst-case scenarios, in which no structural information of the reward/transition-dynamics is utilized. Therefore the best sample upper bound is $\propto \tilde{O}(1/\epsilon^2)$, where $\epsilon > 0$ is the target accuracy of the obtained policy, and can be overly pessimistic. To tackle this issue, we provide an efficient algorithm that utilizes a gap parameter, $\rho > 0$, to reduce the amount of exploration. In particular, for an unknown finite-horizon Markov decision process, the algorithm takes only $\tilde{O}(1/\epsilon \cdot (H^3 SA/\rho + H^4 S^2 A))$ episodes of exploration, and is able to obtain an $\epsilon$-optimal policy for a post-revealed reward with sub-optimality gap at least $\rho$, where $S$ is the number of states, $A$ is the number of actions, and $H$ is the length of the horizon, obtaining a nearly quadratic saving in terms of $\epsilon$. We show that, information-theoretically, this bound is nearly tight for $\rho < \Theta(1/(HS))$ and $H > 1$. We further show that $\propto \tilde{O}(1)$ sample bound is possible for $H = 1$ (i.e., multi-armed bandit) or with a sampling simulator, establishing a stark separation between those settings and the RL setting.

1 Introduction

Unsupervised exploration is an emergent and challenging topic for reinforcement learning (RL) that inspires research interests in both application [Riedmiller et al., 2018, Finn and Levine, 2017, Xie et al., 2018, 2019, Schaul et al., 2015, Riedmiller et al., 2018] and theory [Hazan et al., 2018, Jin et al., 2020, Zhang et al., 2020a, Kaufmann et al., 2020, Ménard et al., 2020, Zhang et al., 2020b, Wu et al., 2020, Wang et al., 2020b]. The formal formulation of an unsupervised RL problem consists of an exploration phase and a planning phase [Jin et al., 2020]: in the exploration phase, an agent interacts with the unknown environment without the supervision of reward signals; then in the planning phase, the agent is prohibited to interact with the environment, and is required to compute a nearly optimal policy for some revealed reward function based on its exploration experiences. In particular, if the reward function is fixed yet unknown during exploration, the problem is called task-agnostic exploration (TAE) [Zhang et al., 2020a], and if the reward function is allowed to
be chosen arbitrary, the problem is called reward-free exploration (RFE) [Jin et al., 2020]. The performance of an unsupervised exploration algorithm is measured by the sample complexity, i.e., the number of samples the algorithm needs to collect during the exploration phase in order to complete the planning task near-optimally up a small error (with high probability). Existing algorithms for unsupervised RL exploration [Jin et al., 2020, Zhang et al., 2020a, Wu et al., 2020, Zhang et al., 2020b, Wang et al., 2020b] suffer a sample complexity (upper bounded by) \( \propto \tilde{O}(1/\epsilon^2) \)

\(^1\) for a target planning error tolerance \( \epsilon \). In a worst-case consideration, this rate, in terms of dependence on \( \epsilon \), is known to be unimprovable except for logarithmic factors [Jin et al., 2020, Dann and Brunskill, 2015].

However, the above worst-case sample bounds can be overly pessimistic in practical scenarios, since the planning task is usually a benign instance. For example, the revealed reward in the planning phase could induce a constant minimum nonzero sub-optimality gap (or simply gap, which we denote as \( \rho \), that measures the minimum gap between the best action and the second best action in the optimal Q-value function, and is defined formally in Section 2) [Tewari and Bartlett, 2007, Ortner and Auer, 2007, Ok et al., 2018]. For the supervised RL setting, where a reward function is given in prior, a constant gap significantly improves the sample complexity bounds, e.g., from \( \propto \tilde{O}(1/\epsilon^2) \) to \( \propto \tilde{O}(1) \) [Jaksch et al., 2010, Simchowitz and Jamieson, 2019, Yang et al., 2020, He et al., 2020, Xu et al., 2021]. However, to the best of our knowledge, no unsupervised RL algorithm is known to actively take advantage of the gap information in the rewards, and the following question remains open:

**Can unsupervised RL problems be solved faster when only targeting on tasks with constant gap?**

**A Case Study on Multi-Armed Bandit.** To gain more intuition on this problem, let us take a quick look at the (gap-dependent) unsupervised exploration problem for multi-armed bandit (MAB). In the worst-case setup, there is a minimax lower bound \( \propto \Omega(1/\epsilon^2) \) for unsupervised exploration on an MAB instance [Mannor and Tsitsiklis, 2004], where \( \epsilon \) is a small tolerance for the planning error. On the other hand, if the MAB instance has a constant gap, a rather simple uniform exploration strategy achieves \( \propto \tilde{O}(1) \) sample complexity upper bound (see, e.g., Theorem 33.1 in [Lattimore and Szepesvári, 2020], or Appendix D). This example provides positive evidence that a constant gap could accelerate unsupervised exploration for RL, too.

**Our Contributions.** In this paper, we study the gap-dependent task-agnostic exploration (gap-TAE) problem\(^2\) on a finite-horizon Markov decision process (MDP) with \( S \) states, \( A \) actions and \( H \geq 2 \) decision steps per episode. We consider a variant of upper-confidence-bound (UCB) algorithm that explores the unknown environment through a greedy policy that minimizes the cumulative exploration bonus [Zhang et al., 2020a, Wang et al., 2020b, Wu et al., 2020]; our exploration bonus is of UCB-type, and is clipped according to the gap parameter. Theoretically, we show that 

\[
\tilde{O}(H^2SA/(\rho\epsilon) + H^4S^2A/\epsilon) \numberoftrajectories \text{ is sufficient for the proposed algorithm to plan \( \epsilon \)-optimally for a task with gap, \( \rho \), where } \epsilon > 0 \text{ is the planning error parameter. This fast rate } \propto \tilde{O}(1/\epsilon) \text{ improves the existing, pessimistic rates } \propto \tilde{O}(1/\epsilon^2) \text{ [Zhang et al., 2020a, Wang et al., 2020b, Wu et al., 2020]} \text{ significantly when } \epsilon \ll \rho. \text{ Furthermore, we provide an information-theoretic lower bound, } \Omega(H^2SA/(\rho\epsilon)), \text{ on the number of trajectories required to solve the problem of gap-TAE on MDPs with } H \geq 2. \text{ This indicates that, for gap-TAE on MDP with } H \geq 2, \text{ the } \propto \tilde{O}(1/\epsilon) \text{ rate achieved by our algorithm is nearly the best possible.}
\]

Interestingly, our results imply that RL is truly harder than MAB in terms of gap-dependent unsupervised exploration. In particular, a finite-horizon MDP with \( H = 1 \) reduces to an MAB problem, where it is known that \( \propto \tilde{O}(1) \) samples are sufficient for solving gap-TAE; however when \( H \geq 2 \) which corresponds to the general RL setting, our results show that at least \( \Omega(1/\epsilon) \) amount of samples are required for solving gap-TAE. This is against an emerging wisdom from the supervised RL theory, that RL is nearly as easy as learning MAB [Jiang and Agarwal, 2018, Wang et al., 2020a, Zhang et al., 2020c].

\(^1\)Here we use \( \propto \tilde{O}(\cdot) \) to emphasize the rates’ dependence on \( \epsilon \), where the other parameters are treated as constants. Similarly hereafter.

\(^2\)Our algorithm as well as its theoretic results can be easily extended to other unsupervised exploration problems, e.g., reward-free exploration, by a covering and union bound argument.
we use $\epsilon$ and the agent is provided with the full-information of the reward function in the planning phase. However, the transition $P$ revealed to the agent in this phase is ended, the agent switches to the unsupervised phase, in this phase the agent is unsupervised and cannot observe reward feedback. When the exploration trajectories generated by the unknown transition probability using its exploration policy. Note that the set of two phases. In the exploration phase, the task-agnostic exploration is a finite Markov decision process (MDP), which is specified by a tuple, $(S, A, H, P, x, 1, r)$. $S$ is a finite state set where $|S| = S$. $A$ is a finite action set where $|A| = A$. $H$ is the length of the horizon. $P : S \times A \rightarrow [0, 1]^{|S|}$ is an unknown, stationary transition probability. Without lose of generality, we assume the MDP has fixed initial state $x_1$. For simplicity, we only consider deterministic and bounded reward function, which is denoted by $r = \{r_1, \ldots, r_H\}$ where $r_h : S \times A \rightarrow [0, 1]$ is the reward function at the $h$-th step. A policy is represented by $\pi := \{\pi_1, \ldots, \pi_H\}$, where each $\pi_h : S \rightarrow [0, 1]^4$ is a potentially random policy at the $h$-th step. Fixing a policy $\pi$, the Q-value function and the value function are defined as

$$Q^\pi_h(x, a) := E[r_h(x, a) + \cdots + r_H(x, a)| x_h = x, a_h = a], \quad V^\pi_h(x) := Q^\pi_h(x, \pi_h(x)),$$

where $x_j \sim P(\cdot | x_{j-1}, a_{j-1})$ and $a_j \sim \pi_j(x_j)$ for $j > h$. For an optimal policy $\pi^* \in \arg \max_{\pi} V^\pi_1(x_1)$, the induced optimal Q-value function and the optimal value function are denoted by $Q^*_h(x, a) := Q^*_{h+1}(x, a)$ and $V^*_h(x) := V^*_h(x)$, respectively. Last but not least, we remark the well-known Bellman equations:

$$\begin{cases}
Q^*_h(x, a) = r_h(x, a) + E_{y \sim P(\cdot | x, a)} V^*_{h+1}(y), & Q^*_h(x, a) = r_h(x, a) + E_{y \sim P(\cdot | x, a)} V^*_{h+1}(y), \\
V^*_h = Q^*_h(x, \pi_h(x)), & V^*_h = \max_a Q^*_h(x, a).
\end{cases}$$

**Task-Agnostic Exploration.** The problem of task-agnostic exploration (TAE) [Zhang et al., 2020a] consists of two phases. In the exploration phase, the agent interacts with the environment to draw $K$ trajectories generated by the unknown transition probability using its exploration policy. Note that in this phase the agent is unsupervised and cannot observe reward feedback. When the exploration phase is ended, the agent switches to the planning phase, and a reward function (independent of the collected dataset, or equivalently, determined before exploration but revealed after exploration) is revealed to the agent. Then the agent needs to compute a probably-approximately-correct (PAC)

---

1We may as well consider an MDP with an external initial state $x_0$ with zero reward for all actions, and a transition $P_0(\cdot | x_0, a) = P_0(\cdot)$ for all action $a$, which is equivalent to our setting by letting the horizon length $H = H + 1$.

