The regularity of almost all edge ideals

Alexander Engström*  Milo Orlich†

August 18, 2021

Abstract

A fruitful contemporary paradigm in graph theory is that almost all graphs that do not contain a certain subgraph have common structural characteristics. The “almost” is crucial, without it there is no structure. In this paper we transfer this paradigm to commutative algebra and make use of deep graph theoretic results. A key tool are the critical graphs introduced by Balogh and Butterfield.

We consider edge ideals $I_G$ of graphs and their Betti numbers. The numbers of the form $\beta_{i,2i+2}$ constitute the “main diagonal” of the Betti table. It is well known that any Betti number $\beta_{i,j}(I_G)$ below (or equivalently, to the left of) this diagonal is always zero. We identify a certain “parabola” inside the Betti table and call parabolic Betti numbers the entries of the Betti table bounded on the left by the main diagonal and on the right by this parabola. Let $\beta_{i,j}$ be a parabolic Betti number on the $r$-th row of the Betti table, for $r \geq 3$. Our main results state that almost all graphs $G$ with $\beta_{i,j}(I_G) = 0$ can be partitioned into $r-2$ cliques and one independent set, and in particular for almost all graphs $G$ with $\beta_{i,j}(I_G) = 0$ the regularity of $I_G$ is $r-1$.

1 Introduction

In this paper we consider edge ideals $I_G$ and their Betti numbers $\beta_{i,j}(I_G)$. It is well known that these numerical invariants of $I_G$ can be computed with Hochster’s formula by studying the simplicial homology of the independence complex $\text{Ind}(G)$ of $G$, that is, the simplicial complex whose faces are the independent sets of $G$. Ultimately, this amounts to understanding whether $G$ contains some specific induced subgraphs or not, and this is a problem in extremal graph theory.

For graphs $G$ and $H$, one says that $G$ is $H$-free if $G$ does not contain a copy of $H$ as an induced subgraph. Balogh and Butterfield [2] introduced relatively recently the concept of critical graph, a rather technical notion, giving a characterization for critical graphs $H$ in terms of almost all graphs that are $H$-free. This is the key tool for our main results, and we believe that we are the first to employ this method in commutative algebra.

*alexander.engstrom@aalto.fi
†milo.orlich@aalto.fi
In this paper we say that a Betti number \( \beta_{i,j} \) on the \( r \)-th row of the Betti table, for \( r \geq 3 \), is a parabolic Betti number if the following hold:

\[
\begin{align*}
    r - 2 & \leq i \leq r - 2 + \binom{r - 1}{2}, \\
    2(r - 1) & \leq j \leq 2(r - 1) + \binom{r - 1}{2}.
\end{align*}
\]

The region of the Betti table consisting of the parabolic Betti numbers is bounded from the left by the diagonal consisting of \( \beta_{1,4}, \beta_{2,6}, \beta_{3,8}, \ldots \), and from the right by the “parabola” consisting of \( \beta_{1,4}, \beta_{2,6}, \beta_{3,7}, \ldots \). In Figure 1 the Betti numbers on row \( r \), for \( 3 \leq r \leq 10 \), are marked with gray squares, and the diagonal and the parabola bounding the region of parabolic Betti numbers are also drawn. The reason for considering these parabolic Betti numbers \( \beta_{i,j}(I_G) \) is that when one of them is zero, \( G \) is \( H \)-free for some critical graphs \( H \).

We say that a graph \( G \) is an \( (s,t) \)-template if \( G \) can be covered with \( s \) cliques (i.e., complete graphs) and \( t \) independent sets. One of our main results describes the structure of almost all graphs with some vanishing parabolic Betti number:

**Theorem (Theorem 32).** Let \( \beta_{i,j} \) be a parabolic Betti number on the \( r \)-th row of the Betti table, for some \( r \geq 3 \). Almost every graph \( G \) with \( \beta_{i,j}(I_G) = 0 \) is an \( (r-2,1) \)-template.

Recall that the regularity of \( I_G \), denoted \( \text{reg}(I_G) \), is the largest index of a non-zero row in the Betti table. The other main result, which (partially) follows from the theorem above, is the following:

**Theorem (Theorem 33).** Let \( \beta_{i,j} \) be a parabolic Betti number on the \( r \)-th row of the Betti table, for some \( r \geq 3 \). Then, for almost every graph \( G \) with \( \beta_{i,j}(I_G) = 0 \),

1. \( \text{reg}(I_G) = r - 1 \), and
2. every parabolic Betti number of \( I_G \) above row \( r \) is non-zero.

### 1.1 Outline of the paper

In Section 2.1 we recall all the necessary graph theory background, with plenty of examples so as to give a friendly introduction to critical graphs. In Section 2.2 we recall some
background notions in commutative algebra. In particular we do not define Betti numbers
in the most general way, since Hochster’s formula is enough for the purposes of this paper.

In Section 3 we define the main objects that come into play: parabolic clusters and
parabolic Betti numbers. The parabolic clusters are the critical graphs to which we apply
the machinery of Balogh and Butterfiled [3], and they are the graphs that do not appear
as induced subgraph of $G$ exactly when some suitable parabolic Betti number $\beta_{i,j}(I_G)$ is
zero.

In Section 4 we prove some preliminary results concerning $(d,1)$-templates, that is,
graphs that can be covered with $d$ cliques and one independent set. In Section 5 we state
and prove the two main theorems mentioned above.

One may wonder how “sharp” our results are. More precisely, we prove that for
almost all graphs with a parabolic Betti number $\beta_{i,j}(I_G) = 0$ on the $r$-th row we get
reg$(I_G) = r - 1$, and one may ask if the “almost” is just due to the special methods we
employed, and how often it actually happens that the regularity is not equal to $r - 1$:
we answer this question in Section 6. The other natural question is whether one may be
able to generalize the results above to arbitrary Betti numbers, and not just the parabolic
ones: in Section 7 we show how this falls apart in the case of non-parabolic Betti numbers.

In Section 8 we relate our results to the famous Erdős–Hajnal conjecture. Lastly, in
Section 9 we consider a tentative “space of graphs” and prove that the $(d,1)$-templates
are connected in that space.

1.2 Relation to papers on edge ideals of random graphs

In this paper we work with unlabeled graphs. Most papers on edge ideals of random graphs
consider labeled graphs instead, so that one would for instance make a distinction between
the ideals $(xy, yz)$ and $(xz, zy)$ in $k[x, y, z]$. With a slight abuse of notation, we consider
edge ideals on unlabeled graphs, essentially meaning that we do not distinguish $(xy, yz)$
from $(xz, zy)$: indeed, we are only interested in the Betti numbers of edge ideals, and
those do not depend on the labeling of the vertices. There are geometric and probabilistic
pros and cons with both approaches. In selecting almost all graphs, we do not privilege
those with a particular number of edges. By keeping the number of edges low instead of
requiring a parabolic Betti number to be zero, Erman and Yang [14] and Dochtermann
and Newman [12] proved similar regularity and vanishing results as in our main theorems.
Both of those papers build on the theory of random flag complexes developed by Kahle [16]
[17, 18].

There are more recent interesting results on resolutions of ideals of random graphs,
see for example [2, 4, 5, 13, 3, 8, 20].

2 Background

2.1 Tools from graph theory: critical graphs

In this section we recall all the necessary notions from graph theory. The definition of critical graph (see Definition 8) is quite technical and requires several instrumental concepts. We introduce the term “(s, t)-template”. For the rest we follow [3] closely, both in notation and terminology. Because the concept of critical graph is not yet standard in commutative algebra, we offer several examples meant for the more algebraic readers to illustrate all the unavoidable notational technicalities.

A finite simple graph is a pair \((V_G, E_G)\) where \(V_G\) is the (finite) set of vertices of \(G\) and \(E_G \subseteq \binom{V_G}{2}\) is the set of edges. That is, the edges have no direction and we allow no multiple edges nor loops. For a subset \(U \subseteq V_G\), we denote by \(G[U]\) the subgraph of \(G\) induced by \(U\), which by definition is the subgraph with vertex set \(U\) and the edges of \(G\) with both endpoints in \(U\).

By graph we will actually most often mean an unlabeled graph, that is, the isomorphism class of a finite simple graph. One may still consider the edge ideal of an unlabeled graph, up to permutation of the variables of the polynomial ring. We observe that this does not affect in any way any of the results of this paper.

Recall that a clique (or complete graph) is a graph where every any two vertices are adjacent, that is, connected by an edge. We denote by \(K_a\) the clique on \(a\) vertices. An independent set is the complement of a clique, that is, a graph where no two vertices are adjacent.

In its most commonly known version, a coloring of a graph \(G\) is a partition of the vertex set \(V_G\) into independent subsets. More formally, a coloring of a graph \(G\) is a function \(f: V_G \rightarrow [k] = \{1, \ldots, k\}\) such that, if we set \(V_i := \{v \in V_G \mid f(v) = i\}\), then each induced subgraph \(G[V_i]\) is an independent set. That is, in this situation one doesn’t allow adjacent vertices to have the same “color” (i.e., the value of \(f\)). If such a coloring exists, one says that \(G\) is \(k\)-colorable.

