Unsupervised Person Re-identification with Stochastic Training Strategy

Tianyang Liu, Yutian Lin and Bo Du

Abstract—Unsupervised person re-identification (re-ID) has attracted increasing research interests because of its scalability and possibility for real-world applications. State-of-the-art unsupervised re-ID methods usually follow a clustering-based strategy, which generates pseudo labels by clustering and maintains a memory to store instance features and represent the centroid of the clusters for contrastive learning. This approach suffers two problems. First, the centroid generated by unsupervised learning may not be a perfect prototype. Forcing images to get closer to the centroid emphasizes the result of clustering, which could accumulate clustering errors during iterations. Second, previous methods utilize features obtained at different training iterations to represent one centroid, which is not consistent with the current training sample, since the features are not directly comparable.

To this end, we propose an unsupervised re-ID approach with a stochastic learning strategy. Specifically, we adopt a stochastic updated memory, where a random instance from a cluster is used to update the cluster-level memory for contrastive learning. In this way, the relationship between randomly selected pair of images are learned to avoid the training bias caused by unreliable pseudo labels. The stochastic memory is also always up-to-date for classifying to keep the consistency. Besides, to relieve the issue of camera variance, a unified distance matrix is proposed during clustering, where the distance bias from different camera domain is reduced and the variances of identities is emphasized. Extensive experiments show that our proposed method is not only superior to state-of-the-art unsupervised re-ID approaches, but also performs favorably compared with other competing unsupervised domain adaptation methods (UDA) and semi-supervised re-ID methods. The code will be available at https://github.com/lithium770/Unsupervised-Person-Re-identification-with-Stochastic-Training-Strategy.

Index Terms—Person Re-identification, Unsupervised Learning, Contrastive Learning

I. INTRODUCTION

PERSON re-identification (re-ID) aims to match identities across disjoint cameras. Due to the need for public safety and intelligent surveillance, it has drawn wide attention in the computer vision community [1], [2], [3]. With the advancement of deep learning, fully-supervised person re-ID has gained great progress these years [4], [5], [6], [7], [8], [9], [10]. However, these methods rely on a large scale of annotated data, which is not realistic in practical applications. To overcome the scalability issue, recent studies focus on unsupervised settings to learn a re-ID model without annotations. The kind of unsupervised methods can be further divided into unsupervised domain adaptation (UDA) [11], [12], [13], [14], [15], [16], [17] and fully-unsupervised [18], [19], [20]. This paper addresses fully unsupervised person re-ID, which does not require labeled source datasets and is thus more challenging.

The state-of-the-art unsupervised methods on person re-ID usually follow a clustering-based strategy, which alternates between generating pseudo labels by clustering the unlabeled training data and training the network with the pseudo labels [18], [21]. To conduct contrastive learning [22], [23], [24], a momentum-updated memory is usually adopted. As in a common pipeline [21], an instance-level memory is usually adopted, where the average instance features from each clusters is used to represent the centroid of the cluster and is further used for contrastive learning. However, this strategy may cause three problems. First, as shown in Fig. 1 (a), training with cluster centroids letting all instances get closer to their centroid, making the clustering result more stable, which will provide less supervision signal for training in the next iteration and accumulate errors in the pseudo labels during iterations. Besides, contrastive learning benefits from observing sufficient negative samples [25]. Replace a large number of negatives with only the cluster centroids would damage the diversity of the contrastive pairs. Second, as shown in Fig. 1 (b), the instance memories are saved during training where the features are not consistent with the current training sample, making the relationship hard to be measured.

To address the above problems, in this paper, we propose an unsupervised person re-identification method with a stochastic learning strategy. The main idea is, instead of using the
cluster centroid as the positive and negative samples, all the instances are taken as candidate pools to provide positive and negative samples randomly. Specifically, our framework adopts a stochastic updated memory for contrastive learning. During training, a random instance is used to update the corresponding cluster-level memory to represent the class. Then for each training data, the feature embedding is learned to be close/away to the randomly selected instance, instead of the centroid of the class. On the one hand, without converging toward a definite target, the accumulated errors caused by noisy pseudo-labels is eliminated, and the large amount of negatives introduce diversity into the model learning. On the other hand, the online stochastically updated memory makes a consistent feature embedding to learn the relation with the current training sample.