2For the sake of presentation, we focus on bounded deterministic reward functions in this work. The techniques can be readily extended to stochastic reward settings and the obtained bounds will match our presented ones.

3In the original setup of TAE [Zhang et al., 2020b], $N$ reward functions are revealed in the planning phase, and only bandit feedback is available. For the sake of presentation, we assume there is only 1 reward function and the agent is provided with the full-information of the reward function in the planning phase. However, the presented results and the techniques are ready to be extended to these settings as well in a standard manner.
policy based on the collected samples. Formally, a policy $\pi$ is $(\epsilon, \delta)$-PAC, if
\[
\Pr \{ V^*_h(x) - V_1^\pi(x) > \epsilon \} < \delta,
\]
where the probability is over all the randomness in the procedure of producing $\pi$. The sample complexity of a TAE algorithm is measured by the number of trajectories $K$ that the agent needs to collect during the exploration phase to guarantee being $(\epsilon, \delta)$-PAC in planning phase.

We have a few remarks on TAE. Firstly, the reward function in TAE is independent of the randomness used in the exploration phase, in other words, the reward function is not allowed to be adversarial. Due to this non-adversarial nature, TAE can be achieved with much less information than that of estimating the environment accurately [Zhang et al., 2020a, Wu et al., 2020]. Secondly, if the planning reward is allowed to be chosen adversarially, the problem is known as reward-free exploration (RFE) [Jin et al., 2020]. Due to the adversarial nature of RFE, PAC-algorithms must estimate the environment with high precision, and a $S^2$ factor is unavoidable in their sample complexity bounds [Jin et al., 2020]. Thirdly, we chose TAE as a representative unsupervised RL problem to present our results. In particular we will show an efficient algorithm for TAE with a sample complexity upper bound that depends on only one $S$ factor (ignoring logarithmic factors) — then with standard covering argument (on the value functions) our algorithm can be applied to RFE with a revised sample complexity that depends on a $S^2$ factor (ignoring logarithmic factors). Similarly, our results can be extended to other unsupervised exploration problems as well, e.g., preference-free exploration [Wu et al., 2020].

**Sub-Optimality Gap.** Given an MDP, the stage-dependent state-action sub-optimality gap [Jaksch et al., 2010, Tewari and Bartlett, 2007, Ok et al., 2018, Simchowitz and Jamieson, 2019] is defined as
\[
\text{gap}_h(x, a) := V^*_h(x) - Q^*_h(x, a) \geq 0.
\]
Clearly, $\text{gap}_h(x, a) = 0$ if and only if $a$ is an optimal action at state $x$ and at the $h$-th decision step. Intuitively, when $\text{gap}_h(x, a) > 0$, $\text{gap}_h(x, a)$ characterizes the difficult to distinguish the sub-optimal action $a$ from the optimal actions at state $x$ and at the $h$-th step; and the larger $\text{gap}_h(x, a)$ is, the easier should it be distinguishing $a$ from the optimal actions. We now define the minimum non-zero stage-dependent state-action sub-optimality gap as:
\[
\rho := \min_{h, x, a} \{ \text{gap}_h(x, a) : \text{gap}_h(x, a) > 0 \}.
\]
For simplicity, we often refer $\rho$ to the minimum sub-optimality gap of an MDP, or simply gap, across the paper. Intuitively, an MDP with a constant $\rho$ is easy to learn [Simchowitz and Jamieson, 2019, Yang et al., 2020] since (intuitively) constant number of visitations to an state-action pair suffices to distinguish whether it is optimal.

We will use the following clip operator [Simchowitz and Jamieson, 2019]
\[
\text{clip}_\rho(z) := z \cdot \mathbb{1}[z \geq \rho], \text{ for } z \in \mathbb{R} \text{ and } \rho > 0,
\]
to clip a quantity smaller than $\rho$ to 0.

**Gap-Dependent Task-Agnostic Exploration.** We are now ready to formally state the gap-dependent task-agnostic exploration (gap-TAE) problem. In this problem, an agent is provided with a parameter $\rho$ to start the exploration phase of gap-TAE, where the agent explores the environment without the guidance of any reward. After the exploration phase, the agent is revealed with a reward, with which the ground truth MDP is guaranteed to have a minimum sub-optimality gap at least $\rho$. The agent then computes a policy under this reward. In the following sections, we will propose a sample efficient algorithm for gap-TAE (Section 3), and provide its sample complexity analysis (Section 4).

### 3 A Sample-Efficient Algorithm for Gap-TAE

In this section, we introduce UCB-Clip for solving gap-TAE in a sample-efficient manner. The algorithm is formally presented as Algorithms 1 and 2, for exploration and planning, respectively.

In the exploration phase, UCB-Clip (Algorithm 1) maintains an estimated maximum cumulative bonus based on the current empirical transition kernel (Algorithm 1, line 5), then explores the environment through executing a greedy policy according to this maximum cumulative bonus.
Algorithm 1 UCB-Clip (Exploration)

Require: gap parameter $\rho$, number of episodes $K$
1: initialize history $H^0 = \emptyset$, $t = \log(2HS^2AK/\delta)$
2: for episode $k = 1, 2, \ldots, K$ do
3:   $N^k(x, a), \hat{P}^k(y \mid x, a) \leftarrow \text{Empi-Prob}(H^{k-1})$
4:   compute exploration bonus $c^k(x, a) := \text{clip}_{\text{err}} \left[ \sqrt{\frac{8H^2_s}{N^k(x, a)}} + \frac{120(S+H)H^3_s}{N^k(x, a)} + \frac{240H^6S^2}{(N^k(x, a))^2} \right]$
5:   $(\hat{Q}_h^k(x, a), \hat{V}_h^k(x))_{h=1}^H \leftarrow \text{UCB-Q-Value}(\hat{P}^k, r = 0, c^k)$
6:   receive initial state $x_1^k = x_1$
7:   for step $h = 1, 2, \ldots, H$ do
8:     take action $a_h^k = \arg \max_a Q_h^k(x_h^k, a)$, and obtain a new state $x_{h+1}^k$
9:   end for
10: update history $H^k = H^{k-1} \cup \{x_h^k, a_h^k\}_{h=1}^H$
11: end for
12: return History $H^k$

Function Empi-Prob
13: Require: history $H^{k-1}$
14: for $(x, a, y) \in S \times A \times S$ do
15:   $N^k(x, a, y) := \# \{ (x, a, y) \in H^{k-1} \}$, and $N^k(x, a) := \sum_y N^k(x, a, y)$
16:   if $N^k(x, a) > 0$ then
17:     $\hat{P}^k(y \mid x, a) = N^k(x, a, y)/N^k(x, a)$
18:   else
19:     $\hat{P}^k(y \mid x, a) = 1/S$
20: end if
21: end for
22: return $N^k(x, a), \hat{P}^k(y \mid x, a)$

Function UCB-Q-Value
23: Require: empirical transition $\hat{P}^k$, reward function $r$, bonus function $b^k$
24: set $V_{H+1}^k(x) = 0$
25: for step $h = H, H - 1, \ldots, 1$ do
26:   for $(x, a) \in S \times A$ do
27:     $Q_h^k(x, a) = \min \left\{ H, r_h(x, a) + b^k(x, a) + \hat{P}_h^kV_{h+1}^k(x, a) \right\}$
28:     $V_h^k(x) = \max_a Q_h^k(x, a)$
29: end for
30: return $\{Q_h^k(x, a), V_h^k(x)\}_{h=1}^H$

Roughly speaking, the exploration bonus at a state-action pair is inversely proportional to the number of visitations to the state-action pair (Algorithm 1, line 4), thus the exploration policy is encouraged to pay more visits to the state-actions that have not yet been visited for sufficient times, where its induced bonus is larger. In this manner, UCB-Clip collects a dataset that contains sufficient samples at every state-action pair for the later planning task. In the planning phase, UCB-Clip (Algorithm 2) receives the reward, computes a sequence of optimistic estimations to the value function based on the collected samples (Algorithm 2, line 5), and outputs, uniformly at random, a greedy policy that corresponds to one of the optimistic estimated value functions (Algorithm 2, line 6).

UCB-Clip is inspired by two existing algorithms: UCBVI [Azar et al., 2017], a model-based algorithm that achieves minimax-optimal sample complexity for supervised RL problems, and PF-UCB [Wu et al., 2020], a variant of UCBVI that efficiently solves the preference-free exploration problems in the context of unsupervised multi-objective RL. Similar to both UCBVI and PF-UCB, in the planning phase UCB-Clip (Algorithm 2) adopts an upper-confidence-bound (UCB) type bonus to perform optimistic planning (based on samples collected in the exploration phase). Similar to PF-UCB but different from UCBVI, UCB-Clip (Algorithm 1) explores the unknown environment through a greedy
policy that minimizes the maximum cumulative exploration bonus. Different from either PF-UCB or UCBVI, in the exploration phase, UCB-Clip adopts a clipped bonus (Algorithm 1, line 4).

Algorithm 2 UCB-Clip (Planning)

Require: history $\mathcal{H}^K$, reward function $r$
1: initialize $i = \log(2HS^2AK/\delta)$
2: for $k = 1, 2, \ldots, K$ do
3: $N^k(x, a), \hat{P}^k(y \mid x, a) \leftarrow \text{Empi-Prob}(\mathcal{H}^{k-1})$
4: compute planning bonus $b^k(x, a) := \frac{\sqrt{H2x^k}}{2N^k(x, a)}$
5: $\{Q_h^k(x, a), V_h^k(x)\}_{k=1}^H \leftarrow \text{UCB-Q-Value}(\hat{P}^k, r, b^k)$
6: infer greedy policy $\pi_h^k(x) = \arg \max_a Q_h^k(x, a)$
7: end for
8: return $\pi$ drawn uniformly from $\{\pi^1, \ldots, \pi^K\}$

The clipped bonus turns out to be a key ingredient for UCB-Clip to save samples for gap-TAE problems. Specifically, the leading-order term in the UCB-type bonus will be brute-force clipped to zero, when a state-action pair has been visited for sufficiently many times, i.e., when $N(x, a) \approx H^4/\rho^2$ (Algorithm 1, line 5). This will cause a sudden decrease of the bonus, and discourages the agent to continue to visit this state-action pair. Note that the considered MDP has a minimum sub-optimality gap, $\rho$, thus $N(x, a) \approx H^4/\rho^2$ amount of samples is already sufficient to distinguish sub-optimal actions from the optimal ones at the state-action pair. Then by clipping the bonus at such state-action pairs, UCB-Clip spends less unnecessary visitations to these pairs, and thus saves opportunities for visiting the state-actions that have not yet been visited sufficiently. In this way, UCB-Clip accelerates TAE utilizing the sub-optimality gap parameter. We formally justify the above intuitions in the next section.