In this paper we consider a more general version of graph coloring, which is also well studied in graph theory but perhaps less popular in other branches of math. We partition the vertex set \(V_G\) into cliques and independent sets:

**Definition 1.** We say that a pair of non-negative integers \((s, t)\) is a covering pair for a graph \(G\) if there is a function \(f: V_G \rightarrow [s+t]\) such that, if we set \(V_i := \{v \in V_G \mid f(v) = i\}\), then \(G[V_i]\) is a clique for \(1 \leq i \leq s\) and \(G[V_s+i]\) is an independent set for \(s+1 \leq i \leq s+t\). If \((s, t)\) is a covering pair for \(G\), we call \(G\) an \((s, t)\)-template.

One may observe the following:

1. Any of the cliques or independent sets in the definition above may be empty. So in particular if a graph \(G\) is an \((s, t)\)-template, then \(G\) is also an \((s', t')\)-template for any \(s' \geq s\) and \(t' \geq t\).

2. The \((0, k)\)-templates are exactly the \(k\)-colorable graphs in the “classical” sense, and the \((1, 1)\)-templates are commonly known as split graphs.

**Example 2.** Consider \(P_5\), the path on five vertices. The pair \((2, 0)\) is not a covering pair for \(P_5\) because the largest cliques in \(P_5\) are edges, and two edges are not enough to cover
Figure 2: The graphs in Examples 4 and 9.

all of $P_5$. On the other hand $(2, 1)$ is a covering pair for $P_5$: one may pick as independent set the middle point of $P_5$ and as the two cliques the first and last edge. Notice that this is not the unique way to cover $P_5$ with two cliques and one independent set. For instance, the independent set could also consist of the first, third and fifth vertex, and the two cliques would then consist of the two remaining vertices, one vertex each.

**Definition 3.** We call coloring number of a graph $G$, denoted $\chi_c(G)$, the minimum $k$ such that every pair $(s, t)$ of non-negative integers with $s + t = k$ is a covering pair for $G$. If a pair $(s, t)$ with $s + t = \chi_c(G) - 1$ is not a covering pair for $G$, we call $(s, t)$ a witnessing pair for $G$.

**Example 4.** Consider the five-cycle $C_5$ and the seven-cycle $C_7$ (drawn in Figure 2 to help visualize things). One may check that $\chi_c(C_5) = 3$ and that $(2, 0)$, $(1, 1)$ and $(0, 2)$ all are witnessing pairs for $C_5$. One may also check that $\chi_c(C_7) = 4$ and that the witnessing pairs for $C_7$ are $(3, 0)$ and $(2, 1)$, whereas $(1, 2)$ and $(0, 3)$ are covering pairs for $C_7$.

One needs to measure how much of a graph $H$ is left when we cover as much as possible of $H$ with $s$ cliques and $t$ independent sets. The next definition captures this idea:

**Definition 5.** For a graph $H$ and non-negative integers $s$ and $t$, denote by $F(H, s, t)$ the set of minimal (by induced containment) graphs $F$ such that $H$ can be covered by $s$ cliques, $t$ independent sets, and a copy of $F$. In other words, $F(H, s, t)$ consists of the graphs in the set

$$ \{ H - U \mid U \subseteq V_G \text{ and } H[U] \text{ is an (s, t)-template} \} $$

which are minimal with respect to induced containment.

In particular, one gets $F(H, s, t) = \{ \emptyset \}$ if $H$ itself is an (s, t)-template. Notice moreover that in practice when trying to determine what a specific $F(H, s, t)$ is, we consider maximal cliques and independent sets, because if they were not maximal then we would just end up with a graph $F$ that is not minimal, that is, a graph $F$ that strictly contains some other $F'$, obtained with maximal cliques and independent sets, as an induced subgraph.

**Example 6.** Consider $H = P_5$. The set $F(P_5, 1, 0)$ consists of two graphs $F_1$ and $F_2$: $F_1$ is the path on three vertices, obtained when we choose to cover one of the external edges of $P_5$, and $F_2$ is the disjoint union of an edge and a vertex, obtained when we choose to cover one of the internal edges of $P_5$. Indeed, neither $F_1$ nor $F_2$ is an induced subgraph of the other.
**Definition 7.** A graph $G$ is called $H$-free if $G$ does not contain a copy of $H$ as an induced subgraph. For a family $\mathcal{F}$ of graphs, let

$$\mathcal{P}(n, \mathcal{F}) := \{\text{graphs } G \text{ on } n \text{ vertices } | \text{ for all } H \in \mathcal{F}, G \text{ is } H\text{-free}\}.$$ 

If $\mathcal{F} = \{H\}$ consists of a single graph, we simplify the notation to $\mathcal{P}(n, H)$.

We finally come to the main definition of this section, from [3]:

**Definition 8.** A graph $H$ is critical if, for all non-negative integers $s$ and $t$ with $s + t = \chi_c(H) - 2$ and for all large enough $n$, there are at most two graphs in $\mathcal{P}(n, \mathcal{F}(H, s, t))$.

**Example 9.** For the graphs in Figure 2, we know from Example 4 that $\chi_c(C_5) = 3$ and $\chi_c(C_7) = 4$. To determine whether $C_5$ is critical one needs to consider the pairs $(s, t)$ such that $s + t = 3 - 2$, namely $(1, 0)$ and $(0, 1)$. We have

$$\mathcal{F}(C_5, 1, 0) = \{\bigcirc\}, \quad \mathcal{F}(C_5, 0, 1) = \{\bigotimes\}.$$ 

Then $C_5$ is not critical, because for large $n$ the set $\mathcal{P}(n, \mathcal{F}(C_5, 1, 0))$ consists of more than two elements: in particular it always contains at least the graph on $n$ vertices with no edges, the graph on $n$ vertices with one edge, and the complete graph $K_n$. On the other hand, $C_7$ is critical: as $\chi_c(C_7) = 4$, we need to inspect values of $s$ and $t$ such that $s + t = 4 - 2$, which give

$$\mathcal{F}(C_7, 2, 0) = \{\bigcirc, \bigotimes\}, \quad \mathcal{F}(C_7, 1, 1) = \{\bullet\}, \quad \mathcal{F}(C_7, 0, 2) = \{\bullet\}.$$ 

Thus, for large $n$ we get

$$\mathcal{P}(n, \mathcal{F}(C_7, 2, 0)) = \{K_n, \overline{K_n}\}, \quad \mathcal{P}(n, \mathcal{F}(C_7, 1, 1)) = \{K_n\}, \quad \mathcal{P}(n, \mathcal{F}(C_7, 0, 2)) = \emptyset$$

and therefore $C_7$ is critical.

**Definition 10.** Let $\mathcal{A}(n)$ and $\mathcal{B}(n)$ be two families of graphs on $n$ vertices such that $\mathcal{B}(n) \subseteq \mathcal{A}(n)$. We say that almost every graph in $\mathcal{A}(n)$ is in $\mathcal{B}(n)$ if

$$\lim_{n \to \infty} \frac{|\mathcal{A}(n)|}{|\mathcal{B}(n)|} = 1.$$ 

We also write “almost all” or “for almost all”, with the same connotation.

We prove an immediate observation that will be used later.

**Lemma 11.** Let $\mathcal{A}(n)$, $\mathcal{B}(n)$ and $\mathcal{C}(n)$, with $\mathcal{C}(n) \subseteq \mathcal{B}(n) \subseteq \mathcal{A}(n)$, be families of graphs on $n$ vertices such that almost all graphs in $\mathcal{A}(n)$ are in $\mathcal{B}(n)$ and almost all graphs in $\mathcal{B}(n)$ are in $\mathcal{C}(n)$. Then almost all graphs in $\mathcal{A}(n)$ are in $\mathcal{C}(n)$.

**Proof.** One may simply write

$$\lim_{n \to \infty} \frac{|\mathcal{A}(n)|}{|\mathcal{C}(n)|} = \lim_{n \to \infty} \frac{|\mathcal{A}(n)|}{|\mathcal{B}(n)|} \frac{|\mathcal{B}(n)|}{|\mathcal{C}(n)|} = 1.$$ 

$\square$
The following is the main theorem of [3] and one of the key tools for us.

**Lemma 12** ([3], Theorem 1.9). Let $H$ be a graph such that $\chi_c(H) \geq 3$. The following are equivalent:

1. almost every $H$-free graph is an $(s,t)$-template, for some $s$ and $t$ such that $(s,t)$ is a witnessing pair for $H$ (that is, $s + t = \chi_c(H) - 1$ and $(s,t)$ is not a covering pair for $H$);

2. $H$ is critical.

### 2.2 Combinatorial commutative algebra: Betti numbers of edge ideals

A simplicial complex $\Delta$ on vertex set $V$ is a family of subsets of $V$ such that, whenever $\sigma \in \Delta$ and $\sigma' \subseteq \sigma$, we have $\sigma' \in \Delta$. We call the elements of $\Delta$ its faces, and for a face $\sigma$ we say that the dimension of $\sigma$ is $\dim \sigma := |\sigma| - 1$. The simplicial complexes that we will consider in this paper are the following:

**Definition 13.** The independence complex of a finite simple graph $G$, denoted $\text{Ind}(G)$, is the complex whose faces are the independent sets of $G$.