As a minor contribution, we improve the procedure of clustering to generate more reliable pseudo labels. Since the style of images is various across different cameras, we propose a unified distance matrix to relieve the camera variance. Specifically, the mean value of target instances’ cosine similarities is calculated for each intra-camera and inter-camera case, which implicitly reflects the distance caused by camera variances. At each epoch before clustering, we subtract the corresponding value from the similarities of instance pairs according to their camera labels and then softmax the distance vector of each instance. In this way, the camera variance is reduced and images of the same identity cross cameras will be more likely to be clustered. Moreover, we adopt a temporal ensembling based embedding for clustering. Instead of using the feature extracted from the current model, the embedding is further assembled with past temporally information. Specifically, an instance-level memory is adopted during training to save feature embeddings with history information, leading to more robust features.

Our contribution can be summarized in three-fold:

1. We explore the elements affecting contrastive learning for unsupervised person re-identification, e.g. the contrast target, and the consistency between the contrasting samples. A stochastic learning strategy is proposed to learn the relationship between two randomly selected samples and use the up-to-date features to keep the consistency. The effectiveness of the proposed method is quantitatively analyzed.

2. Camera and temporal information is adopted for more precise clustering. We emphasize the importance of camera variances in unsupervised re-ID methods, and propose a unified distance matrix to highlight the identity variance while reducing the camera variance. Besides, temporal ensembling is also adopted to build more robust features for clustering.

3. Extensive experiments are conducted on three common large-scale datasets. Our method significantly outperforms the state-of-the-art unsupervised re-ID approaches and also beats some unsupervised domain adaptation methods for re-ID.

II. RELATED WORK

Fully unsupervised person re-ID. Existing fully unsupervised person re-ID methods usually explore pseudo labels for learning [18], [19], [20], [26]. In BUC [18], a bottom-up clustering method is proposed to gradually obtain more reasonable clusters for network training. In SSL [19], the K-nearest neighbours for each training sample are explored to assign soft pseudo labels for training. HCT [20] uses hierarchical clustering to generate pseudo labels and sample a part of them for hard-batch triplet loss. These clustering-based methods usually work in a camera-agnostic way, which may result in noisy pseudo labels caused by camera variances. To overcome it, DAL [27] and UGA [28] divide the training task into intra-camera and inter-camera stage. Intra-camera labels have less noise, and knowledge from intra-camera labels can help association across cameras. However, utilizing camera labels to generate more precise pseudo labels has been undervalued.

Recently, combination with contrastive loss and momentum-updated memory has gained great attention [21], [26]. SPCL [21] is an UDA-based method that can work in both unsupervised domain adaptation and fully unsupervised setting. It adopt an instance-level memory for instance features and contrastive loss. In CAP [26], camera variance is emphasized, where a proxy-level memory is constructed by considering the camera label. This method works well especially on the dataset with multiple cameras. Comparing with above methods, our work follows the same clustering based pipeline. However, we focus more on the contrastive learning strategy, where a stochastic learning strategy is adopted to avoid the accumulation of clustering error, ensure the diversity of negative samples and keep the comparison samples consistent.

Unsupervised domain adaptation (UDA) person re-ID. UDA-based methods require some labeled source domain datasets and aim to train a model that generalizes well on the unlabeled target domain. They can be divided into two categories: domain translation-based methods [11], [12], [13] and pseudo-label-based methods [14], [29], [30], [21], [17]. The former focuses on transferring knowledge from labeled source domain to unlabeled target domain via performing image-to-image translations. While these methods usually adopt translated instances for training and leave the target data unexploited. The pseudo-label-based methods were found more effective to capture the target distributions. These methods using a unified framework to learn from labeled source datasets and unlabeled target datasets, which repeatedly generate pseudo labels and train the model with pseudo labels. The pseudo labels can be generated by clustering instance features or comparing with exemplar features. The core of these methods is to ensure the reliability of pseudo labels. Among them, SSG [14] exploits local features to generate multi-scale pseudo labels. MMT [29] proposes to improve the robustness of pseudo label via mutual learning. ECN [30] combines exemplar-invariance, camera-invariance and neighbor-invariance in the target domain. SPCL [21] designs cluster reliability criterion to measure the independence and compactness of clusters.