4 Theoretic Results

In this part, we first present a theoretic justification for the proposed algorithm, and then discuss a separation between RL vs. MAB based on the theoretical results.

4.1 Upper and Lower Bounds

We first present the following two theorems to rigorously justify a sample-complexity upper bound for UCB-Clip and a sample-complexity lower bound for the gap-TAE problem, respectively.

Theorem 1 (An upper bound for UCB-Clip). Suppose UCB-Clip (Algorithm 1) runs for $K$ episodes and collects a dataset $\mathcal{H}^K$. Let policy $\pi$ be outputted by UCB-Clip (Algorithm 2) for an arbitrary input task that is independent of $\mathcal{H}^K$ and has a minimum sub-optimality gap $\rho$. Then with probability at least $1 - \delta$, the planning error is bounded by

$$V_1^*(x_1) - V_1^*(x_1) \leq \frac{H^3SA}{\rho K} \cdot \log \frac{HSAK}{\delta} + \frac{H^4S^2A}{K} \cdot \log^2 \frac{HSAK}{\delta}.$$ 

Theorem 2 (A lower bound for gap-TAE). Fix $S \geq 5, A \geq 2, H \geq 2 + \log_A S$. There exist positive constants $c_1, c_2, \rho_0, \delta_0$, such that for every $\rho \in (0, \rho_0)$, $\epsilon \in (0, \rho)$, $\delta \in (0, \delta_0)$, and for every $(\epsilon, \delta)$-PAC algorithm that runs for $K$ episodes, there exists some gap-TAE instances with minimum sub-optimality gap $\rho$, such that

$$\mathbb{E}[K] \geq c_1 \cdot \frac{H^2SA}{\rho \epsilon} \cdot \log \frac{c_2}{\delta},$$

where the expectation is taken with respect to the randomness of choosing the MDP instances and the randomness of the algorithm.

Remark 1. According to Theorem 1, UCB-Clip only requires $\propto \tilde{O}(1/\epsilon)$ number of episodes to solve TAE when there is a constant minimum sub-optimality gap, which improves the existing, pessimistic rates $\propto \tilde{O}(1/\epsilon^2)$ achieved by the TAE algorithms that focus on worst-case instances [Zhang et al.,
where \( \pi \) is the planning policy at the \( k \)-th episode and \( c^k(x, a) \) is the clipped exploration bonus at the \( k \)-th episode. The right hand side of (4.1) can be further improved to have a uniform upper bound \( H \) per decision step. Note that the right hand side of (4.1) is the expected cumulative bonus over the trajectory induced by policy \( \pi^k \) and the true transition \( \mathbb{P} \), and that the bonus contains lower order terms that control the error of an inaccurately estimated probability transition (Algorithm 1, line 4). Therefore, up to some constant factors, it can be bounded by the expected cumulative bonus over the trajectory induced by policy \( \pi^k \) and the empirical transition \( \hat{\mathbb{P}}^k \). Moreover, the latter does not exceed the exploration value function \( \hat{V}^k_1(x_1) \) in Algorithm 1, since \( \hat{V}^k_1(x_1) \) is the maximum possible cumulative bonus at the \( k \)-th episode and over the empirical transition \( \hat{\mathbb{P}}^k \) (it maximizes the cumulative bonus over the empirical transition by dynamic programming according to Algorithm 1).

In this way, we establish \( V^*_1(x_1) - V^k_1(x_1) \leq \hat{V}^k_1(x_1) \) for every \( k \). Finally, a standard regret analysis for the exploration phase shows that the total exploration values in the exploration phase is logarithmic, thanks to the clipped exploration bonus, and thus the total planning error is also logarithmic. The presented error upper bound is established by averaging over the \( K \) episodes. Some of proving techniques are motivated by [Simchowitz and Jamieson, 2019, Wu et al., 2020]. Our key novelty is to carefully incorporate the clip operator in the bonus function and use that to build a connection between the planning and exploration phases. See Appendix B for more details.

**Proof Sketch of Theorem 1.** We first look at the planning phase (Algorithm 2). Since the reward induces a gap \( \rho \), with some computations we can obtain the following error estimation of the planning error per episode:

\[
V^*_1(x_1) - V^k_1(x_1) \lesssim E_{\pi^k, \mathbb{P}} \sum_{h=1}^{H} c_h^k(x_h, a_h), \quad \text{for every } k,
\]

where \( \pi^k \) is the planning policy at the \( k \)-th episode and \( c^k(x, a) \) is the clipped exploration bonus at the \( k \)-th episode. The right hand side of (4.1) can be further improved to have a uniform upper bound \( H \) per decision step. Note that the right hand side of (4.1) is the expected cumulative bonus over the trajectory induced by policy \( \pi^k \) and the true transition \( \mathbb{P} \), and that the bonus contains lower order terms that control the error of an inaccurately estimated probability transition (Algorithm 1, line 4). Therefore, up to some constant factors, it can be bounded by the expected cumulative bonus over the trajectory induced by policy \( \pi^k \) and the empirical transition \( \hat{\mathbb{P}}^k \). Moreover, the latter does not exceed the exploration value function \( \hat{V}^k_1(x_1) \) in Algorithm 1, since \( \hat{V}^k_1(x_1) \) is the maximum possible cumulative bonus at the \( k \)-th episode and over the empirical transition \( \hat{\mathbb{P}}^k \) (it maximizes the cumulative bonus over the empirical transition by dynamic programming according to Algorithm 1).

In this way, we establish \( V^*_1(x_1) - V^k_1(x_1) \leq \hat{V}^k_1(x_1) \) for every \( k \). Finally, a standard regret analysis for the exploration phase shows that the total exploration values in the exploration phase is logarithmic, thanks to the clipped exploration bonus, and thus the total planning error is also logarithmic. The presented error upper bound is established by averaging over the \( K \) episodes. Some of proving techniques are motivated by [Simchowitz and Jamieson, 2019, Wu et al., 2020]. Our key novelty is to carefully incorporate the clip operator in the bonus function and use that to build a connection between the planning and exploration phases. See Appendix B for more details.

**Proof Sketch of Theorem 2.** A hard instance that witnesses the lower bound is shown in Figure 1. The hard instance is motivated by [Mannor and Tseitsiklis, 2004, Dann and Brunskill, 2015]. One can verify that this instance has a minimum sub-optimality gap \( \rho/2 \). Indeed, the only states that have sub-optimal actions are the left orange states in Type I model or Type II model. For the left orange state in Type I model, the optimal action has value \( H/2 + \rho/2 \), but the sub-optimal ones have value \( H/2 \), where the gap is \( \rho/2 \). Similarly we can verify the gap in Type II model is \( \rho \). Moreover, in order to be \( \epsilon/3 \)-correct, the agent needs to identify the optimal action at the left orange states, otherwise it takes a sub-optimal action and incurs a value error at least \( \epsilon/\rho \cdot \rho/2 = \epsilon/2 \). Now the problem is reduced to identify the best action at the left orange states. Let us ignore \( H, S, A \) factors and focus on \( \rho \) and \( \epsilon \). Then at the left orange states, the probability gap between the best action and the second best action is \( \propto \Theta(\rho) \), thus \( \propto \Omega(1/\rho^2) \) samples are needed to identify the optimal action. On the other hand, in each episode there is only \( \epsilon/\rho \) chance to visit the left orange states, thus \( \propto \Omega(1/(\rho^2)) \) episodes are needed to provide \( \propto \Omega(1/\rho^2) \) samples at the left orange states. This justifies the \( \propto \Omega(1/(\rho^2)) \) rate in the lower bound. A complete proof is deferred to Appendix C.

### 4.2 Comparison with Multi-Armed Bandit

Theorems 1 and 2 show that for unsupervised exploration problems on an MDP, even when the instance is benign and has a constant minimum sub-optimality gap, a \( \propto \Omega(1/\epsilon) \) sample complexity must be paid. This establishes a stark contrast to the gap-dependent unsupervised exploration problems on a multi-armed bandit (MAB) [Lattimore and Szepesvári, 2020]. In particular, for an MAB with \( A \) arms and a constant minimum sub-optimality gap \( \rho \) between the expected rewards associated with the arms, a rather simple uniform exploration strategy, with \( T = \mathcal{O}(\frac{A}{\rho^2} \log \frac{A}{\rho}) \), suffices. This is in stark contrast to the accelerated algorithms for the multi-armed bandit, which require \( \mathcal{O}(\frac{A}{\rho^2} \log \frac{A}{\rho}) \) samples to achieve a near-optimal performance.
Figure 1: A hard-to-learn MDP example. States are denoted by circles. A state-determined reward function takes value 1 at the state denoted by a circle with a plus sign and takes value zero otherwise. The plot only shows the structure of the last three layers of the MDP, which consists of a Type I model, a Type II model, and $S - 2$ Type III model. These models are connected by a $(\log_A S)$-layer tree with $A$-branches in each layer, and with deterministic and known transition. In the Type III model, from the green state and for all actions, it transits to the left orange state with probability $\epsilon/\rho$, or to the self-absorbing right orange state with probability $1 - \epsilon/\rho$. Then from the left orange state and for all actions, it transits to the two blue states evenly. The Type I (II) model is only different from the Type III model at the left orange state: in Type I (II) model, there exists and only one action such that it transits to the left blue state with probability $1/2 + \rho/(2H)$ (with probability $1/2 + \rho/H$), and to the right blue state otherwise. In other words, in the left orange states, an optimal action exists in the Type I model, and all other actions are equivalent and are sub-optimal.

is $(\epsilon, \delta)$-correct for identifying the best arm (see, e.g., Theorem 33.1 in Lattimore and Szepesvári [2020], or Appendix D). These observations from gap-dependent unsupervised exploration establish a clear separation between general RL (corresponds to MDP with $H \geq 2$) and MAB (corresponds to MDP with $H = 1$), with a sample complexity comparison $\propto \tilde{O}(1/\epsilon)$ vs. $\propto \tilde{O}(1)$, i.e., RL is significantly more challenging than MAB. This is against an emerging wisdom from the supervised reinforcement learning theory, that RL is nearly as easy as solving MAB [Jiang and Agarwal, 2018, Wang et al., 2020a, Zhang et al., 2020c].

Let us take a deeper look at where MDP is harder than MAB. The hard instance in Figure 1 clearly illustrates the issue: there could exist some important states in MDP that cannot be ignored, but are hard to reach in the same time, e.g., ignoring the left orange states in Figure 1 would result in a $\Theta(\epsilon)$ error, but there is only $\Theta(\epsilon)$ chance to reach these states per episode, thus in order to reach the left orange states for at least constant times, an algorithm must run $\propto \Omega(1/\epsilon)$ episodes.