One may define the reduced homology of a simplicial complex $\Delta$ over a field $K$. We refer to [21] for a brief introduction. In short, denoting by $F_i$ the set of faces of $\Delta$ of dimension $i$ and defining suitable differentials, one gets a chain complex

$$
0 \longrightarrow K F_{i+1} \xrightarrow{\partial_{i+1}} \cdots \longrightarrow K F_i \xrightarrow{\partial_i} K F_{i-1} \xrightarrow{\partial_{i-1}} \cdots \longrightarrow K F_0 \xrightarrow{\partial_0} K F_{-1} \longrightarrow 0,
$$

and the $i$-th reduced homology of $\Delta$ over $K$ is defined as

$$
\tilde{H}_i(\Delta; K) := \ker(\partial_i)/\im(\partial_{i+1}).
$$

In this paper we will fix a field $K$ and write simply $\tilde{H}_i(\Delta) = \tilde{H}_i(\Delta; K)$. The calculations homology computations in this paper are not particularly involved, especially for what concerns our main results. The facts about homology that we use are in fact very standard and we refer for instance to [21] for the proofs.

**Definition 14.** For a finite simple graph $G$, one defines the edge ideal of $G$ as

$$
I_G := (x_v x_w \mid \{v, w\} \in E_G)
$$

inside the polynomial ring $S = K[x_v \mid v \in V_G]$, where $K$ is a field.

**Remark 15.** Notice that we consider unlabeled graphs almost everywhere in the paper. The edge ideal of an unlabeled graph is not well defined, but the main results of this paper concern homological invariants of edge ideals, and these invariants are the same for any labeling of $G$. Therefore we shall talk about the “edge ideal of an unlabeled graph”.

7
The \textit{(graded) Betti numbers} of a finately generated, graded $S$-module $M$ are numerical invariants that one can define in terms of a minimal free resolution of $M$. For any $i \geq 0$ and $j \in \mathbb{Z}$, they are written $\beta_{i,j}(M)$ or just $\beta_{i,j}$ if there is no ambiguity on what $M$ is. We refer the interested reader to [23]. These numbers are usually arranged in the so-called \textit{Betti table} of $M$, so that in column $i$ and row $j$ one puts the number $\beta_{i,i+j}$:

<table>
<thead>
<tr>
<th></th>
<th>0</th>
<th>1</th>
<th>2</th>
<th>3</th>
<th>$\cdots$</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>$\beta_{0,0}$</td>
<td>$\beta_{1,1}$</td>
<td>$\beta_{2,2}$</td>
<td>$\beta_{3,3}$</td>
<td>$\cdots$</td>
</tr>
<tr>
<td>1</td>
<td>$\beta_{0,1}$</td>
<td>$\beta_{1,2}$</td>
<td>$\beta_{2,3}$</td>
<td>$\beta_{3,4}$</td>
<td></td>
</tr>
<tr>
<td>2</td>
<td>$\beta_{0,2}$</td>
<td>$\beta_{1,3}$</td>
<td>$\beta_{2,4}$</td>
<td>$\beta_{3,5}$</td>
<td></td>
</tr>
<tr>
<td>3</td>
<td>$\beta_{0,3}$</td>
<td>$\beta_{1,4}$</td>
<td>$\beta_{2,5}$</td>
<td>$\beta_{3,6}$</td>
<td></td>
</tr>
<tr>
<td>4</td>
<td>$\beta_{0,4}$</td>
<td>$\beta_{1,5}$</td>
<td>$\beta_{2,6}$</td>
<td>$\beta_{3,7}$</td>
<td></td>
</tr>
<tr>
<td>$\vdots$</td>
<td>$\vdots$</td>
<td>$\beta_{1,2}$</td>
<td>$\beta_{2,3}$</td>
<td>$\beta_{3,4}$</td>
<td>$\cdots$</td>
</tr>
</tbody>
</table>

It turns out that there is only a finite number of non-zero entries in the Betti table, and the \textit{regularity} of $M$

$$\text{reg}(M) := \max\{j \mid \beta_{i,i+j}(M) \neq 0 \text{ for some } i\}$$

is the highest index of a row with a non-zero entry.

The modules $M$ that we consider in this paper are always edge ideals $I_G$, and for this purpose one may consider the following special case of Hochster’s formula (see [21]) as a definition of Betti numbers for edge ideals:

$$\beta_{i,j}(I_G) = \sum_{W \in \mathcal{V}(G)^j} \dim_k \tilde{H}_{j-2}(\text{Ind}(G)[W]).$$

It turns out that in the case of edge ideals many Betti numbers are known to be zero by default. First of all, the Betti numbers in rows 0 and 1 of the table are always zero, so the Betti numbers that we need to consider are on row 2 onwards. Secondly, by \textit{main diagonal} of the Betti table we mean the diagonal consisting of the numbers $\beta_{0,2}, \beta_{1,4}, \beta_{2,6}, \beta_{3,8}, \ldots$, that is,

$$\beta_{k,2(k+1)}, \quad \text{for } k \geq 0.$$ 

One may also write these numbers in the form $\beta_{r-2,2(r-1)}$, where $r \geq 2$ is the row index. Any Betti number on the $r$-th row can be written as $\beta_{i,r+i}$, for $i \geq 0$, and more explicitly for these numbers one has

$$\beta_{i,r+i}(I_G) = \sum_{W \in \mathcal{V}(G)^r} \dim_k \tilde{H}_{r-2}(\text{Ind}(G)[W]).$$

For our purposes it will actually be more convenient to write the numbers on row $r$ as $\beta_{r-2+p,2(r-1)+p}$, for some integer $p$ that shows how far we move horizontally from the main diagonal. If $p < 0$, then the corresponding Betti number is zero by well-known results. That is, we always have zeros to the left of (or equivalently, under) the main diagonal.
3 Parabolic clusters and parabolic Betti numbers

A graph is $k$-partite if the vertex set can be partitioned into $k$ independent sets. Following the notation of [10], we denote by $K_{a_1,\ldots,a_k}$ the complete $k$-partite graph whose independent sets have orders $a_1,a_2,\ldots,a_k$ and where any two vertices in different independent sets are connected with an edge. Recall that $K_a$ denotes the clique on $a$ vertices. We moreover denote by $\overline{G}$ the complement of a graph $G$, that is, the graph on the vertex set of $G$ with exactly the edges that $G$ does not have.

**Definition 16.** A $k$-cluster is the disjoint union of $k$ cliques, or equivalently the complement of a complete $k$-partite graph. If the number $k$ of cliques is clear, we omit it. We denote a $k$-cluster by

$$K_{a_1,\ldots,a_k} = K_{a_1} \sqcup K_{a_2} \sqcup \cdots \sqcup K_{a_k},$$

where $a_1,a_2,\ldots,a_k$, that we assume being ordered as $a_1 \leq a_2 \leq \cdots \leq a_k$, are the number of vertices in the $k$ cliques. Let $k \geq 2$. If $a_1 = 2$ and $2 \leq a_i \leq i$ for all $i \in \{2,3,\ldots,k\}$, then we say that the $k$-cluster $K_{a_1,\ldots,a_k}$ is parabolic.

**Example 17.** There is only one parabolic 2-cluster: $K_{2,2}$; two parabolic 3-clusters: $K_{2,2,2}$, $K_{2,2,3}$; and five parabolic 4-clusters: $K_{2,2,2,2}$, $K_{2,2,2,3}$, $K_{2,2,2,4}$, $K_{2,2,3,3}$, $K_{2,2,3,4}$.

Recall that, for a natural number $n$, the $n$-th Catalan number is

$$C_n = \frac{1}{n+1} \binom{2n}{n}.$$

**Definition 18.** A Dyck path of length $2n$ is a monotonic lattice path on an $(n \times n)$-grid from the point $(0,0)$ to $(n,n)$, below the diagonal.

It is well-known that the number of Dyck paths of length $2n$ is equal to the $n$-th Catalan number $C_n$. We use this fact to count the number of parabolic $k$-clusters:

**Proposition 19.** There is a bijection between Dyck paths of length $2(k-1)$ and parabolic $k$-clusters. In particular the number of parabolic $k$-clusters is $C_{k-1}$.

**Proof.** For a parabolic $k$-cluster $C = K_{a_1,\ldots,a_k}$, set $h_0 = a_1 - 2$ and $h_i = a_{i+1} - 1$ for $1 \leq i \leq k-1$. The bijection is defined by associating to $C$ the monotonic lattice path in a $(k-1) \times (k-1)$-square with height function $h$. This path is below the diagonal, hence it is a Dyck path.

Our next step is relating $k$-clusters and Betti numbers.