Camera variances of person re-ID. Person images taken by different cameras have various poses, illumination, resolution, etc. In other words, they subject to different distributions. Different camera labels can cause severe variances between two instances, even they belong to the same identity. Camera variances is an important factor in person re-
ID tasks, especially for UDA-based or fully unsupervised setting, in which the pseudo labels will be influenced by camera variances. There are some methods that take camera variances into consideration: CBN [31] aligns the data in feature space. Camera-aware neighbor invariance learning [32] divides the neighbor search procedure into the intra-camera condition and inter-camera condition. In [33], [30] camera labels is adopted to generate new instances with GAN-based techniques. Although various attempts have been made, how to alleviate the influence for pseudo labels under the unsupervised setting is still under-explored. Unlike previous methods, our work aligns the data for each intra-camera and inter-camera condition when computing similarities, through which we can gain more precise pseudo labels.

**Contrastive learning.** As a dictionary look-up task, contrastive learning [22], [23], [24] aims to discriminate each instance via treating them as distinct classes. More specifically, an instance-level contrastive loss is adopted to make the feature of an instance close to itself (or augmented feature), and pushed away from other instance features. Although the instance-level contrastive loss can generalize well to downstream tasks, it does not perform well when applied to person re-ID directly. Considering the need to handle intra-class affinities, SPCL [21] adopts contrastive loss for person re-ID and gains impressive results.

### III. Clustering-based Re-ID Baseline

In the context of fully unsupervised person re-ID, we are given a dataset with \( N \) person images without any annotations, where \( X = \{x_i\}_{i=1}^{N} \). The goal is to train a model that can discriminate identities and generalize well. Our work follows a widely applied clustering-based re-ID pipeline, which iterates between network training with an instance-level memory (an external memory bank) for contrastive learning and clustering to generate pseudo labels. The encoder is initialized by an ImageNet pre-trained model. The encoded features of all the instances via this model are used to construct the instance-level memory. After the initialization, the framework alternates between two steps:

1. **Clustering.** At the beginning of each epoch, features in the instance-level memory are adopted to compute the distance (cosine similarities) matrix for clustering. Clustering algorithms such as K-means [34], DBSCAN [35] are applied to generate clusters. To generate more accurate pseudo labels, some unreliable images are regarded as outliers that not belonging any cluster. Then, instances are assigned with pseudo labels according to the clustering result, while outliers are discarded. Through this step, the unlabeled dataset with pseudo labels are generated. The dataset is denoted as \( \{x_i, y_i\}_{i=1}^{N} \), where \( y_i \in \{1, \ldots, Y\} \). \( Y \) denotes the number of clusters and is dynamically changed during iterations.

2. **Network training.** For each batch, the CNN encoder \( f_\theta \) is optimized with pseudo labeled dataset and a contrastive loss:

\[
\mathcal{L} = - \sum_{i=1}^{N} \log \frac{\exp \left( \langle f_\theta(x_i), c[y_i]\rangle / \tau \right)}{\sum_{j=1}^{Y} \exp \left( \langle f_\theta(x_i), c[j]\rangle / \tau \right)},
\]

where \( c[j] \) is the cluster centroid corresponding to pseudo label \( j \), which is computed as the mean vector of memory features \( w \) that belong to this cluster. \( w \in \mathbb{R}^{N \times d} \) stores the feature of each instances. \( \tau \) is a temperature factor, and \( \langle \cdot, \cdot \rangle \) indicates the inner product of two feature vectors to measure their similarity. The contrastive loss makes an instance close to the centroid of its cluster, and pushed away from other clusters.
number, the beginning of each iteration, we construct a memory bank for each cluster. The features of the stochastic memory are used as the classifier for contrastive loss. At the beginning of each iteration, we construct a memory bank $M \in \mathbb{R}^{Y \times d}$ to represent each cluster, where $Y$ is the cluster number, $d$ is the feature dimension, and $m_i$ denotes the feature of the $i$-th class.