To further verify our understanding, let us consider an MDP with a sampling simulator [Sidford et al., 2018a,b, Wang, 2017, Azar et al., 2013]. The sampling simulator allows us to draw samples at any state-action pair, thus exempts the “hard-to-reach” states. The following theorem shows that for MDP with a sampling simulator, the gap-TAE problem can also be solved with $\propto \tilde{O}(1)$ samples, as in the case of MAB. A proof is included in Appendix D.

**Theorem 3** (MDP with a sampling simulator). Suppose there is a sampling simulator for the MDP considered in the gap-TAE problem. Consider exploration with the uniformly sampling strategy, and planning with the dynamic programming method with the obtained empirical probability. If $T$ samples are drawn, where

$$T \geq \frac{2H^4 S A}{\rho^2} \cdot \log \frac{2H S A}{\delta},$$

then with probability at least $1 - \delta$, the obtained policy is optimal ($\epsilon = 0$).

### 5 Additional Discussions and Open Questions

The $H$ Dependence. In the regime that $\rho \lesssim 1/(HS)$, our upper bound can potentially be improved for an $H$ factor, comparing with the provided lower bound. Technically, this is because Algorithm 1 utilizes a Hoeffding-type bonus, which is known to be less tight compared with a Bernstein-type bonus [Azar et al., 2017]. Hoeffding-type bonus has the benefits of being reward-independent,
which allows us to construct a reward-independent, hence unsupervised, exploration policy that minimizes an upper bound of the per-episode, reward-dependent planning error. Due to this issue, a Bernstein-type bonus is not helping in our problem. We leave this the problem of further tightening the $H$ factor as a future work.

Removing the Gap-Independent Term. The bound presented in Theorem 1 has a gap-independent term, $\tilde{O}(H^4 S^2 A/K)$, which is still linear in $\tilde{O}(1/K)$ but is quadratic in $S$. This $S^2$-dependence appears in the sample-complexity lower-order term of all the model-based algorithms that we are aware of, e.g., [Azar et al., 2017, Zanette and Brunskill, 2019, Simchowitz and Jamieson, 2019], and could potentially be mitigated by model-free algorithms [Jin et al., 2018, Yang et al., 2020].

Visiting Ratio Based Approaches. In the context of reward-free exploration, Zhang et al. [2020b] extends a visiting ratio based approach that is initially proposed by Jin et al. [2020], and achieves a nearly minimax optimal sample complexity for reward-free exploration. These approaches, however, involve a $S^2$-dependence on the obtained sample bound, which is sub-optimal in the context of task-agnostic exploration (see [Zhang et al., 2020a, Wu et al., 2020] and Theorem 2).

Interpolating with Gap-Independent Bounds. For supervised RL problems, Simchowitz and Jamieson [2019] show a bound that (smoothly) interpolates between the benign-case, gap-dependent bound and the minimax, gap-independent bound, where the latter could be even tighter in finite time when the minimum sub-optimality gap is small (e.g., $\rho \ll \epsilon$). They achieve such a bound by discussing whether or not a state-action pair has a large enough gap, $\min_h \text{gap}_h(x, a) > \epsilon$. for those who have a large gap, a gap-dependent bound is applied, and for the others the gap-independent bound is used. In our unsupervised setting, the quantity $\min_h \text{gap}_h(x, a)$ is reward-dependent and cannot be known during exploration. Hence the algorithm is not possible to figure out whether or not a state-action pair has large enough gap. This prevents us from obtaining a similar mixed bound for unsupervised RL problems. We leave this question for future investigation.

6 Related Works

Gap-Dependent Supervised Reinforcement Learning. In the literature of supervised RL, the state-action sub-optimality gap has been long embraced to characterize instance-dependent theoretic guarantees. Ortner and Auer [2007], Tewari and Bartlett [2007], Ok et al. [2018] study gap-dependent bounds in the asymptotic sense, and Jaksch et al. [2010] establish a finite time, gap-dependent bound. More recently, in the setting of finite-horizon MDP and for a broad class of UCB-type, model based algorithms, Simchowitz and Jamieson [2019] provide a finite, gap-dependent regret bound that comprehensively interpolates the minimax, gap-independent regret bound and a logarithmic, gap-dependent regret bound. Similar results are further built for model-free algorithms [Yang et al., 2020], linear MDP [He et al., 2020], and MDP with corruptions [Lykouris et al., 2019]. In addition to this line, Jonsson et al. [2020] study the gap-dependent bound for a Monte-Carlo tree search algorithm, and Xu et al. [2021] establish a fine-grained gap-dependent bound through a non-UCB type algorithm. However, all these results explores the environment under the guidance of an observable reward signal, thus are not applicable to the unsupervised exploration problems studied in this paper.

Worst-Case Considerations of Unsupervised Exploration. The arguably most typical unsupervised exploration problem is the reward-free exploration problem formalized by Jin et al. [2020], where the agent collects samples in the unsupervised fashion in order to be able to plan nearly optimally for arbitrary rewards. Before Jin et al. [2020], Hazan et al. [2018], Brafman and Tennenholtz [2002], Du et al. [2019] also study exploratory policies with certain covering properties; and following Jin et al. [2020], the sample complexity of reward-free exploration is further improved to nearly minimax optimal by Kaufmann et al. [2020], Ménard et al. [2020], Zhang et al. [2020b]. Besides reward-free exploration problems, Zhang et al. [2020a], Wang et al. [2020b] introduce and study task-agnostic exploration problems where the planning reward is fixed but unknown during exploration, and Wu et al. [2020] study preference-free exploration problems in the context of multi-objective RL. Nonetheless, the above considerations of unsupervised exploration problems and their algorithms take no advantage of the sub-optimality gap, and the obtained theoretic results are pessimistic and restricted by the worst-case tasks.
7 Concluding Remarks

In this paper we study sample-efficient algorithms for gap-dependent unsupervised exploration problems in RL. When the targeted planning tasks have a constant minimum non-zero sub-optimality gap, the proposed algorithm achieves a gap-dependent sample complexity upper bound that significantly improves the existing minimax bounds. Moreover, an information-theoretic lower bound is provided to justify the tightness of the obtained upper bound. These results establish an interesting separation between RL and MAB (or RL with a simulator) in terms of gap-dependent unsupervised exploration problems.

References

A Numerical Simulations

Figure 2 illustrates the fast rate achieved by UCB-Clip for task-agnostic exploration on a benign MDP with constant minimum sub-optimality gap. The curve for UCB-Clip indicates the planning error of UCB-Clip when running on a random MDP with $H = 5$, $S = 10$, $A = 10$, $ρ = 0.4$, and $K = 50,000$. By comparing with the minimax rate, we observe that UCB-Clip solves task-agnostic exploration with a faster rate, when the task has a constant minimum sub-optimality gap.

B Proof of the Upper Bound (Theorem 1)

Our proof is inspired by [Simchowitz and Jamieson, 2019] and [Wu et al., 2020].

Preliminaries. Let $π^k$ be the planning policy at the $k$-th episode, i.e., a greedy policy that maximizes $Q^∗_h(x,a)$. Let $̂π^k$ be the exploration policy at the $k$-th episode, i.e., a greedy policy given that maximizes $Q^k_h(x,a)$. Let $w^k_h(x,a) := P\{(x_h, a_h) = (x, a) | ̂π^k, P\}$ and $w^k(x,a) := \sum_h w^k_h(x,a)$. In the following, if not otherwise noted, we define $ι := \log 2\frac{HS^2AK}{δ}$.

Consider the following good events

\[ G_1 := \left\{ \forall x, a, h, k, \left| (\hat{P}^k - P)V^*_h(x,a) \right| \leq \sqrt{\frac{H^2}{2N^k(x,a)}} \log \frac{2HSAK}{δ} \right\}, \tag{G1} \]

\[ G_2 := \left\{ \forall x, a, y, k, \left| \hat{P}^k(y | x, a) - P(y | x, a) \right| \leq \sqrt{\frac{2P(y|x,a)}{N^k(x,a)}} \log \frac{2S^2AK}{δ} + \frac{2}{3N^k(x,a)} \log \frac{2S^2AK}{δ} \right\}, \tag{G2} \]

\[ G_3 := \left\{ \forall x, a, y, k, \left| \hat{P}^k(y | x, a) - P(y | x, a) \right| \leq \sqrt{\frac{2\hat{P}^k(y | x, a)}{N^k(x,a)}} \log \frac{2S^2AK}{δ} + \frac{7}{3N^k(x,a)} \log \frac{2S^2AK}{δ} \right\}. \tag{G3} \]
Proof. By Hoeffding’s inequality and a union bound, we have that $\mathbb{P}\{G_1\} \geq 1 - \delta$.

By Bernstein’s inequality, a union bound and that $1 - \mathbb{P}(y | x, a) \leq 1$, we have that $\mathbb{P}\{G_2\} \geq 1 - \delta$.

By empirical Bernstein’s inequality [Maurer and Pontil, 2009], a union bound and that $1 - \hat{P}^k(y | x, a) \leq 1$, we have that $\mathbb{P}\{G_3\} \geq 1 - \delta$.

According to Lemma F.4 by [Dann et al., 2017] and a union bound, we have that $\mathbb{P}\{G_4\} \geq 1 - \delta$.

Finally, a union bound over the four events proves the claim. $\Box$

Planning Phase. Recall the planning bonus is set to be

$$b^k(x, a) := \sqrt{\frac{H^2t}{2N^k(x, a)}}. \tag{B.1}$$

Lemma 2 (Optimistic planning). If $G_1$ holds, then $Q^k_h(x, a) \geq Q^*_h(x, a)$ for every $k, h, x, a$.