**Lemma 20.** Let $C$ be a $k$-cluster with each clique containing at least two vertices. Then

$$H_i(\text{Ind}(C)) \neq 0 \iff i = k - 1.$$

**Proof.** This follows from the fact that the independence complex of a chordal graph is shellable (see [11] [25] [26]).

**Lemma 21.** Let $k \geq 2$ and let $C = K_{a_1,\ldots,a_k}$ be a $k$-cluster with $a_i \geq 2$ for all $i$. Denote $p = a_1 + \cdots + a_k - 2k$. If a graph $G$ is such that

$$\beta_{k-1+p,2k+p}(I_G) = 0,$$

then $G$ is $C$-free.
Proof. By Hochster’s formula we have

\[ \beta_{k-1+p,2k+p}(I_G) = \sum_{W \in \mathcal{V}(G)} \dim K \tilde{H}_{k-1}(\text{Ind}(G)[W]). \]

Notice that the \( k \)-cluster \( C \) has \( 2k + p = a_1 + \cdots + a_n \) vertices, and by Lemma 20 we know that \( \tilde{H}_{k-1}(\text{Ind}(C)) \neq 0 \).

Example 22. We illustrate the phenomenon of Lemma 21 for parabolic \( k \)-clusters with \( 2 \leq k \leq 5 \). We omit the commas in the subscripts of the clusters to lighten the notation:

\[
\begin{array}{cccccccccccc}
3 & \beta_{1,4} & & & & & & & & & & \\
& \hline
4 & & & & & & & & & & & \\
& & \beta_{2,6} & \beta_{3,7} & & & & & & & & \\
5 & & & \beta_{3,8} & \beta_{4,9} & \beta_{5,10} & \beta_{6,11} & & & & & \\
& & & \hline
6 & & & \beta_{4,10} & \beta_{5,11} & \beta_{6,12} & \beta_{7,13} & \beta_{8,14} & \beta_{9,15} & \beta_{10,16} & \\
& & & & \hline
\end{array}
\]

By Lemma 21 if a Betti number \( \beta_{i,j}(I_G) \) written in the table above is zero, then \( G \) is \( C \)-free, for any parabolic cluster \( C \) written in the same cell as \( \beta_{i,j}(I_G) \).

We give a name to the Betti numbers whose vanishing implies the absence of parabolic \( k \)-clusters as induced subgraphs:

Definition 23. Let \( r \geq 3 \). A Betti number \( \beta_{i,j} \) on the \( r \)-th row of the Betti table is called a parabolic Betti number if the following hold:

\[
2 \leq i \leq r - 2 + \binom{r-1}{2}, \quad \text{and} \quad 2(r-1) \leq j \leq 2(r-1) + \binom{r-1}{2}.
\]

Recall from Section 2.2 that the Betti numbers on the \( r \)-th row of the Betti table can be written as \( \beta_{r-2+p,2(r-1)+p} \), where \( p \) represents the distance from the main diagonal \( \beta_{0,2}, \beta_{1,4}, \beta_{2,6}, \ldots \). In several proofs it will be helpful to keep in mind that parabolic Betti numbers on the \( r \)-th row are exactly those of the form

\[
\beta_{r-2+p,2(r-1)+p} \quad \text{for } r \geq 2 \text{ and } 0 \leq p \leq \binom{r-1}{2}.
\]

More explicitly, the region of the Betti table consisting of the parabolic Betti numbers is bounded by the main diagonal of numbers \( \beta_{i,j} \) with

\[
i = r - 2 \quad \text{and} \quad j = 2(r-1), \quad \text{for } r \geq 3,
\]

10
and the parabola consisting of the numbers $\beta_{i,j}$ with

$$i = r - 2 + \binom{r-1}{2} = \frac{(r-3)(r-2)}{2},$$

$$j = 2(r-1) + \binom{r-1}{2} = \frac{(r-1)(r+2)}{2},$$

for $r \geq 3$. In Figure 1 the parabolic Betti numbers in the top-left portion of the Betti table are marked by gray squares.

**Remark 24.** The parabolic Betti numbers on the $k$-th row of the Betti table are related to the $k$-parabolic clusters as a special case of Lemma 21. However, while that lemma holds in great generality for any cluster, only the parabolic clusters are what we will be using, due to their property of being critical, as discussed in the following section.

### 3.1 Parabolic clusters are critical

**Lemma 25.** Let $C$ be a parabolic $k$-cluster, with $k \geq 2$. The following hold:

(a) $\chi_c(C) = k + 1$.

(b) $(k-1, 1)$ is the only witnessing pair for $C$.

(c) $C$ is critical.

**Proof.** Write $C = \overline{K_{a_1, \ldots, a_k}}$, where $a_1, \ldots, a_k$ are the orders of the cliques of $C$.

(a) In order to prove that $\chi_c(C) = k + 1$, first of all we show that if $s$ and $t$ are non-negative integers such that $s + t = k + 1$, then $(s, t)$ is a covering pair for $C$. We do this by induction on $k$. For $k = 2$ there is only one cluster to consider: the matching consisting of two disjoint edges. One may check that $(3, 0), (2, 1), (1, 2)$ and $(0, 3)$ are covering pairs in this base case. To continue the induction, let $k > 2$. If $s > 1$, then $(s, t)$ is a covering pair for $C$ because $(s - 1, t)$ is a covering pair for the $(k-1)$-cluster $K_{a_1} \sqcup \cdots \sqcup K_{a_{k-1}}$ by induction hypothesis: one is simply simultaneously adding a clique and a color in the induction step, and one may use that new color for the new clique. So we only need to check that the remaining pair $(0, k + 1)$ is a covering pair for $C$. Indeed, the cliques of $C$ have order at most $k$, so $k$ independent sets are already enough to cover even the largest possible parabolic $k$-clusters.

Thus, every pair $(s, t)$ with $s + t = k + 1$ is a covering pair for $C$, which means that $\chi_c(C) \leq k + 1$. In order to show that the equality holds, we need to exhibit a witnessing pair $(s, t)$ with $s + t = k$, and we pick $(s, t) = (k - 1, 1)$. The pair $(k - 1, 1)$ is indeed not a covering pair for $C$, that is, we cannot cover $C$ with $k - 1$ cliques and one independent set. Indeed, we may use the $k - 1$ cliques at our disposal to cover at most only $k - 1$ of the $k$ cliques of the cluster $C$. The remaining clique $K_{a_i}$ of $C$ cannot be covered by an independent set, because we have $a_i \geq 2$ by definition of parabolic cluster.

(b) In the proof of part (a) we show that $(k - 1, 1)$ is a witnessing pair for $C$. Now we prove that any other pair $(s, t)$ with $s + t = k$ is a covering pair for $C$. The pair $(k, 0)$ is a covering pair by definition of $k$-cluster. And for any pair $(s, k-s)$, with $0 \leq s \leq k-2$, one may cover the $s$ subgraphs $K_{a_{k-s+1}}, \ldots, K_{a_k}$ of $C$ with $s$ cliques, and cover the remaining
cliques $K_{a_1}, \ldots, K_{a_{k-s}}$ with the $k-s$ independent sets, which are enough because $a_i \leq k-s$ for $i \leq k-2$, by definition of parabolic cluster.

(c) We need to consider the families of graphs $\mathcal{F}(C, s, t)$—see Definition 5—for all pairs $(s, t)$ with $s + t = \chi_c(C) - 2 = k - 1$. The easiest cases are those of the pairs $(k - 1, 0)$ and $(k - 2, 1)$: if we cover as much as possible of $C$ with $k - 1$ cliques, we are left with the smallest clique of $C$, which is $K_2$. And if we cover as much as possible of $C$ with $k - 2$ cliques and one independent set, we are left with two isolated vertices, which one may write as $\overline{K_2}$. These are the best ways to cover $C$ with the pairs $(k - 1, 0)$ and $(k - 2, 1)$: all other “residue graphs” that are left after covering $C$ with the pairs $(k - 1, 0)$ or $(k - 2, 1)$ contain respectively $K_2$ and $\overline{K_2}$ as induced subgraphs. That is, we have

$$\mathcal{F}(C, k - 1, 0) = \{K_2\} \quad \text{and} \quad \mathcal{F}(C, k - 2, 1) = \{\overline{K_2}\}.$$ 

As for the remaining cases, we claim that for any pair $(s, k - 1 - s)$, with $0 \leq s \leq k - 3$, one has

$$\mathcal{F}(C, s, k - 1 - s) \subseteq \{\emptyset, K_1\}. $$

We may cover the $s$ largest cliques $K_{a_{k-s+1}}, \ldots, K_{a_k}$, and we are left with $K_{a_1}, \ldots, K_{a_{k-s}}$. With the $k - 1 - s$ independent sets at our disposal we may cover all of these, except when $a_{k-s} = k - s$, in which case we cover everything except one single vertex. So in this case $\mathcal{F}(C, s, k - 1 - s) = \{K_1\}$, and otherwise if $a_{k-s} < k - s$, then $\mathcal{F}(C, s, k - 1 - s) = \{\emptyset\}$. In order to show that $C$ is critical, one needs to check that, for all $s$ and $t$ with $s + t = \chi_c(C) - 2$ and for all large $n$, the family of graphs $\mathcal{P}(n, \mathcal{F}(C, s, t))$—see Definition 7—contains at most two elements. By the discussion above, there are exactly four cases to check: for all large $n$, we have

$$\mathcal{P}(n, \{K_2\}) = \{\overline{K_n}\}, \quad \mathcal{P}(n, \{K_1\}) = \emptyset, \quad \mathcal{P}(n, \{\overline{K_2}\}) = \{K_n\}, \quad \mathcal{P}(n, \emptyset) = \emptyset.$$ 

All of these sets have cardinality smaller than 2, so indeed $C$ is critical.