After the network forward, the memory is updated with the encoded features:

$$w_i = \mu \cdot w_i + (1 - \mu) f_\theta(x_i), \quad (2)$$

where $i$ means the instance index of $x$ in the memory, and $\mu$ is a momentum factor.

### IV. Method

In this section, we introduce our method in detail. Following the pipeline discussed in Section III, our framework contains two procedures, i.e., network training with pseudo labels and clustering. In this paper, we re-think the elements that affect contrastive learning for unsupervised re-ID and perform network training with a stochastic learning strategy. As for clustering, two efforts are made to boost its performance: (1) Temporal ensembling is adopted to improve the quality of feature embeddings for clustering; (2) A unified distance matrix is proposed to reduce the camera variance while emphasize the identity variance. The overview of our framework is illustrated in Figure 2.

#### A. Stochastic Learning Strategy

As shown in Fig. 3 (a), in the baseline approach, during training, the average feature of each cluster is used as positive and negatives for contrastive loss. However, the pseudo label generated by clustering could be noisy, the negative samples are monotonous and the mean memory features are inconsistent with the current training sample. To alleviate these defects, We propose a stochastic learning strategy. As shown in Fig. 3 (b), for each training sample, we randomly select an image from each cluster as the positive and negatives. In this way, the effect of clustering error is reduced, more negative samples are observed by the network for more robust training, and the features can be updated in time.

Specifically, we adopt a stochastically-updated memory, which is updated with random instance features for each cluster along with network training. The features of the stochastic memory are used as the classifier for contrastive loss. At the beginning of each iteration, we construct a memory bank $M \in \mathbb{R}^{Y \times d}$ to represent each cluster, where $Y$ is the cluster number, $d$ is the feature dimension, and $m_i$ denotes the feature of the $i$-th class.

#### Initialization

To construct the positive and negative samples for each training sample, the stochastically-updated memory $M \in \mathbb{R}^{Y \times d}$ is maintained to represent each cluster. With pseudo label $\{x_i, y_i\}_{i=1}^N$, where $y_i \in \{1, ..., Y\}$, the stochastic memory is initialized with the feature of a random picked instance that belongs to corresponding cluster.

#### Updating

For each $P \times K$ batch, we sample $P$ identities and $K$ instances for each person identity. We adopt the sampler in [21], which guarantees that images for each identity are taken by at least two different cameras.

During training, a random instance $x_i$ is selected for the cluster $y_i$. The stochastic memory is updated with encoded feature extracted by the current network:

$$m_{y_i} = m_{y_i} + (1 - \mu_s) f_\theta(x_i), \quad (3)$$

where $\mu_s$ is a momentum factor.

#### Contrastive loss

The formation of the contrastive loss is the same as Equation 1:

$$\mathcal{L} = - \sum_{i=1}^N \log \frac{\exp((f_\theta(x_i), m_{y_i})/\tau)}{\sum_{j=1}^N \exp((f_\theta(x_i), m_j)/\tau)}, \quad (4)$$

Through initializing and updating, a stochastic memory is maintained that represents each cluster with a randomly selected image. By adopting the stochastic memory, the positive and negative samples are expressed by diverse random instances and are changed along with network training. With the contrastive loss, for each training sample, the relationship between the randomly built positive and negative pairs is learned.