Proof. We prove it by induction. Clearly the hypothesis holds for $H + 1$; now suppose that $Q^k_{h+1}(x, a) \geq Q^*_h(x, a)$, and consider $h$. From Algorithm 2, we see that

$$Q^k_h(x, a) := H \land \left( r_h(x, a) + b^k(x, a) + \hat{P}^k V^k_{h+1}(x, a) \right). \tag{B.2}$$

If $Q^k_h(x, a) = H$, then $Q^k_h(x, a) = H \geq Q^*_h(x, a)$; otherwise, we have that

$$Q^k_h(x, a) - Q^*_h(x, a) = r_h(x, a) + b^k(x, a) + \hat{P}^k V^k_{h+1}(x, a) - r_h(x, a) - PV^*_h(x, a)$$

$$= b^k(x, a) + \hat{P}^k V^k_{h+1}(x, a) - PV^*_h(x, a)$$

$$\geq b^k(x, a) + (\hat{P}^k - P)V^*_h(x, a) \quad \text{(since $Q^k_{h+1}(x, a) \geq Q^*_h(x, a)$)}$$

$$\geq 0 \quad \text{(since $G_1$ holds)}.$$

These complete our induction. $\Box$

Let us denote the optimistic surplus [Simchowitz and Jamieson, 2019] as

$$E^k_h(x, a) := Q^k_h(x, a) - (r_h(x, a) + PV^k_{h+1}(x, a)). \tag{B.3}$$

Lemma 3 (Optimistic surplus bound). If $G_1, G_2$ and $G_3$ hold, then for every $k, h, x, a$,

$$E^k_h(x, a) \leq H \land \left( \sqrt{\frac{2H^2t}{N^k(x, a)}} + \frac{HS_t}{N^k(x, a)} + E_{\pi_t} \sum_{t \geq h+1} \left( \frac{4e^2H^3t}{N^k(x_t, a_t)} + \frac{8e^2H^5S^2t^2}{(N^k(x_t, a_t))^2} \right) \right).$$

Proof. By (B.3) and (B.2) we have $E^k_h(x, a) \leq Q^k_h(x, a) \leq H$. As for the second bound, note that

$$E^k_h(x, a) = Q^k_h(x, a) - (r_h(x, a) + PV^k_{h+1}(x, a)) \quad \text{(use (B.3))}$$

$$\leq r_h(x, a) + b^k(x, a) + \hat{P}^k V^k_{h+1}(x, a) - r_h(x, a) - PV^*_h(x, a) \quad \text{(use (B.2))}$$

$$= b^k(x, a) + (\hat{P}^k - P)V^*_h(x, a) + (\hat{P}^k - P)(V^k_{h+1} - V^*_h)(x, a)$$

$$\leq 2b^k(x, a) + (\hat{P}^k - P)(V^k_{h+1} - V^*_h)(x, a) \quad \text{(use (B.1) and that $G_1$ holds)}$$

$$\leq \sqrt{\frac{2H^2t}{N^k(x, a)}} + \frac{HS_t}{N^k(x, a)} + P (V^k_{h+1} - V^*_h)^2 (x, a). \quad \text{(use Lemma 4)} \tag{B.4}$$

$$G_4 := \left\{ \forall x, a, k, N^k(x, a) \geq \frac{1}{2} \sum_{j<k} w^j(x, a) - H \log \frac{HSA}{\delta} \right\}. \tag{G.4}$$

Lemma 1 (The probability of good events). $\mathbb{P}\{G_1 \cap G_2 \cap G_3 \cap G_4\} \geq 1 - 4\delta$.
We next bound $V_h^k(x) - V_h^*(x)$ by
\[
V_h^k(x) - V_h^*(x) \leq Q_h^k(x, a) - Q_h^*(x, a) \quad \text{(set } a = \pi_k(x)\text{)}
\]
\[
\leq b^k(x, a) + \tilde{P}k \, V_{h+1}^k(x, a) - P \, V_{h+1}^*(x, a) \quad \text{(use (B.2))}
\]
\[
= \left(b^k + P \left( V_{h+1}^k - V_{h+1}^* \right) + (\tilde{P}k - P) \left( V_{h+1}^k - V_{h+1}^* \right) \right) (x, a)
\]
\[
\leq \left(2b^k + P \left( V_{h+1}^k - V_{h+1}^* \right) + (\tilde{P}k - P) \left( V_{h+1}^k - V_{h+1}^* \right) \right) (x, a) \quad \text{(use (B.1) and G_1)}
\]
\[
\leq \sqrt{\frac{2H^2 \ell}{N^k(x, a)}} + \left(1 + \frac{1}{H}\right) P \left( V_{h+1}^k - V_{h+1}^* \right) (x, a) + \frac{2H^2 S_t}{N^k(x, a)}.
\]
(see use Lemma 4)

Solving the recursion we obtain
\[
V_h^k(x) - V_h^*(x) \leq e \cdot \mathbf{E}_{x^k, l} \sum_{t \geq h} \left( \sqrt{\frac{2H^2 \ell}{N^k(x_t, a_t)}} + \frac{2H^2 S_t}{N^k(x_t, a_t)} \right),
\]
where $x_h = x$. This implies that
\[
\left( V_h^k(x) - V_h^*(x) \right)^2 \leq \left( e \cdot \mathbf{E}_{x^k, l} \sum_{t \geq h} \left( \sqrt{\frac{2e^2 H^2 \ell}{N^k(x_t, a_t)}} + \frac{2eH^2 S_t}{N^k(x_t, a_t)} \right) \right)^2
\]
\[
\leq e \cdot \mathbf{E}_{x^k, l} \sum_{t \geq h} \left( \sqrt{\frac{2e^2 H^2 \ell}{N^k(x_t, a_t)}} + \frac{2eH^2 S_t}{N^k(x_t, a_t)} \right)^2
\]
\[
\leq H \cdot e \cdot \mathbf{E}_{x^k, l} \sum_{t \geq h} \left( \sqrt{\frac{2e^2 H^2 \ell}{N^k(x_t, a_t)}} + \frac{2eH^2 S_t}{N^k(x_t, a_t)} \right)^2
\]
\[
\leq e \cdot \mathbf{E}_{x^k, l} \sum_{t \geq h} \left( \frac{4e^2 H^3 \ell}{N^k(x_t, a_t)} + \frac{8e^2 H^5 S_t^2}{N^k(x_t, a_t)} \right)
\]
\[
\text{inserting which to (B.4) we have that}
\]
\[
E_h^k(x, a) \leq \sqrt{\frac{2H^2 \ell}{N^k(x, a)}} + \frac{H S_t}{N^k(x, a)} + e \cdot \mathbf{E}_{x^k, l} \sum_{t \geq h+1} \left( \frac{4e^2 H^3 \ell}{N^k(x_t, a_t)} + \frac{8e^2 H^5 S_t^2}{N^k(x_t, a_t)} \right),
\]
where $(x_h, a_h) = (x, a)$. The two upper bounds on $E_h^k(x, a)$ together complete the proof.

\[\square\]

Lemma 4 (Bounds for the lower order term). If $G_2$ and $G_3$ hold, we have that for every $V_1, V_2$ such that $0 \leq V_1(x) \leq V_2(x) \leq M$ and for every $k, x, a$, the following inequalities hold:
\[
(P_k - P)(V_2 - V_1)(x, a) \leq P \left( V_2 - V_1 \right)^2 (x, a) + \frac{MS_t}{N^k(x, a)};
\]
\[
(P_k - P)(V_2 - V_1)(x, a) \leq \frac{1}{H} P \left( V_2 - V_1 \right) (x, a) + \frac{2MS_t}{N^k(x, a)};
\]
\[
(P_k - P)(V_2 - V_1)(x, a) \leq \frac{1}{H} \tilde{P}k \left( V_2 - V_1 \right) (x, a) + \frac{3MS_t}{N^k(x, a)}.
\]

Proof. For simplicity let us denote $p(y) := P(y \mid x, a)$ and $\tilde{p}(y) := \tilde{P}k(y \mid x, a)$. For the first inequality,
\[
\left| (P_k - P)(V_2 - V_1)(x, a) \right| \leq \sum_{y \in S} \left| \tilde{p}(y) - p(y) \right| (V_2(y) - V_1(y))
\]
\[
\leq \sum_{y \in S} \left( \sqrt{\frac{2p(y)}{N^k(x, a)}} + \frac{2t}{3N^k(x, a)} \right) (V_2(y) - V_1(y)) \quad \text{(since } G_2 \text{ holds)}
\]
\[
\begin{aligned}
&\leq \sum_{y \in S} \sqrt{\frac{2t}{N^k(x, a)}} \cdot \sqrt{p(y) (V_2(y) - V_1(y))^2} + \frac{2MS_t}{3N^k(x, a)} \\
&\leq \sum_{y \in S} \left( \frac{t}{N^k(x, a)} + p(y) (V_2(y) - V_1(y))^2 \right) + \frac{2MS_t}{3N^k(x, a)} \quad \text{(use } \sqrt{ab} \leq a + b) \\
&\leq \mathbb{P} (V_2 - V_1)^2 (x, a) + \frac{MS_t}{N^k(x, a)}.
\end{aligned}
\]

For the second inequality,
\[
\begin{aligned}
&\left| (\hat{E}^k - \mathbb{P})(V_2 - V_1)(x, a) \right| \leq \sum_{y \in S} |p^k(y) - p(y)| (V_2(y) - V_1(y)) \\
&\leq \sum_{y \in S} \left( \frac{2p(y)t}{N^k(x, a)} + \frac{2t}{3N^k(x, a)} \right) (V_2(y) - V_1(y)) \quad \text{(since } G_2 \text{ holds)} \\
&\leq \sum_{y \in S} \left( \frac{p(y)}{H} + \frac{H \cdot 2t}{2N^k(x, a)} + \frac{2t}{3N^k(x, a)} \right) (V_2(y) - V_1(y)) \quad \text{(use } \sqrt{ab} \leq 1/2 (a + b)) \\
&\leq \sum_{y \in S} \frac{p(y)}{H} (V_2(y) - V_1(y)) + \frac{2MH \cdot S_t}{N^k(x, a)} \\
&= \frac{1}{H} \mathbb{P} (V_2 - V_1)(x, a) + \frac{2MH \cdot S_t}{N^k(x, a)}.
\end{aligned}
\]

The third inequality is proved in a same way as the second inequality, except that in the second step we use event \( G_3 \) rather than \( G_2 \). \( \square \)

**Lemma 5** (Half-clip trick). If \( G_1 \) holds, then for every \( k \),
\[
V^*_i(x_1) - V^*_i\pi(x_1) \leq 2 \cdot E_{\pi^k, \mathbb{P}} \sum_{h=1}^{H} \operatorname{clip}_{\mathbb{P}} \mathbb{E}^k_{h}(x, a_h).
\]

**Proof.** Following [Simchowitz and Jamieson, 2019], let us consider
\[
\hat{E}^k_h(x, a) := \operatorname{clip}_{\mathbb{P}} \mathbb{E}^k_h(x, a) = \mathbb{E}^k_h(x, a) \cdot \mathbb{1} \left[ \mathbb{E}^k_h(x, a) \geq \frac{\rho}{2H} \right] \geq 0 \quad \text{(B.5)}
\]

and
\[
\begin{align*}
\hat{V}^k_h(x) &:= \hat{Q}^k_h(x, \pi^k(x)), \\
\check{Q}^k_h(x, a) &:= r_h(x, a) + \hat{E}^k_h(x, a) + \mathbb{P} \hat{V}^k_{h+1}(x, a).
\end{align*}
\]