Theorem 26. Let $k \geq 2$ and let $H$ be a parabolic $k$-cluster. Then almost every $H$-free graph is a $(k - 1, 1)$-template.

Proof. This follows directly from Lemma 12 and Lemma 25.

4 Results on $(d, 1)$-templates

In this section we collect the last two main preliminary results, namely Proposition 30 and Lemma 31 needed for our main theorems.

The following lemma by Prömel and Steger [24] is explicitly stated here with the details available in its proof by them. Recall that $\mathcal{P}(n, H)$ is the set of graphs on $n$ vertices without an induced copy of the graph $H$.

Lemma 27 ([24], Theorem 1.3). For any graph $H$ on at least two vertices and $\varepsilon > 0$, there is an $n_0$ such that

$$2^{\left(1 - \frac{\varepsilon}{\chi_c(H) - 1}\right)\binom{n}{2}} < |\mathcal{P}(n, H)| < 2^{\left(1 - \frac{\varepsilon}{\chi_c(H) - 1 + \varepsilon}\right)\binom{n}{2}}$$ 

for all $n > n_0$. 

12
The following is a special case of an estimate by Balogh and Butterfield.

**Lemma 28** ([3], Corollary 2.3). For any positive integer $d$ and $\varepsilon > 0$, there is an $n_0$ such that

$$2^{1 - \frac{1}{\chi_c(H) - 1} - \varepsilon} < \left\lfloor \frac{(d,1)\text{-templates on } n \text{ vertices}}{\chi_c(H) - 1} \right\rfloor < 2^{1 - \frac{1}{\chi_c(H) - 1} + \varepsilon}(\frac{n}{2})$$

for all $n > n_0$.

**Proof.** The original statement of Corollary 2.3 of [3] is that

$$2^{1 - \frac{1}{\chi_c(H) - 1}} \left\lvert Q(n, H) \right\rvert < 2^{\chi_c(H) - 1} 2^{1 - \frac{1}{\chi_c(H) - 1}}(\frac{n}{2})^{\chi_c(H) - 1},$$

where $Q(n, H)$ is the family of graphs on $n$ vertices that are $(s, t)$-templates for some witnessing pair $(s, t)$ of $H$. If $H$ is a fixed parabolic $(d + 1)$-cluster, this reduces to the desired estimate by parts (a) and (b) of Lemma 25.

Lastly, we recall the following folklore estimate.

**Lemma 29.** For any natural number $d$, the Catalan numbers satisfy

$$\sum_{k=0}^{d} C_k \leq 2^{2d}.$$  

**Proposition 30.** For any positive integer $d$, almost every $(d,1)$-cluster contains all parabolic $k$-clusters, with $k \leq d$, as induced subgraphs.

**Proof.** More explicitly, we want to show that

$$\lim_{n \to \infty} \left\lfloor \frac{(d,1)\text{-templates on } n \text{ vertices}}{\text{all parabolic } k\text{-clusters with } k \leq d \text{ are induced subgraphs of } G} \right\rfloor = 1.$$

Set $\varepsilon = \frac{1}{3d(d+1)}$. By Lemma 25 and Lemma 27, for any parabolic $k$-cluster $C$ with $k \leq d$ we have that

$$|\mathcal{P}(n, C)| < 2^{1 - \frac{1}{\chi_c(H) - 1} + \varepsilon}(\frac{n}{2})$$

$$= 2^{1 - \frac{1}{d+1} + \frac{1}{3d(d+1)}}(\frac{n}{2})$$

$$\leq 2^{1 - \frac{1}{d+1} + \frac{1}{3d(d+1)}}(\frac{n}{2})$$

$$= 2^{1 - \frac{3d+2}{3d(d+1)}}(\frac{n}{2})$$

for all large enough $n$. By Proposition 19 and Lemma 29, there are at most $2^{2(d-1)}$ parabolic $k$-clusters for $k \leq d$. Thus, for large enough $n$, the number of graphs on $n$ vertices avoiding some induced parabolic $k$-clusters with $k \leq d$ is less than

$$2^{1 - \frac{3d+2}{3d(d+1)}}(\frac{n}{2}) + 2^{2(d-1)}.$$  

13
By Lemma 28, for large enough $n$, the number of $(d,1)$-templates is more than

$$2^{\left(1 - \frac{3d+1}{3d(d+1)}\right)} = 2\left(1 - \frac{3}{3d+1}\right).$$

Since $1 - \frac{3}{3d+1} \leq 1 - \frac{3}{3d}$, we have that

$$\left|\left\{ \text{graphs } G \text{ on } n \text{ vertices} \mid \begin{array}{c} \text{some parabolic } k\text{-clusters with } k \leq d \\ \text{is not an induced subgraph of } G \end{array} \right\} \right| \to 0$$

and

$$\left|\left\{ \text{(d,1)-templates } G \text{ on } n \text{ vertices} \mid \begin{array}{c} \text{some parabolic } k\text{-clusters with } k \leq d \\ \text{is not an induced subgraph of } G \end{array} \right\} \right| \to 0$$

as $n \to \infty$. By taking the complement one gets the desired statement:

$$\left|\left\{ \text{(d,1)-templates } G \text{ on } n \text{ vertices} \mid \begin{array}{c} \text{all parabolic } k\text{-clusters with } k \leq d \\ \text{are induced subgraphs of } G \end{array} \right\} \right| \to 1$$

as $n \to \infty$. \hfill \Box

The following is Theorem 2 of [27], and as stated there it follows from Theorem 1.2 of [19].

**Lemma 31.** If $G$ is a $(d,1)$-template, then $\text{reg}(I_G) \leq d + 1$.

## 5 Main results

**Theorem 32.** Let $\beta_{i,j}$ be a parabolic Betti number on the $r$-th row of the Betti table, for some $r \geq 3$. Almost every graph $G$ with $\beta_{i,j}(I_G) = 0$ is an $(r-2,1)$-template.

**Proof.** By the discussion following Definition 23, the parabolic Betti number $\beta_{i,j}$ in the statement can be written in the form $\beta_{r-2+p,2(r-1)+p}$, for a non-negative integer $p \leq \binom{r-1}{2}$. Let $H$ be any parabolic $(r-1)$-cluster of order $2(r-1) + p$. For any $n$, consider the families

$$B(n) := \{\text{graphs on } n \text{ vertices with } \beta_{r-2+p,2(r-1)+p}(I_G) = 0\},$$

$$\mathcal{H}(n) := \mathcal{P}(n,H) = \{\text{graphs on } n \text{ vertices that are } H\text{-free}\},$$

$$\mathcal{T}(n) := \{\text{graphs on } n \text{ vertices that are } (r-2,1)\text{-templates}\}.$$

We will show that almost every $G \in B(n)$ is in $\mathcal{T}(n)$. By Lemma 31, if $G$ is an $(r-2,1)$-template, then $\text{reg}(I_G) \leq r - 1$, and therefore any Betti number on the $r$-th row is zero, in particular the number that we are considering in the statement. Hence we have the
inclusion $\mathcal{T}(n) \subseteq \mathcal{B}(n)$, implying that $|\mathcal{B}(n)|/|\mathcal{T}(n)| \geq 1$. By Lemma 21, the vanishing of $\beta_{r-2+p,2(r-1)+p}(I_G)$ implies that $G$ is $H$-free, that is, $\mathcal{B}(n) \subseteq \mathcal{H}(n)$. In particular, $|\mathcal{B}(n)|/|\mathcal{H}(n)| \leq 1$. Therefore we have

$$1 \leq \frac{|\mathcal{B}(n)|}{|\mathcal{T}(n)|} = \frac{|\mathcal{H}(n)|}{|\mathcal{T}(n)|} \leq \frac{|\mathcal{H}(n)|}{|\mathcal{T}(n)|}. $$

By Theorem 20, almost every $H$-free graph is an $(r-2,1)$-template, which means that

$$\lim_{n \to \infty} \frac{|\mathcal{H}(n)|}{|\mathcal{T}(n)|} = 1.$$ 

So by the squeeze theorem

$$\lim_{n \to \infty} \frac{|\mathcal{B}(n)|}{|\mathcal{T}(n)|} = 1,$$

and this concludes the proof.

Theorem 33. Let $\beta_{i,j}$ be a parabolic Betti number on the $r$-th row of the Betti table, for some $r \geq 3$. Then, for almost every graph $G$ with $\beta_{i,j}(I_G) = 0$,

1. $\text{reg}(I_G) = r - 1$, and
2. every parabolic Betti number of $I_G$ above row $r$ is non-zero.