#### B. Temporal Ensembling based Camera-aware Clustering

Temporal ensembling based feature embedding. As the training targets are obtained by clustering, during training, some positive and negative samples can be expected to be noisy. Then the noise for the final network and its extracted features is inevitable. To build more robust feature for clustering, temporal ensembling [36] is adopted to aggregate the features of multiple previous networks into an ensemble feature embedding.

To retain temporal features for each embedding, we maintain an instance-level memory to represent instance features. Although stochastically-updated memory performs better as a classifier, it loses instance history information among epochs because the cluster changes every epoch. We combine two-level memories. Instance-level memory maintains an exponential moving average (EMA) feature for each of the training samples. During training, the EMA features are updated with up-to-date features. Consequently, the EMA feature of each instance is formed by an ensemble of the feature extracted from the model’s current version and those earlier versions. This ensembling improves the quality of the features, and the features will be further used to generate pseudo labels and re-initialize the stochastic memory at the beginning of each iteration.

We store the temporal features $V \in \mathbb{R}^{N \times d}$, where $v_i$ is the $i$-th column of $V$ indicating the feature of $i$-th instance. The instance-level memory is initialized only once during the

![Fig. 3: The positive and negative pairs for contrastive learning. (a) depicts the baseline method that adopts mean features of the clusters as the classifier. (b) depicts the stochastic learning strategy that the contrastive pairs are randomly selected among the cluster pools.](image-url)
training stage by the ImageNet [37] pre-trained model. At the beginning of each epoch, features in instance memory will be used to compute the distance matrix, which will be clustered to generate pseudo labels.

For each training instance $x_i$, the temporal ensembling based feature is updated with the newly encoded feature $f_{\theta}(x)$:

$$v_i = \mu_t \cdot v_i + (1 - \mu_t)f_{\theta}(x),$$  \hspace{1cm} (5)

where $\mu_t$ is a momentum factor.

Because outliers are discarded, their corresponding features won’t be updated during this epoch. At the end of epoch, we update outlier features by encoder to retain the consistence of the temporal features.

**Unified distance matrix for camera aware clustering.** At each iteration, we compute the distance matrix with temporal ensembling based features, then apply the clustering algorithm to group target instances into clusters and un-clustered instances. Since images across different cameras are subject to different distribution, for some sample pairs, the inter-camera variance can be more severe than the inter-identity variance. Instances may be assigned to the wrong clusters because of camera variances, which will do harm to the model training. When computing the distance matrix and generating pseudo labels, it is essential to take camera variances into consideration.

In this paper, we propose a unified distance matrix to conduct camera-aware clustering. We denote the corresponding camera ID of each training sample as $\{c_i\}_{i=1}^N$. To efficiently alleviate the influence of the camera variance, we set a camera domain offset matrix $D^{\text{cam}} \in N_{\text{cam}} \times N_{\text{cam}}$ reflects the image differences between different camera domains (or in a domain), where $N_{\text{cam}}$ denotes the number of cameras. At each iteration, the matrix $D^{\text{cam}}$ is computed by the mean similarity of instance pairs belong to the corresponding camera domain. Then a unified distance $\tilde{D}$ is computed by the original similarity matrix $D \in N \times N$ and the offset matrix $D^{\text{cam}}$, where we try to reduce the camera variance $D^{\text{cam}}$ from $D$. Then in $\tilde{D}$ the distance between instances would better reflect the variance between identities.

The original distance matrix $D \in N \times N$ is calculated by the cosine similarities between the temporal ensembling based features $V$, where $D_{i,j}$ denotes the similarities between the $i_{th}$ instance and the $j_{th}$ instance. While the number of identities is far greater than the number of camera domains, we can expect that the mean value of similarities that belong to each camera pairs implicitly denotes the variances caused by corresponding inter-domain or intra-domain conditions (or similarities affected by camera labels). Then the camera variance between camera $i$ and camera $j$ in the camera domain offset matrix is calculated by:

$$D_{i,j}^{\text{cam}} = \frac{1}{N_{i}^{\text{cam}} \times N_{j}^{\text{cam}}} \sum_{i=1}^{N_{i}^{\text{cam}}} \sum_{j=1}^{N_{j}^{\text{cam}}} D_{u,v|c_u=i,c_v=j},$$  \hspace{1cm} (6)