Notice that
\[
\begin{aligned}
V^k_h(x) - V^*_h(x) &= E_{\pi^k, \mathbb{P}} \sum_{t \geq h} E^k_t(x_t, a_t), \\
\hat{V}^k_h(x) - V^*_h(x) &= E_{\pi^k, \mathbb{P}} \sum_{t \geq h} \hat{E}^k_t(x_t, a_t) \geq 0,
\end{aligned} \quad \text{(B.6)}
\]

then we immediately see that
\[
\begin{aligned}
\hat{V}^k_h(x) - V^*_h(x) &\geq E_{\pi^k, \mathbb{P}} \sum_{t \geq h} \left( E^k_t(x_t, a_t) - \frac{\rho}{2H} \right) = V^k_h(x) - V^*_h(x) - \frac{H - h + 1}{H} \cdot \frac{\rho}{2} \\
&\geq V^k_h(x) - V^*_h(x) - \frac{\rho}{2}. \quad \text{(B.8)}
\end{aligned}
\]

Given a sequence of a random trajectory \( \{x_h, a_h\}_{h=1}^{H} \) induced by policy \( \pi^k \) and \( \mathbb{P} \), let \( F_h \) be the event such that
\[
F_h := \{ a_h \notin \pi^*_h(x_h), \forall t < h, a_t \in \pi^*_t(x_t) \}. 
\]
where \( \text{gap}_h(x_h, a_h) \geq \rho > 0 \) under \( F_h \) (since \( a_h \notin \pi^*_h(x_h) \)). Similarly we have that

\[
\tilde{V}^k_1(x_1) - V^*_1(x_1) \geq E_{\pi^k, P} \sum_{h=1}^{H} \mathbb{I} [F_h] \left( \tilde{V}^k_1(x_1) - V^*_1(x_1) \right) + E_{\pi^k, P} \sum_{h=1}^{H} \mathbb{I} [H_{k+1}] \left( \tilde{V}^k_1(x_1) - V^*_1(x_1) \right)
\]

(\text{use Lemma 2, and that gap}_h(x_h, a_h) \geq \rho \text{ under } F_h)

\[
= E_{\pi^k, P} \sum_{h=1}^{H} \mathbb{I} [F_h] \left( \frac{1}{2} \text{gap}_h(x_h, a_h) + Q^*_h(x_h, a_h) - V^*_h(x_h) \right)
\]

(note that \( Q^*_h(x_h, a_h) \geq 0 \))

\[
= \frac{1}{2} \left( V^*_1(x_1) - V^*_1(x_1) \right).
\]

The above inequality plus (B.7) (B.5) completes the proof.

\( \square \)

**Lemma 6.** If \( G_1, G_2 \) and \( G_3 \) hold, then

\[
V^*_1(x_1) - V^*_1(x_1) \leq \sum_{h=1}^{H} \left( \text{clip}_{\frac{8H^2}{Nk(x_h, a_h)^2}} + \frac{120(H^3 + S)H}{Nk(x_h, a_h)} + \frac{240H^6S^2l^2}{(Nk(x_h, a_h))^2} \right).
\]

**Proof.** We proceed the proof as follows:

\[
V^*_1(x_1) - V^*_1(x_1) \leq 2 \cdot E_{\pi^k, P} \sum_{h=1}^{H} \text{clip}_{\frac{8H^2}{Nk(x_h, a_h)^2}} [E^k_h(x_h, a_h)] \quad \text{(use Lemma 5)}
\]

\[
\leq 2 \cdot E_{\pi^k, P} \sum_{h=1}^{H} \text{clip}_{\frac{8H^2}{Nk(x_h, a_h)^2}} \left[ \sqrt{\frac{2H^2l}{Nk(x, a)}} + \frac{HS_l}{Nk(x, a)} \right] + E_{\pi^k, P} \sum_{t \geq h+1} \left( \frac{4e^2H^3l}{Nk(x_t, a_t)} + \frac{8e^2H^5S^2l^2}{(Nk(x_t, a_t))^2} \right) \quad \text{(use Lemma 3)}
\]
\begin{equation}
\leq 2 \cdot E_{\pi^k} \sum_{h=1}^{H} \left\{ \text{clip}_{\pi^T} \left[ \sqrt{\frac{2H^2 \ell}{N^k(x_h, a_h)}} + \frac{2HS_{\ell}}{N^k(x_h, a_h)} \right] + E_{\pi^k} \sum_{t \geq h+1} \left( \frac{8e^2H^3 \ell}{N^k(x_t, a_t)} + \frac{16e^2H^5S^2t^2}{(N^k(x_t, a_t))^2} \right) \right\} \quad \text{(use Lemma 11)}
\end{equation}

\begin{equation}
\leq 2 \cdot E_{\pi^k} \sum_{h=1}^{H} \left\{ \text{clip}_{\pi^T} \left[ \sqrt{\frac{8H^2 \ell}{N^k(x_h, a_h)}} + \frac{4HS_{\ell}}{N^k(x_h, a_h)} + \frac{16e^2H^4 \ell}{N^k(x_h, a_h)} + \frac{32e^2H^6S^2t^2}{(N^k(x_h, a_h))^2} \right] \right\} - 2H \cdot E_{\pi^k} \sum_{h=1}^{H} \left( \frac{8H^2 \ell}{N^k(x_h, a_h)} + \frac{120(H^3 + S)H_{\ell}}{N^k(x, a)} + \frac{240H^6S^2t^2}{(N^k(x, a))^2} \right).
\end{equation}

**Exploration Phase.** Recall the exploration bonus in Algorithm 1 is defined as

\begin{equation}
c^k(x, a) := \text{clip}_{\pi^T} \left[ \sqrt{\frac{2H^2 \ell}{N^k(x, a)}} + \frac{200H^3 \ell}{N^k(x, a)} + \frac{240H^6S^2t^2}{(N^k(x, a))^2} \right],
\end{equation}

and the exploration value function in Algorithm 1 is given by

\begin{align}
\{ V^k_h(x) = \max_a Q^k_h(x, a), \\
Q^k_h(x, a) = H \land \left( c^k(x, a) + P^k \nabla^k_{h+1}(x, a) \right) \}.
\end{align}

Let us also define the following population and empirical *bonus value functions* (for some policy \( \pi \)):

\begin{align}
\{ \bar{V}^k_h(x) = \bar{Q}^k_h(x, \pi(x)), \\
\bar{Q}^k_h(x, a) = H \land \left( c^k(x, a) + P^k \bar{\nabla}^k_{h+1}(x, a) \right) \}.
\end{align}

**Lemma 7** (Exploration value function maximizes empirical bonus value functions). For every \( \pi \) and every \( k, h, x, a \),

\begin{equation}
\bar{Q}^k_h(x, a) \leq \bar{Q}^k_h(x, a) \quad \text{and} \quad \bar{V}^k_h(x) \leq \bar{V}^k_h(x).
\end{equation}

**Proof.** Use induction and (B.10) (B.12).

**Lemma 8** (Planning error is upper bounded by population bonus value function). For every \( \pi^k \)

\begin{equation}
V^*_1(x_1) - V^\pi^k_1(x_1) \leq V^k_1(x_1). \quad \text{(B.13)}
\end{equation}

**Proof.** Let \( A_h \) be the \( \sigma \)-field generated by \( \{x_1, a_1, \ldots, x_h, a_h\} \) (induced by \( \pi^k \) and \( P \)). For simplicity, denote \( E_{\geq h}[\cdot] := E[\cdot | A_{h-1}] \), i.e., taking conditional expectation given a trajectory \( \{x_1, a_1, \ldots, x_{h-1}, a_{h-1}\} \). Then \( E_{\geq 1}[\cdot] \) is taking the full expectation. From (B.11) we obtain

\begin{align}
E_{\geq h} \left[ \bar{Q}^k \bar{\pi}_{h+1}(x_{h+1}) \right] &= E_{\geq h} \left[ H \land \left( c(x_h, a_h) + E_{\geq h+1} \left[ \bar{V}^k \bar{\pi}_{h+1}(x_{h+1}) \right] \right) \right] \\
&= E_{\geq h} \left[ H \land \left( c(x_h, a_h) + E_{\geq h+1} \left[ Q^k_{h+1}(x_{h+1}, a_{h+1}) \right] \right) \right] \\
&= E_{\geq h} \left[ H \land E_{\geq h+1} \left[ c(x_h, a_h) + Q^k_{h+1}(x_{h+1}, a_{h+1}) \right] \right]
\end{align}
we proceed by induction over $h$ which completes our proof.

we obtain that

$$\tilde{V}_1^{k,\pi}(x_1) = E_{\pi,1} \left[ Q_1^{k,\pi}(x_1, a_1) \right] \geq E_{\pi,1} \left[ H \wedge \sum_{h=1}^{H} c(x_h, a_h) \right] = E_{\pi,1} \left[ H \wedge \sum_{h=1}^{H} c(x_h, a_h) \right].$$

Finally, by Lemma 6 and that $V_1^*(x_1) - V_1^{\pi^k}(x_1) \leq H = E_{\pi,1} \left[ H \right]$, we have that

$$V_1^*(x_1) - V_1^{\pi^k}(x_1) \leq E_{\pi,1} \left[ H \wedge \sum_{h=1}^{H} c(x_h, a_h) \right] \leq \tilde{V}_1^{k,\pi}(x_1),$$

which completes our proof.

**Lemma 9 (Empirical vs. population bonus value functions).** If $G_2$ and $G_3$ hold, then for every $k$ and for every policy $\pi$, we have that

$$\frac{1}{e} \cdot \tilde{V}_1^{k,\pi}(x_1) \leq V_1^{k,\pi}(x_1) \leq e \cdot \tilde{V}_1^{k,\pi}(x_1).$$

**Proof.** For the second inequality, we only need to prove that for every $k$ and $\pi$,

$$\tilde{V}_h^{k,\pi}(x) \leq \left( 1 + \frac{1}{H} \right)^{H-h+1} \cdot \tilde{V}_h^{k,\pi}(x),$$

for every $h, x$.