Proof. By Theorem 32, almost every $G$ with $\beta_{i,j}(I_G) = 0$ is an $(r-2,1)$-template. By Proposition 30, almost all of those ones contain all parabolic $k$-clusters for $k \leq r-2$. Then of the parabolic Betti numbers above row $r$ are non-zero, by Lemma 21. In particular, $\text{reg}(I_G) \geq r - 1$.

On the other hand, $\text{reg}(I_G) \leq r - 1$ for any $(r-2,1)$-template $G$ by Lemma 31. 

6 How often is the regularity not $r - 1$?

According to our main result, Theorem 33, the regularity of $I_G$ is $r - 1$ for almost all graphs $G$ with a vanishing parabolic Betti number $\beta_{i,j}(I_G) = 0$ on row $r$. One may ask how many graphs with $\beta_{i,j}(I_G) = 0$ do not have regularity $r - 1$. In particular, it is natural to ask if the “almost all” in our main result is simply an artifact of our proof technique. In this section it is demonstrated that there are many graphs whose edge ideal has regularity different from $r - 1$ and with some vanishing Betti number on row $r$. We show that for large $n$, there are at least $2.99^n$ such graphs on $n$ vertices.

The number of unlabeled trees on $n$ vertices was determined asymptotically by Otter [22], and this is today a textbook exercise in singularity analysis [15]. The following is a slightly suboptimal simplified lower bound.

Lemma 34. There are at least $2.995^n$ trees on $n$ vertices, for large $n$.

Lemma 35. For integers $a \geq 3$ and $b, c \geq 0$, let

$$G = C_a \sqcup T_b \sqcup M_c,$$

where $C_a$ is the cycle on $a$ vertices, $T_b$ is a tree on $b$ vertices, and $M_c$ is the perfect matching on $c$ edges.
(1) If $a + 2c \leq m \leq a + b + 2c$, then there is an induced subgraph $H$ of $G$ on $m$ vertices with $\dim \tilde{H}_{c+1}(\Ind(H)) = 1$;

(2) If $m < a + 2c$, then for any induced subgraph $H$ of $G$ on $m$ vertices, we have $\dim \tilde{H}_{c+1}(\Ind(H)) = 0$;

(3) For any induced subgraph $H$ of $G$, we have $\dim \tilde{H}_{c+i}(\Ind(H)) = 0$ for $i > 1$.

Proof. First we make some elementary observations on the homotopy type of the independence complexes of the graphs related to this situation.

For any graph $F$, the independence complex of $\overline{F}$ is the graph $F$ itself seen as a simplicial complex. The complex is empty if $F$ is empty, it is zero-dimensional if $F$ has vertices but no edges, and it is one-dimensional if $F$ has edges. The number $\dim \tilde{H}_0(\Ind(\overline{F}))$ is the number of connected components of $F$, and $\dim \tilde{H}_1(\Ind(\overline{F})) = 0$ if and only if $F$ is a forest. In particular, $\dim \tilde{H}_1(\Ind(\overline{F})) = 1$ if $F$ is a cycle.

For any graph $F$, the complex $\Ind(\overline{F} \sqcup \text{edge})$ is the suspension of $\Ind(F)$ and it has the same homology of $\Ind(F)$ shifted by one position. By iteration, the independence complex of the disjoint union of $F$ and a perfect matching on $e$ edges has the homology of the independence complex of $F$, but shifted by $e$ positions.

We prove (2) and (3): Let $H$ be an induced subgraph of $G = \overline{C_a \sqcup T_b \sqcup M_c}$. If $H \cap M_c$ has an isolated vertex, then so does $H$, and so $\Ind(H)$ has no homology. Otherwise, $H \cap M_c$ is a perfect matching on $c'$ edges, and $\Ind(H)$ has the homology of $\Ind(H \cap \overline{C_a \sqcup T_b})$ shifted upwards by $c'$ degrees. The homology of $\Ind(H \cap \overline{C_a \sqcup T_b})$ is zero in dimension $i > 1$, which establishes statement (3) as $c' \leq c$. To get $\dim \tilde{H}_{c+1}(\Ind(H)) > 0$ we need that $\overline{C_a} \subseteq H$ and $c = c'$. In particular, there will be at least $a + 2c$ vertices in $H$, establishing statement (2).

Finally, we prove (1): For $a + 2c \leq m \leq a + b + 2c$, construct $H$ by only removing vertices from $G$ that are in $\overline{T_b}$. By the preceding homology calculation, $\dim \tilde{H}_{c+1}(\Ind(H)) = 1$.

Theorem 36. Let $r \geq 3$ and $i \geq 2r - 4$ be integers. For large $n$, there are at least $2.99^n$ graphs $G$ on $n$ vertices such that

(1) on row $r$, one has $\beta_{j,r+j}(I_G) > 0$ for $i < j \leq n - r$;

(2) on row $r$, one has $\beta_{j,r+j}(I_G) = 0$ for $j \leq i$;

(3) below row $r$, all Betti numbers are zero.

Proof. Consider graphs $G = \overline{C_{i-2r+7} \sqcup T_{n-i+r-4} \sqcup M_{r-3}}$ for $n \geq i + r - 4$. By Hochster’s formula

$$\beta_{j,r+j}(I_G) = \sum_{W \in \mathcal{Y}_{j,r}} \dim \tilde{H}_{r-2}(\Ind(G)[W])$$

and by Lemma 35 with some elementary index calculations, the statements (1), (2) and (3) are true. By Lemma 34 there are at least $2.995^{n-i+r-4}$ such graphs for large $n$ by modifying $T_{n-i+r-4}$, and thus there are $2.99^n$ of them for large $n$. 

16
7 Non-parabolic Betti numbers

Our main theorems concern parabolic Betti numbers. One may wonder if the situation can be reasonably generalized to any Betti number. Here we show what goes wrong.

In Section 7.1 we consider the Betti numbers on row 2 of the Betti table: not only our methods with critical graphs cannot be applied, we actually show that the vanishing of a non-parabolic Betti number in row 2 does not imply any constant bound on the regularity.

In Section 7.2 we show that the situation gets quite messy in the case of the first two non-parabolic Betti numbers on row 3.

7.1 Non-parabolic Betti numbers on row 2: absence of constant bounds on the regularity

Definition 37. For a graph $G$, let $\iota(G)$ be the number of edges in a largest induced matching of $G$.

Lemma 38. If $G$ is a graph on $e$ edges and of maximal degree $d > 0$, then $\iota(G) \geq \frac{e}{2d^2}$.

Proof. We describe an algorithm that produces an induced matching. Start by coloring all edges black and set $I = \emptyset$. Pick a black edge and add it to $I$. Color that edge, all edges that are incident to that one, and all edges that are incident to those ones, in red. Pick a new black edge, add it to $I$ and repeat the procedure until all edges are red.

The edges in $I$ form an induced matching. Denoting by $|I|$ the cardinality of $I$, the algorithm ends after $|I|$ steps, and at most $1 + 2(d - 1) + 2(d - 1)(d - 1) < 2d^2$ edges are colored red in each step. Therefore, one has $e \leq |I|2d^2$.

Observe that every induced matching, and in particular those of largest size, can be found by this algorithm. The point of the algorithm is to bound the number of red edges at each step.

Lemma 39. Fix $k \geq 3$. For any natural number $n$, denote

$$\mathcal{G}_n = \left\{ \begin{array}{c} \text{graphs } G \text{ on } n \text{ vertices} \\ \text{for all induced subgraphs } H \text{ of } G \text{ of order } k, \\ \text{the complement of } H \text{ is connected} \end{array} \right\}.$$

Then

$$\frac{1}{|\mathcal{G}_n|} \sum_{G \in \mathcal{G}_n} \iota(G) \geq \frac{n - 1}{4(k - 2)^2}.$$

Proof. For a graph $G$, let $G'$ be the induced subgraph of $G$ consisting of the connected components of $G$ on at least three vertices. Introduce an equivalence relation on $\mathcal{G}_n$ by $G_1 \sim G_2$ if $G'_1$ and $G'_2$ are isomorphic (actually the same, as we deal with unlabeled graphs).

We now describe the equivalence classes. Take a class $G \in \mathcal{G}_n/\sim$ and let $G'$ be the graph on $m$ vertices that is the same for any $G \in G$. Then the equivalence class $G$ consists of the graphs

$$G' \sqcup (\text{matching on } i \text{ edges}) \sqcup (n - m - 2i \text{ isolated vertices})$$
for $i = 0, 1, \ldots, \lfloor (n-m)/2 \rfloor$. In particular,

$$\sum_{G \in \mathcal{G}} \imath(G) = \sum_{i=0}^{\lfloor (n-m)/2 \rfloor} (\imath(G') + i) = |\mathcal{G}| \left( \imath(G') + \frac{n-m}{2} \right).$$

Next we estimate $\imath(G')$. There are at least $\frac{2}{3}m'$ edges in each connected component of $G'$ on $m'$ vertices, as $m' \geq 3$. Thus, in total, there are at least $\frac{2}{3}m$ edges in $G'$.