where $c_u$ denotes the camera label of the $u_{th}$ instance, $N_{i}^{\text{cam}}$ denotes the number of instances captured by camera $i$. Note that when $i$ equals to $j$, the offset distance $D_{i,i}^{\text{cam}}$ represents the intra-camera similarity value. A greater value represents more similar domains, and the values of intra-domain (same camera label) should be the largest. We subtract the corresponding value from the distance matrix $D$ as a penalty item. Then the element $\tilde{D}_{u,v}$ in $\tilde{D}$ is calculated by:

$$\tilde{D}_{u,v} = D_{u,v} - \lambda \cdot D_{c_u,c_v}^{\text{cam}},$$  \hspace{1cm} (7)

where $\lambda$ is a factor to control the effect of camera variance. For the dataset with significant camera variance, $\lambda$ will be set larger accordingly.

After getting the new distance matrix $\tilde{D} \in N \times N$, softmax is applied to each line of the matrix. In this way, the distance between instances is represented as the relative distance. Then the unified distance matrix $\hat{D}$ is adopted for clustering algorithm to generate pseudo labels. By taking each intra-camera and inter-camera pair into consideration, we can align instances in the distance space and generate pseudo labels with a new distance matrix that is more related to the variances of identities.

**C. Summary of the framework**

The framework iteratively trains the network and conducts clustering to generate pseudo labels for further network updating. In this framework, we consider the factors that improve contrastive learning and clustering. During training, the network is learned from random positive and negatives, which reduces the effect of label noise from clustering. For clustering, the unified distance matrix is proposed to deal with the camera variance and temporal ensembling is adopted to provide a more robust feature for clustering. The whole procedure is summarized in Algorithm 1.

TABLE I: Comparison with state-of-the-art methods on three datasets. SOTA unsupervised, UDA and supervised methods are shown. The best results among unsupervised methods are marked in bold type. * denotes the UDA-based method working under the fully unsupervised setting.

V. EXPERIMENTS

A. Datasets and Evaluation Protocol

We evaluate the proposed method on three large-scale person re-ID benchmarks: Market-1501, DukeMTMC-reID and MSMT17.

Market-1501 includes 32,668 labeled person images of 1,501 identities collected from six camera views. For evaluation, the dataset is divided into 12,936 images of 751 identities for training, 3,368 query images and 19,732 images of 705 identities for testing.

DukeMTMC-reID is a subset of the DukeMTMC dataset [47]. The dataset is captured from eight cameras, including 36,411 person images from 1,812 identities. A number of 1,404 identities appear in more than two cameras, and the rest 408 IDs are distractor images. Using the evaluation protocol specified in [48], the dataset is divided with 16,522 images of 702 identities for training, 2,228 query images of 702 identities and 17,611 gallery images for testing.

MSMT17 is composed of 126,411 person images from 4,101 identities collected by an 15-camera system. These cameras include 12 outdoor cameras and 3 indoor ones. The training set consists of 32,621 images of 1,041 identities, and the testing set contains 11,659 images as query and 82,161 images as gallery. With large-scale images and multiple cameras, this dataset is more challenging than the other two benchmarks.

Evaluation protocol. In the training stage, we use an unlabeled dataset. In testing stage, Mean average precision (mAP) and cumulative matching characteristic (CMC) are adopted to measure performance. The presumption is that CMC reflects retrieval precision, while MAP reflects the recall. No post processing technique like re-ranking is used.

Implementation Details. We adopt an ImageNet-pretrained ResNet-50 [49] as the backbone of encoder θ. The L2 normalized feature is used to update instance-level memory and cluster-level memory. The update rate is empirically set as 0.2, the temperature factor is 0.04. At each iteration, we adopt DBSCAN to cluster target data and generate pseudo labels. The threshold of DBSCAN is 0.5 for DukeMTMC-reID and Market-1501, 0.7 for MSMT17. At the end of every iteration, instance memory is updated for consistency.