We proceed by induction over $h$. For $H + 1$ the hypothesis holds trivially as $\tilde{V}_{H+1}^{k,\pi}(x) = 0 = \tilde{V}_{H+1}^{k,\pi}(x)$. Now suppose the hypothesis holds for $h + 1$, and let us consider $h$:

$$\tilde{V}_h^{k,\pi}(x) = Q_h^{k,\pi}(x, a) \text{ (set } a = \pi(x))$$

$$\leq c_h^k(x, a) + PV_{h+1}^{\pi}(x, a) \text{ (by (B.11))}$$

$$= c_h^k(x, a) + \tilde{P}_h^{k,\pi}V_{h+1}^{\pi}(x, a) + (P - \tilde{P}_h^{k,\pi})V_{h+1}^{\pi}(x, a)$$

$$\leq c_h^k(x, a) + \left( 1 + \frac{1}{H} \right) \tilde{P}_h^{k,\pi}V_{h+1}^{\pi}(x, a) + \frac{3H^2S}{N^{k+1}(x, a)} \text{ (by Lemma 4 and } \tilde{V}_{h+1}^{k,\pi} \leq H)$$

$$\leq \left( 1 + \frac{1}{H} \right) c_h^k(x, a) + \left( 1 + \frac{1}{H} \right) \tilde{P}_h^{k,\pi}V_{h+1}^{\pi}(x, a). \text{ (by (B.9))}$$

$$\leq \left( 1 + \frac{1}{H} \right) c_h^k(x, a) + \left( 1 + \frac{1}{H} \right)^{H-h+1} \tilde{P}_h^{k,\pi}V_{h+1}^{\pi}(x, a) \text{ (by induction hypothesis)}$$

$$\leq \left( 1 + \frac{1}{H} \right)^{H-h+1} \cdot \left( c_h^k(x, a) + \tilde{P}_h^{k,\pi}V_{h+1}^{\pi}(x, a) \right),$$

moreover from (B.11) we have that $\tilde{V}_h^{k,\pi}(x) \leq H$. In sum, we have

$$\tilde{V}_h^{k,\pi}(x) \leq \left( 1 + \frac{1}{H} \right)^{H-h+1} \cdot \left( c_h^k(x, a) + \tilde{P}_h^{k,\pi}V_{h+1}^{\pi}(x, a) \right)$$

$$= \left( 1 + \frac{1}{H} \right)^{H-h+1} \cdot \tilde{V}_{h+1}^{k,\pi}(x, a).$$

This completes our induction, and as a consequence proves the second inequality.

The first inequality is proved by repeating the above argument to show that for every $k$ and $\pi$

$$\tilde{V}_h^{k,\pi}(x) \leq \left( 1 + \frac{1}{H} \right)^{H-h+1} \cdot \tilde{V}_h^{k,\pi}(x), \text{ for every } h, x.$$
Lemma 10 (Exploration regret). If $G_2$, $G_3$ and $G_4$ hold, then

$$\sum_{k=1}^{K} V_1^k(x_1) \lesssim \frac{H^3 S A_t}{\rho} + H^4 S^2 A_t^2.$$ 

Proof. Recall $\tilde{\pi}^k$ is the exploration policy at the $k$-th episode, i.e., a greedy policy given by maximizing $Q_k^*(x, a)$. Recall $w_k^h(x, a) := P \{ (x_h, a_h) = (x, a) \mid \tilde{\pi}^k, P \}$ and $w^k(x, a) = \sum_h w_k^h(x, a)$. Let us consider the following “good sets”:

$$L^k := \{ (x, a) : \sum_{j < k} w^j(x, a) \geq H^3 S_t \}.$$  \hfill (B.14) 

Then we have

$$\sum_{k=1}^{K} \bar{V}_1^k(x_1) \leq e \sum_{k=1}^{K} \bar{V}_1^{k, \tilde{\pi}^k}(x_1) \quad \text{(use Lemma 9)}$$

$$\leq e \cdot \sum_{k=1}^{K} \sum_{x, a \in L^k} \sum_{h=1}^{H} w_k^h(x, a) e^k(x, a) + e \cdot \sum_{k=1}^{K} \sum_{x, a \notin L^k} \sum_{h=1}^{H} w_k^h(x, a) H$$

$$= e \cdot \sum_{k=1}^{K} \sum_{x, a \in L^k} w^k(x, a) e^k(x, a) + e \cdot \sum_{k=1}^{K} \sum_{x, a \notin L^k} w^k(x, a) H$$

$$\leq e \cdot \sum_{k=1}^{K} \sum_{x, a \in L^k} w^k(x, a) \left( \text{clip}_{\rho} \left[ \sqrt{\frac{8H^2 t}{N^k(x, a)}} + \frac{120(H + S)H^3 t}{N^k(x, a)} + \frac{240H^6 S^2 t^2}{(N^k(x, a))^2} \right] \right)$$

$$+ e \cdot \sum_{k=1}^{K} \sum_{x, a \notin L^k} w^k(x, a) H \quad \text{(use (B.9)).}$$

We then bound each terms using integration tricks and that $G_4$ holds. The fourth term is bounded by

$$e \sum_{k=1}^{K} \sum_{x, a \notin L^k} w^k(x, a) H \lesssim SA \cdot (H + H^3 S_t) \cdot H \lesssim H^4 S^2 A_t.$$ 

The third term is bounded by

$$e \sum_{k=1}^{K} \sum_{x, a \in L^k} w^k(x, a) \frac{240H^6 S^2 t^2}{(N^k(x, a))^2}$$

$$\lesssim H^6 S^2 t^2 \sum_{k=1}^{K} \sum_{x, a} \frac{w^k(x, a)}{\left( \sum_{j < k} w^j(x, a) - 2H t \right)^2} \cdot 1 \left[ \sum_{j < k} w^j(x, a) \geq H^3 S_t \right] \quad \text{(use $G_4$ and (B.14))}$$

$$\lesssim H^6 S^2 t^2 \cdot SA \cdot \frac{1}{H^3 S_t - 2H t} \lesssim H^3 S^2 A_t. \quad \text{(integration trick)}$$

The second term is bounded by

$$e \sum_{k=1}^{K} \sum_{x, a \in L^k} w^k(x, a) \frac{120(H + S)H^3 t}{N^k(x, a)}$$

$$\lesssim (H + S)H^3 t \sum_{k=1}^{K} \sum_{x, a} \frac{w^k(x, a)}{\sum_{j < k} w^j(x, a) - 2H t} \cdot 1 \left[ \sum_{j < k} w^j(x, a) \geq H^3 S_t \right] \quad \text{(use $G_4$ and (B.14))}$$

$$\lesssim (H + S)H^3 t \cdot SA \cdot \log(HK) \lesssim (H + S)H^3 S A_t^2. \quad \text{(integration trick)}$$
The first term is bounded by
\[ e \sum_{k=1}^{K} \sum_{x,a \in L^k} w^k(x, a) \text{clip}_{\frac{\rho}{\sqrt{n}}} \left[ \frac{8H^2t}{N^k(x, a)} \right] \]
\[ = e \sum_{k=1}^{K} \sum_{x,a} w^k(x, a) \cdot \sqrt{\frac{8H^2t}{N^k(x, a)}} \cdot 1 \left[ \sum_{j<k} w^j(x, a) \geq H^3S_t \right] \cdot 1 \left[ N^k(x, a) \leq \frac{32H^4t}{\rho^2} \right] \]
\[ \lesssim H^{1/2} \cdot \sum_{k=1}^{K} \sum_{x,a} \frac{w^k(x, a)}{\sqrt{\sum_{j<k} w^j(x, a) - 2H_t}} \cdot 1 \left[ \sum_{j<k} w^j(x, a) \leq \frac{64H^4t}{\rho^2} + 2H_t \right] \] (use G4)
\[ \lesssim H^{1/2} \cdot S_A \cdot \sqrt{\frac{H^4t}{\rho^2} + H_t} \lesssim \frac{H^3S_A t}{\rho}. \] (integration trick)

Summing up everything yields that
\[ \sum_{k=1}^{K} V^k_1(x_1) \lesssim \frac{H^3S_A t}{\rho} + (H + S)H^3S_A t^2 + H^4S^2 A_t + H^4S^2 A_t \lesssim \frac{H^3S_A t}{\rho} + H^4S^2 A_t. \]

**Theorem 4 (Restatement of Theorem 1).** With probability at least \( 1 - \delta \), the planning error is bounded by
\[ V^*_1(x_1) - V^*_1(x_1) \lesssim \frac{H^3S_A t}{\rho K} \cdot \log \frac{HSAK K}{\delta} + \frac{H^4S^2 A t}{K} \cdot \log^2 \frac{HSAK K}{\delta}. \]

**Proof.** First by Lemma 1, we have that with probability at least \( 1 - \delta \), \( G_1, G_2, G_3 \) and \( G_4 \) hold. Next we have the following:
\[ V^*_1(x_1) - V^*_1(x_1) = \frac{1}{K} \sum_{k=1}^{K} \left( V^*_1(x_1) - V^*_1(x_1) \right) \] (by Algorithm 2)
\[ \leq \frac{1}{K} \sum_{k=1}^{K} \tilde{V}^k_1(x_1) \] (by Lemma 8)
\[ \leq \frac{e}{K} \sum_{k=1}^{K} \tilde{V}^k_1(x_1) \] (by Lemma 9)
\[ \leq \frac{e}{K} \sum_{k=1}^{K} V^k_1(x_1) \] (by Lemma 7)
\[ \lesssim \frac{H^3S_A t}{\rho K} + \frac{H^4S^2 A t}{K}. \] (by Lemma 10)

**Lemma 11 (Properties of the clip operator).** Let \( \rho, \rho', a > 0 \), then
- \( a \cdot \text{clip}_\rho [A] = \text{clip}_{a \rho} [a \cdot A] \);
- Let \( \rho \geq \rho' \) and \( A \leq A' \), then \( A - \rho \leq \text{clip}_\rho [A] \leq \text{clip}_{\rho'} [A'] \leq A' \);
- \( \text{clip}_\rho [A + B] \leq \text{clip}_\rho [A] + 2B \) for \( B \geq 0 \);
- \( \text{clip}_\rho [A_1 + \cdots + A_m] \leq 2 \left\{ \text{clip}_{\rho m} [A_1] + \cdots + \text{clip}_{\rho m} [A_m] \right\} \).
Proof. The first three claims are easy to see by the definition of the clip operator. The last claim is from [Simchowitz and Jamieson, 2019], for which we provided a proof here for completeness. Without loss of generality, assume that \( A_1 + \cdots + A_m \geq \rho \). Let us divide \( \{ A_i \}_{i=1}^m \) into two groups by examining whether or not \( A_i \geq \frac{\rho}{2m} \). Without loss of generality, assume that

\[
A_1, \ldots, A_k \geq \frac{\rho}{2m}, \quad A_{k+1}, \ldots, A_m < \frac{\rho}{2m}.
\]

The latter implies that \( A_{k+1} + \cdots + A_m < \frac{\rho}{2m} \cdot (m-k) \leq \frac{\rho}{2} \), then by \( A_1 + \cdots + A_m \geq \rho \) we obtain that

\[
A_1 + \cdots + A_k \geq \frac{\rho}{2} > A_{k+1} + \cdots + A_k,
\]

In sum, we have that

\[
\text{RHS} = 2 \left\{ \text{clip}_{ \frac{\rho}{2m} }[A_1] + \cdots + \text{clip}_{ \frac{\rho}{2m} }[A_m] \right\}
= 2 \{ A_1 + \cdots + A_k \}
\geq A_1 + \cdots + A_k + A_{k+1} + \cdots + A_m
= \text{LHS}.
\]

C Proof of the Lower Bound (Theorem 2)

Lemma 12 ([Mannor and Tsitsiklis, 2004], Theorem 1). There exist positive constants \( c_1, c_2, \epsilon_0, \) and \( \delta_0 \), such that for every \( n \geq 2, \epsilon \in (0, \epsilon_0), \delta \in (0, \delta_0) \), and for every \( (\epsilon, \delta) \)-correct policy, there exists some Bernoulli multi-armed bandit model with \( n \) arms, such that the policy needs at least \( T \) number of trials where

\[
E[T] \geq c_1 \frac{n}{\epsilon^2} \log \frac{c_2}{\delta}.
\]

In particular, the bandit model can be chosen such that one arm pays \( 1 \) w.p. \( 1/2 + \epsilon/2 \), one arm pays \( 1 \) w.p. \( 1/2 + \epsilon \), and the rest arms pay \( 1 \) w.p. \( 1/2 \).