The maximal degree $d$ of $G'$ is at most $k-2$, because if there was a vertex of $G'$ with $k-1$ neighbours, then the induced subgraph of that vertex and those neighbours would not have a connected complement. By Lemma 38,

$$\imath(G') \geq \frac{|\mathcal{G}|(n-1)}{4(k-2)^2},$$

whenever $G'$ is non-empty. If $G'$ is empty, then $\imath(G') = \frac{m}{3(k-2)^2} = 0$. Estimate

$$\frac{m}{3(k-2)^2} + \frac{n-m}{2} \geq \frac{m}{2(k-2)^2} + \frac{n-m-\frac{1}{2}}{2(k-2)^2} = \frac{n-1}{4(k-2)^2}$$

to get

$$\sum_{G \in \mathcal{G}} \imath(G) \geq \frac{|\mathcal{G}|(n-1)}{4(k-2)^2},$$

and altogether

$$\frac{1}{|\mathcal{G}_n|} \sum_{G \in \mathcal{G}_n} \imath(G) \geq \frac{1}{|\mathcal{G}_n|} \sum_{G \in \mathcal{G}_n/\sim} \sum_{G \in \mathcal{G}} \imath(G) \geq \frac{1}{|\mathcal{G}_n|} \sum_{G \in \mathcal{G}_n/\sim} \frac{|\mathcal{G}|(n-1)}{4(k-2)^2} = \frac{n-1}{4(k-2)^2}.$$

\[\square\]

**Theorem 40.** For $k \geq 3$, if $r : \mathbb{N} \to \mathbb{N}$ is a function such that almost all graphs in

$$\{\text{graphs } G \text{ on } n \text{ vertices} \mid \beta_{k-2,k}(I_G) = 0\}$$

satisfy $\operatorname{reg}(I_G) \leq r(n)$, then $r(n)$ goes to infinity with $n$.

**Proof.** For a graph $G$, by Hochster’s formula, it is equivalent that $\beta_{k-2,k}(I_G) = 0$ and that the complement of $H$ is connected for all induced subgraphs $H$ of $G$ order $k$. So the set in the statement of this theorem is the same as $\mathcal{G}_n$ of Lemma 39.

By Lemma 39 the average order of maximal induced matchings of graphs $G$ on $n$ vertices with $\beta_{k-2,k}(I_G) = 0$ is at least $\frac{n-1}{4(k-2)^2}$.

It is well known that an induced matching on $e$ edges has as independence complex a hyper-octahedron with the homology of a sphere of dimension $e-1$. Therefore an induced matching on $e$ edges in a graph $G$ forces the first $e$ Betti numbers on the main diagonal of the Betti table of $I_G$ to be non-zero, and in particular the regularity of $I_G$ is at least $e$. Thus, $r(n)$ grows at least linearly in $n$, with a coefficient $\frac{1}{4(k-2)^2}$. \[\square\]
7.2 Non-parabolic Betti numbers on row 3

In this section we illustrate what happens and what goes wrong when we consider the first Betti numbers in row 3 that are not parabolic, namely $\beta_{2,5}$ and $\beta_{3,6}$. For $\beta_{2,5}$ we are still able to show that almost all graphs $G$ with $\beta_{2,5}(I_G) = 0$ are such that $\text{reg}(I_G) = 2$, using a very ad hoc argument involving critical graphs. For $\beta_{3,6}$ we show that this is not possible.

For any Betti number on row 3, Hochster’s formula becomes

$$\beta_{i,3+i}(I_G) = \sum_{W \in \text{Ind}(G)} \dim K \tilde{H}_1(\text{Ind}(G)[W]).$$

The dimension of the degree-one homology of a complex $\Delta$ is the number of one-dimensional holes of $\Delta$. In our case $\Delta = \text{Ind}(G)$ is a flag complex, and such a complex has one-dimensional holes if and only if the 1-skeleton (that is, the underlying graph of $\Delta$, or equivalently the complement of $G$) contains an induced $k$-cycle with $k \geq 4$, namely if and only if the 1-skeleton is not chordal.

The Betti number $\beta_{2,5}(I_G)$ is determined by the number of induced subgraphs of $G$ on five vertices whose complement contains some induced cycles $C_k$ with $k \geq 4$. The only graph on five vertices with an induced copy of $C_5$ is $C_5$ itself. As for $C_4$, one may start from $C_4$ and add a fifth vertex in all possible ways without destroying the presence of an induced $C_4$, as follows:

The complements of the graphs above are, respectively,

and the complement of $C_5$ is $H_6 := C_5$.

**Lemma 41.** The graphs $H_2$, $H_4$ and $H_5$ are critical, and, and checking that the critical graphs considered here have the appropriate witnessing pairs, the following hold:

(a) almost every $H_2$-free graph is a $(0,2)$-template or a $(1,1)$-template,

(b) almost every $H_4$-free graph is a $(1,1)$-template or a $(2,0)$-template,

(c) almost every $H_5$-free graph is a $(1,1)$-template or a $(2,0)$-template.

The graphs $H_1$, $H_3$ and $H_6$ are not critical.

**Proof.** We just show that $H_5 = P_3 \sqcup P_2$ is critical, the other cases being very similar. First of all we determine that the coloring number is $\chi_c(H_5) = 3$: indeed $(3,0)$, $(2,1)$, $(1,2)$ and
(0, 3) are covering pairs, whereas (2, 0) and (1, 1) are the witnessing pairs. To determine the criticality of \( H_5 \) we need to consider the pairs \((s, t)\) with \(s + t = \chi_c(H_5) - 2 = 1\).

We start with \((s, t) = (1, 0)\). After removing a maximal clique, that in this case is an edge, one is either left with \(P_3\) or \(P_2 \sqcup K_1\). We need to determine what graphs on \( n \) vertices, for large \( n \), do not contain any induced copies of \(P_3\) nor \(P_2 \sqcup K_1\). The graph on \( n \) vertices without edges is one of them. If \( G \) has at least one edge, let \( uv \) be an edge. For any \( w \notin \{u, v\} \), also \( uw \) and \( vw \) need to be vertices in order to avoid an induced \(P_3\) or \(P_2 \sqcup K_1\). Thus \( u \) and \( v \) are adjacent to all the vertices of \( G \). Take any vertex \( w \notin \{u, v\} \). We may repeat the same argument for the new edge \( uw \), so that \( w \) is also adjacent to all vertices of \( G \). And by repeating this for all vertices, it turns out that the graph is complete. So

\[
|\mathcal{P}(n, \mathcal{F}(H_5, 1, 0))| = |\{K_n, \overline{K_n}\}| = 2.
\]

The other pair to examine is \((s, t) = (0, 1)\). There are two maximal independent sets (up to isomorphism). The first one consists of three vertices: both of the endpoints of \(P_3\) and one of \(P_2\); and the second one consists of the middle vertex of \(P_3\) and a vertex of \(P_2\). After removing such a maximal independent set, we are left respectively with three isolated vertices or two isolated vertices. Since we need to care only about the minimal ones by induced inclusion (by Definition 5), we just need to consider the graph consisting of two isolated vertices, denoted \(\overline{K_2}\). For large \( n \), there is only one graph on \( n \) vertices without an induced \(\overline{K_2}\), and that is the complete graph \(K_n\). So

\[
|\mathcal{P}(n, \mathcal{F}(H_5, 0, 1))| = |\{K_n\}| = 1.
\]

Thus \( H_5 \) is critical. By Lemma 12 almost every \( H_5 \)-graph is an \((s, t)\)-template where \((s, t)\) is some witnessing pair of \( H_5 \), hence we get part (c) of the statement.

**Theorem 42.** For almost all graphs \( G \) with \( \beta_{2,5}(I_G) = 0 \), one has \( \text{reg}(I_G) = 2 \).

**Proof.** We know that the vanishing of \( \beta_{2,5}(I_G) \) implies that \( G \) is in particular \( \{H_2, H_5\}\)-free. We show that almost all the \( \{H_2, H_5\}\)-free graphs are \( (1, 1) \)-templates. Then, by Lemma 31 almost all graphs with \( \beta_{2,5}(I_G) \) have edge ideal \( I_G \) with \( \text{reg}(I_G) = 2 \).

Recall that the \( (0, 2) \)-templates are the bipartite graphs and the \( (1, 1) \)-templates are the split graphs. The number of \( (0, 2) \)-templates, that is, bipartite graphs, is equal to the number of \( (2, 0) \)-templates. By Corollary 2.20 of [24], the number of \( (1, 1) \)-templates is asymptotically twice the number of \( (2, 0) \)-templates.