We use ADAM as the optimizer. The initial learning rate is 0.00035. Each training batch consists of 64 images randomly sampled from 16 identities with 4 images per identity. Random flipping, cropping and erasing are applied as data augmentation.

B. Comparison with State-of-the-Arts.

In this subsection, we compare our methods with the state-of-the-arts unsupervised and UDA re-ID methods. The results are shown in Table I.

Comparison with fully unsupervised methods. Our method outperforms existing unsupervised methods by a clear
Fig. 4: Evaluations of the camera offset factor $\lambda$ on MSMT17. The rank-1 accuracy and mAP are shown.

margin. On Market-1501, our method obtain 82.4% of mAP and 93.0% of rank-1 accuracy, which is close to the supervised upper bound. Compared with the baseline, the proposed method can significantly improve the performances on three datasets. The full model gains 4.1% Rank-1 and 8.5% mAP improvements on Market-1501, 6.1% Rank-1 and 8.7% mAP improvements on DukeMTMC-reID. Besides, it gets 22.6% Rank-1 and 17.3% mAP improvements on the most challenging MSMT17, which has complex identity variances and camera variances.

Comparing with the SOTA method CAP [26], we achieve 3.2, 4.9 and 1.5 points of improvement in terms of mAP on Market-1501, DukeMTMC-reID, and MSMT17, respectively. In CAP [26], proxy-level memory bank is adopted to conduct both of the inter and intra-camera contrastive learning, where the K-nearest negative proxies are taken as the hard negative proxies for intra-camera learning.

Comparison with UDA-based methods. Without accessing labeled source domain datasets, our method outperforms the state-of-the-art UDA methods on all of the three datasets, as shown in Table I. Especially, on the challenging MSMT17 dataset, our method achieves 15.5% Rank-1 and 11.9% mAP improvement when compared to SPCL [21]. The main reason is that the UDA methods mainly focus on the model learning of the source domain, while ignore the effect of the target domain and contrastive learning.

Comparison with Supervised methods. We report our supervised upper bound in Table I, in which the model is trained with our backbone and the annotated labels. Comparing with the upper bound, our method achieves competitive performance on Market-1501 and DukeMTMC, while the performance gap is relative large on the most challenging dataset MSMT17. We also observe that, comparing with the classic supervised method PCB [7], our unsupervised method achieves 0.8 and 3.0 points of improvement in terms of mAP on Market-1501 and DukeMTMC-reID, respectively. The remarkable performance demonstrates our superiority.

C. Ablation Studies

In this subsection, we analysis the sub-components of our method and show the performances in Table II. The hyper-parameters are also evaluated and discussed.

Effective of the stochastic learning strategy. Three experiments are conducted to show how the stochastic learning strategy benefits the model. (1) Baseline: the mean vector of instance features of each clusters is used as classifier for contrastive loss. (2) Stochastic: the feature embedding of a random selected image of each cluster is adopted as the classifier. (3) Stochastic (online): the newly extracted feature embedding of a random selected image of each cluster is adopted as the classifier. The results are shown in Table II.

We observe that the performance of baseline is obviously lower than the other two stochastic methods. The main reason is that due to the imperfection of the encoder and clustering algorithm, the error of pseudo labels is inevitable. Thus, the baseline method could accumulate the clustering errors among the training-clustering iterations. Taken random sample to represent each cluster centroid proxies can greatly alleviates the influence of noisy label. Also, we suspect that, the mean operation harms the diversity of the positive and negative samples when conduct contrastive learning, which would impair the model.

Compared with ‘Stochastic’, ‘Stochastic (online)’ brings further improvements on all the three datasets, e.g. 2% and 3% performance gain on mAP and rank-1 accuracy in MSMT17. In ‘Stochastic’, the random selected instance features are encoded by encoder of different periods, which may bring inconsistency when comparing with the current training instance feature to compute contrastive loss. We demonstrate that by storing and updating the stochastic memory online, we can always represent each cluster with newly referred instance, which handles inconsistency and noisy labels simultaneously.