Theorem 5 (Restatement of Theorem 2). Fix \( S \geq 5, A \geq 2, H \geq 2 + \log A \) \( S \). There exist positive constants \( c_1, c_2, \rho_0, \delta_0 \), such that for every \( \rho \in (0, \rho_0), \epsilon \in (0, \rho), \delta \in (0, \delta_0) \), and for every \( (\epsilon, \delta) \)-correct policy, there exists some MDP instance with gap \( \rho \), such that

\[
E[K] \geq c_1 \frac{H^2 S A}{\epsilon \rho} \log \frac{c_2}{\delta}.
\]

Proof. The hard example is constructed as in Figure 1. We prove such example witness our lower bound as follows.

Let us call all left orange states the bandit states. Let \( N_b \) be the number of visits to the bandit states. Then from the construction, we have that

\[
E[N_b] = E[K] \cdot \frac{\epsilon}{\rho}.
\]

We may without loss of generality image the bandit states as an entity, and at this entity, there are \( SA \) arms: one arm pays reward \( H \) w.p. \( \frac{1}{2} + \frac{\rho}{2H} \), one arm pays reward \( H \) w.p. \( \frac{1}{2} + \frac{\delta}{2H} \), and the rest arms pay reward \( H \) w.p. \( \frac{1}{2} \). Next, for any \( (\epsilon, \delta) \)-correct policy on the MDP, it induces a policy that is \( (\rho, \delta) \)-correct policy on the above bandit model. By a linear scaling of the reward from \( H \) to \( 1 \), it is equivalent to a policy that is \( (\frac{\rho}{H}, \delta) \)-correct in a standard hard-to-learn bandit model with \( SA \)-arms.

By Lemma 12, we must have that

\[
E[N_b] \geq c_1 \frac{H^2 S A}{\epsilon^2} \log \frac{c_2}{\delta},
\]

which implies that

\[
E[K] \geq c_1 \frac{H^2 S A}{\epsilon \rho} \log \frac{c_2}{\delta}.
\]

22
We next verify that the MDP has $\rho$ gap. Notice that except in the left orange states, all actions have the same consequence, therefore the gap is zero if the agent is not at a left orange state. When we are at the left orange state at the Type III model, there is no gap. When we are at the left orange state at the Type II model, the gap is $\left(\frac{1}{2} + \frac{\rho}{2T}\right) \cdot H - \frac{1}{T} \cdot H = \frac{\rho}{2}$. By a rescaling of the number of states, length of the horizon, MDP gap, and the absolute constants, the promised lower bound is established.

D Gap-Dependent Unsupervised Exploration for Multi-Armed Bandit and MDP with a Sampling Simulator

Multi-Armed Bandit. The following result is from Theorem 33.1 in [Lattimore and Szepesvári, 2020]. For completeness, we restate the result and the proof here.

Lemma 13 (Uniform Exploration). Consider a Bernoulli bandit with $A$ arms and a minimum non-zero expected reward gap $\rho > 0$. Consider the following policy: in the exploration phase an agent uniformly pulls each arm and collects rewards for $K = T/A$ rounds, and in the planning phase the agent chooses the arm with the highest empirical rewards. Then

1. the output is $(\epsilon, \delta)$-correct for $\epsilon < \rho$ if $T \approx \frac{A}{\rho^2} \log \frac{1}{\delta}$;
2. the expected error is at most $E_\pi[V^* - V^\pi] \lesssim A \exp(-\rho^2T/A) \propto \exp(-T)$.

Proof. Let us denote the expected reward of an arm $a$ as $r_a$, and denote the empirical reward of an arm $a$ as $\hat{R}_a = (R_1^a + \cdots + R_K^a)/K$. Suppose $a$ is the best arm, and $a'$ is the arm with highest empirical reward, then

$$P\{a' \neq a\} = P\left\{\hat{R}_{a'} > \hat{R}_a\right\}$$

$$= P\left\{\left(\hat{R}_{a'} - r_{a'}\right) - \left(\hat{R}_a - r_a\right) > r_a - r_{a'}\right\}$$

$$\leq P\left\{\left(\hat{R}_{a'} - r_{a'}\right) - \left(\hat{R}_a - r_a\right) > \rho\right\}$$

$$\lesssim A \exp(-\rho^2 K) \approx A \exp(-\rho^2 T/A).$$

The proof is completed by noting that $0 \leq r_a \leq 1$.

MDP with a Sampling Simulator. Now we consider gap-TAE for MDP with a sampling simulator. The algorithm is simple: in the exploration phase we sample $N$ data at each pair $(x, a)$ and compute an empirical transition probability $\hat{P}$; in the planning phase we compute the optimal value function over $P$, and output the induced greedy policy $\pi$. Mathematically speaking, the policy $\pi$ is given by

$$\hat{Q}_h(x, a) = r_h(x, a) + \hat{P}\hat{V}_{h+1}^\pi(x, a),$$

$$\hat{V}_h^\pi(x) = \max_a \hat{Q}_h(x, a),$$

$$\pi_h(x) = \arg\max_a \hat{Q}_h(x, a).$$

Next we justify the sample complexity of this algorithm.

Lemma 14 (Good events). Consider the following two events

$$G := \left\{\forall x, a, h, \left|\left(\hat{P} - P\right) V_{h+1}^\pi(x, a)\right| < \frac{\rho}{2H}\right\}, \quad E := \left\{\forall x, h, V_h^\pi(x) - V_h^\pi(x) = 0\right\},$$

then $G$ implies $E$.

Proof. Assume $G$ holds, and define $E_h := \{\forall x, V_h^\pi(x) - V_h^\pi(x) = 0\}$. We prove $E$ holds by induction over $E_h$ for $h \in \{H + 1, H, \ldots, 1\}$. First $E_{H+1}$ holds by definition. Next suppose that $E_{h+1}, \ldots, E_{H+1}$ holds, and consider $E_h$. Since $G$ holds, we have that for every $x$,

$$V_h^\pi(x) - \hat{V}_h^\pi(x) = E_x, P \sum_{t \geq h} (\hat{P} - P) V_{t+1}^\pi(x, a_t) < (H + 1 - h) \cdot \frac{\rho}{2H} < \frac{\rho}{2}.$$
Since $E_t$ holds for $t \geq h+1$, we have that for every $x$,

$$
\hat{V}_h^\pi(x) - V_h^\pi(x) = E_{\pi,\hat{P}} \sum_{t \geq h} (\hat{P} - P)V_{t+1}^\pi(x_t, a_t)
$$

$$
= E_{\pi,\hat{P}} \sum_{t \geq h} (\hat{P} - P)V_{t+1}^\pi(x_t, a_t) \quad (\text{since } E_t \text{ holds for } t \geq h+1)
$$

$$
< (H+1-h) \cdot \frac{\rho^2}{2H} < \frac{\rho^2}{2H^2} \quad (\text{since } G \text{ holds})
$$

The above two inequalities imply that for every $x$,

$$
V_h^\pi(x) - V_0^\pi(x) = V_h^\pi(x) - \hat{V}_h^\pi(x) + \hat{V}_h^\pi(x) - \hat{V}_h^\pi(x) - V_h^\pi(x)
$$

$$
\leq V_h^\pi(x) - \hat{V}_h^\pi(x) + \hat{V}_h^\pi(x) - V_h^\pi(x) < \rho,
$$

which further yields that for every $x$ and $a = \pi_h(x)$,

$$
V_h^\pi(x) - Q_h^\pi(x, a) \leq V_h^\pi(x) - V_h^\pi(x) < \rho,
$$

which forces $a \in \pi_h(x)$ since otherwise $V_h^\pi(x) - Q_h^\pi(x, a) \geq \rho$. Therefore, we have that for every $x$,

$$
V_h^\pi(x) - \hat{V}_h^\pi(x) = Q_h^\pi(x, a) - Q_h^\pi(x, a) = P\left(V_{h+1}^\pi - V_{h+1}^\pi\right)(x, a) = 0,
$$

where the last equality holds since $E_{h+1}$ holds, and by this we show that $E_h$ holds, which completes our induction. \(\square\)

Lemma 15 (Probability of the good event). $\mathbb{P}\{G^c\} < 2HSA \cdot \exp \left( -\frac{\rho^2N}{2H^2} \right)$.

Proof. This is by Hoeffding’s inequality and a union bound over $x, a, h$. \(\square\)

Theorem 6 (Restatement of Theorem 3). Suppose there is a sampling simulator for the MDP considered in the gap-TAE problem. Consider exploration with the uniformly sampling strategy, and planning with the dynamic programming method with the obtained empirical probability. If $T$ samples are drawn, where

$$
T \geq \frac{2H^4SA}{\rho^2} \cdot \log \frac{2HSA}{\delta},
$$

then with probability at least $1 - \delta$, the obtained policy is optimal ($\epsilon = 0$).

Proof. Note that $T \geq \frac{2H^4SA}{\rho^2} \cdot \log \frac{2HSA}{\delta}$ implies that $N = T/(SA) \geq \frac{2H^4}{\rho^2} \cdot \log \frac{2HSA}{\delta}$, then by Lemma 15, we have that

$$
\mathbb{P}\{G\} \geq 1 - \delta,
$$

then according to Lemma 14, the policy is optimal with probability at least $1 - \delta$. \(\square\)