By Lemma 11 we know that almost all \( H_2 \)-free graphs are \( (0, 2) \)-templates or \( (1, 1) \)-templates, and almost all \( H_5 \)-free graphs are \( (1, 1) \)-templates or \( (2, 0) \)-templates. Out of the \( H_2 \)-free graphs, asymptotically \( 2/3 \) are \( (1, 1) \)-templates, \( 1/3 \) are \( (0, 2) \)-templates, and \( 0 \) are something else. And out of the \( H_5 \)-free graphs, asymptotically \( 2/3 \) are \( (1, 1) \)-templates, \( 1/3 \) are \( (2, 0) \)-templates, and \( 0 \) are something else. The number of \( H_2 \)-free graphs and the number of \( H_5 \)-free graphs are equal, asymptotically. Thus, asymptotically the intersection of the \( H_2 \)-free graphs and the \( H_5 \)-free graphs consists completely of \( (1, 1) \)-templates.

**Example 43.** There are \( (2, 0) \)-templates without four-cycles between the two covering cliques and still quite many edges. The canonical extremal example are incidence graphs of finite projective planes. The first example is the complement of the Heawood graph.
(The corresponding simplicial complex is the Bruhat–Tits building of $SL_3(\mathbb{Z}_2)$.) The Betti table is

\[
\begin{array}{cccccccccccc}
 & 0 & 1 & 2 & 3 & 4 & 5 & 6 & 7 & 8 & 9 & 10 & 11 \\
2 & 70 & 476 & 1617 & 3388 & 4648 & 4184 & 2394 & 826 & 161 & 14 & - & - \\
3 & - & - & - & 28 & 224 & 777 & 1442 & 1547 & 994 & 385 & 84 & 8 \\
\end{array}
\]

One can see that $\beta_{2,5}(I_G) = 0$ but the resolution is not 2-linear. The number $\beta_{3,6}(I_G) = 28$ in row 3 is the number of six-cycles in the Heawood graph.

**Remark 44.** To conclude this section we observe that the same type of argument as for $\beta_{2,5}$, on graphs with five vertices, cannot be applied to $\beta_{3,6}$, that is, with induced subgraphs on six vertices. This is demonstrated by the existence of critical graphs with completely different templates. These are some of the critical graphs on six vertices with non-zero homology of degree 1:

- The disjoint union of two paths on three vertices each, call it $H_1$. Almost all $H_1$-free graphs are $(3,0)$-templates.
- The disjoint union of a square and an edge, call it $H_2$. Almost all $H_2$-free graphs are $(2,1)$-templates.
- The disjoint union of two triangles, call it $H_3$. Almost all $H_3$-free graphs are $(1,2)$-templates.
- The disjoint union of a $K_4$ and an edge, call it $H_4$. Almost all $H_4$-free graphs are $(0,3)$-templates.

One has in fact all possible $(s,t)$-templates with $s + t = 3$, and clearly they are not compatible in an argument similar to the one for $\beta_{2,5}$.

**8 Large homogenous sets: the Erdős–Hajnal conjecture**

A subset of vertices in a graph is called a homogenous set if it is a clique or an independent set. In this section we relate our results to the famous Erdős–Hajnal conjecture, which states that for every graph $H$ there is a constant $\tau$ such that any $H$-free graph $G$ has a homogenous set of order at least $|G|^\tau$. It is a difficult conjecture, and versions where several graphs $H$ are forbidden, or almost all $H$-free graph $G$ are considered, have been studied before. Sometimes a stronger result than Erdős–Hajnal is true, stating that there is a homogenous set of linear order $\alpha|G|$ for some $\alpha > 0$. In an $(s,t)$-template $G$ there is always a linear-order homogenous set with $\alpha = 1/(s+t)$ as the vertices of $G$ may be partitioned into $s$ cliques and $t$ independent sets. The following is an immediate consequence of Theorem 32.

**Corollary 45.** Let $\beta_{i,j}$ be a parabolic Betti number on the $r$-th row of the Betti table, for $r \geq 3$. In almost every graph $G$ with $\beta_{i,j}(I_G) = 0$ there is a homogenous set of order $|G|/(r-1)$.
One may wish to consider any Betti number, not just parabolic ones, and to get rid of the “almost”. First we review some results on the Erdős–Hajnal conjecture. We say that a graph \( H \) is an Erdős–Hajnal graph if it satisfies the conjecture. The substitution of a vertex \( v \) in a graph \( F \) by a graph \( H \) is constructed by replacing \( v \) by \( H \) and making all vertices of \( H \) incident to the neighbours of \( v \) in \( F \). The state of the art is

**Theorem 46.** A graph \( G \) is Erdős–Hajnal if \( G \) is

- a vertex, an edge or a path on four vertices,
- a bull (which is a triangle with two horns) \([6]\),
- a five-cycle \([7]\),
- the complement of an Erdős–Hajnal graph, or
- constructed by substitution from Erdős–Hajnal graphs \([1]\).

We need the following result, and it is rather possible that it might be proved without the substitution technology.

**Lemma 47.** Any cluster (i.e., a disjoint union of cliques) is Erdős–Hajnal.

**Proof.** The complete graphs are Erdős–Hajnal because a \( K_1 \) and \( K_2 \) are, and you get \( K_n \) from \( K_{n-1} \) by substituting a vertex by \( K_2 \). The disjoint union of vertices is Erdős–Hajnal, because its complement is a complete graph. The disjoint union of \( k \) complete graphs is Erdős–Hajnal, as one may start off with the disjoint union of \( k \) vertices and then perform \( k \) substitutions of them by complete graphs of appropriate orders. \( \square \)

**Proposition 48.** For any Betti number \( \beta_{i,j} \) (that could be attained by edge ideals) there is a \( \tau > 0 \) such that if \( \beta_{i,j}(I_G) = 0 \) then there is a homogenous set of order \( |G|^\tau \) in \( G \).

**Proof.** Use Lemma 20 to find a disjoint union of complete graphs \( H \) such that \( \beta_{i,j}(I_H) > 0 \). The graph \( H \) is Erdős-Hajnal according to Lemma 47. \( \square \)

In general it is unclear to what extent this might be improved. By an old result by Fröberg, the graphs with only positive Betti numbers on the second line are exactly the complements of chordal graphs. Almost all chordal graphs are split, and thus have a homogenous set spanning half the graph. But the disjoint union of \( \sqrt{n} \) cliques on \( \sqrt{n} \) vertices each is a chordal graph whose complement only has sub-linear homogenous sets.

### 9 Towards a moduli space of graphs

The main structural property for graphs that comes up in this paper is that of \((s,t)\)-template. We investigate the connectedness of the set of \((s,t)\)-templates inside the “space of graphs” introduced below.

Consider the following labeled graph \( G \): the vertices are all the unlabeled graphs on \( n \) vertices, and two such graphs \( G_1 \) and \( G_2 \) are connected by an edge in \( G \) if one can obtain \( G_1 \) by adding an edge to \( G_2 \), or vice versa. We note that one may partition the vertices of \( G \) in \( \binom{n}{2} + 1 \) independent sets, based on the cardinality of the edge set: the
\(i\)-th independent set \(I_i\) consists of all unlabeled graphs on \(n\) vertices with exactly \(i\) edges. Notice that the only edges of \(\mathcal{G}\) are between independent sets of adjacent cardinalities (that is, between \(I_i\) and \(I_{i+1}\)). In particular the graph \(\mathcal{G}\) is bipartite: one can partition the vertices of \(\mathcal{G}\) in two independent sets consisting of the graphs with an odd and even number of edges. Clearly, taking the complement is an automorphism \(G \mapsto \overline{G}\) of \(\mathcal{G}\).

**Lemma 49.** Let \(G\) be an \((s, t)\)-template with \(s \geq 1\) and \(e < \binom{n}{2}\) edges. Then there is a way of adding one edge to \(G\) so that the resulting graph is still an \((s, t)\)-template.

**Proof.** If there is some space “between” the cliques and independent sets, put the new edge there. If not, it means that there is at least one independent set \(S\) that has more than one vertex, because \(e < \binom{n}{2}\). We can take one of the vertices of \(S\) and “move” it to any of the \(s \geq 1\) cliques. Then this moved edge can be connected to another vertex of \(S\), thus getting an \((s, t)\)-template with one more edge than \(G\).

**Proposition 50.** For any non-negative integers \(s\) and \(t\), the set of \((s, t)\)-templates is connected in \(\mathcal{G}\).

**Proof.** We first prove the claim for \(s \geq 1\). Notice that, for any \(s \geq 1\) and for any \(t \geq 0\), the complete graph \(K_n\) is an \((s, t)\)-template. Let \(s \geq 1\) and pick any two \((s, t)\)-templates \(G\) and \(H\). By Lemma 49 there is a path from \(G\) to the complete graph \(K_n\), and there also is a path from \(H\) to \(K_n\). Hence, \(G\) and \(H\) are connected.

For the case with \(s = 0\) and \(t \geq 1\), just take the complements of the elements of \(\mathcal{G}\), which is an automorphism of \(\mathcal{G}\) as observed above and notice moreover that a graph \(G\) is an \((s, t)\)-template if and only if \(\overline{G}\) is a \((t, s)\)-template.

The trivial case of \((0, 0)\)-templates is the empty set, which is connected.