Effectiveness of the temporal ensembling based feature embedding. The performance of with and without temporal ensembling based feature embedding is shown in Table II. The temporal ensembling based feature embedding provides performance improvements on all the three datasets. Specifically, on MSMT17, the temporal ensembling based feature embedding improves the mAP and rank-1 accuracy by 1.0
Fig. 5: Performances along training on MSMT17. The mAP, rank-1 accuracy and the accuracy of clustering along training are shown in the sub-figure (a), (b) and (c), respectively. The performances of the baseline and the method using stochastic training strategy are shown. Note that ‘Stochastic’ stands for using stochastic training strategy without online feature updating temporal ensembling or unified matrix.

Fig. 6: Evaluations with different values of \( \lambda \) on MSMT17. The rank-1 accuracy and mAP are shown. \( N_c \) denotes the number of images in each cluster.

points and 0.4 points, respectively. The improvement demonstrates that, by considering the features extracted by temporal networks, the assembled feature becomes more robust and performs better during clustering.

**Effectiveness of unified distance matrix.** Table II shows the performance of with and without the unified distance matrix. We observe that takes camera information for distance matrix outperforms the counterpart on all the three datasets. Specifically, the improvement of mAP on the three datasets are 0.2%, 1.0%, 4.8%, respectively. We observe that, the effect is quite significant on MSMT17, which has the most cameras and the most severe camera variances. The improvement demonstrates that the proposed matrix successfully reduces the affect of camera variances, but focuses on the variance of person identities. The component is easily be add-on other clustering based method and works well especially facing challenging dataset.

We also evaluate the camera offset factor \( \lambda \) in Fig. 4, which is the weight of camera variances. We vary the value of \( \lambda \) to six different values, the mAP and rank-1 accuracy are illustrated. We observe that, too small \( \lambda \) may undervalue the weight of camera variances, and too large \( \lambda \) will do harm to the computed similarity. When increasing the value, it achieves consistent improvements and gains optimal performance when \( \lambda = 1 \).

**D. Algorithm Analysis**

**Analysis over iterations.** We show the re-ID performance and the clustering accuracy along training in Fig. 5. The clustering accuracy is computed as the proportion of the images of the majority identity in each cluster. It is obvious that the stochastic strategy achieves better performance on all of the three criterion. We observe that, the rank-1 accuracy and mAP of the two methods are similar in the first 20 epochs, after which the performance gap becomes bigger and consistent. We suspect that in the first 20 epochs, both model are relatively weak and have the room for improvement. However, as the network continues to train, the baseline method is limited by the accuracy of clustering and the diversity of the negative samples. We also observe that the clustering accuracy is relatively low, indicating that there is still a large gap to meet towards the supervised upper-bound.

**Analysis of the stochastic learning strategy.** We further dig out how the stochastic strategy work in contrastive learning in Fig. 6. In the experiments, we randomly select different percentage of instances from each cluster to calculate their mean features as the positive and negatives during contrastive learning. When the percentage is \( 1/N_c \), the stochastic learning strategy is adopted, where only one instance is selected. When the percentage is 1, the method converge to the baseline, where the mean feature of all images from each cluster is adopted. We observe that when less instance is involved, a higher performance is obtained, which demonstrates the benefit of the stochastic strategy.

**VI. CONCLUSION**

In this paper, we investigate the problem of unsupervised re-ID. Following the clustering-based pipeline, we propose to learn from a stochastic strategy with a stochastic memory so as to avoid training error accumulation from clustering noise, provide more diverse negative samples as well as maintain consistent contrastive samples for the current training image. To cope with camera variance, we introduce a unified distance matrix, which reduces the effect of camera differences and is more related to identity variance. For a stable clustering
result, temporal ensembling is adopted to generate more robust feature embedding for clustering. Experiments on three datasets and comparison with state-of-the-art methods confirm the validity of our work.
