Abstract—We consider the problem of controlling the group behavior of a large number of dynamic systems that are constantly interacting with each other. These systems are assumed to have identical dynamics (e.g., birds flock, robot swarm) and their group behavior can be modeled by a distribution. Thus, this problem can be viewed as an optimal control problem over the space of distributions. We propose a novel algorithm to compute a feedback control strategy so that, when adopted by the agents, the distribution of them would be transformed from an initial one to a target one over a finite time window. Our method is built on optimal transport theory but differs significantly from existing work in this area in that our method models the interactions among agents explicitly. From an algorithmic point of view, our algorithm is based on a generalized version of proximal gradient descent algorithm and has a convergence guarantee with a sublinear rate. We further extend our framework to account for the scenarios where the agents are from multiple species. In the linear quadratic setting, the solution is characterized by coupled Riccati equations which can be solved in closed-form. Finally, several numerical examples are presented to illustrate our framework.

I. INTRODUCTION

Consider the swarm control task to establish and regulate a formation of $N$ drones (“agents”). There are two substantially different angles from which one may consider this problem. A first (straightforward) approach is to concatenate the states of all the drones into one state vector and then formulate a control problem over this joint state space. Suppose the state dimension of each individual drone is $d$, then the dimension of the joint state space becomes $Nd$, which scales linearly as the group size $N$ increases. An alternative approach is to treat the distribution of the drones as the state of a system, and formulate a corresponding optimal control problem over the space of distributions. One major difference between the two approaches is that, in the former, each individual has a label and the controller aims to jointly optimize the performance of each individual, while in the latter, the individuals are indistinguishable and only group behavior matters. Thus, when the optimality criteria only involves the group behavior of individuals, the problem reduces to a density control problem. In this formulation, the state is a probability distribution and is independent of the group size $N$.

The density control problem is an optimal control problem over distributions where the objective/cost function is fully determined by the evolution of the distribution. The dynamics of the distribution of the group follows the Liouville equation, or the Fokker-Planck equation if the individual dynamics is stochastic, or the McKean-Vlasov equation if the individuals interact with each other. When the number of individuals is large, the distribution of the individuals solves the McKean-Vlasov equation. We propose to build on recent work on mean-field Schrödinger bridges which is a generalization of the Schrödinger bridge theory when the prior dynamics is modeled by a McKean-Vlasov equation, and reformulate this problem into an optimization over the space of path measures. With proper discretization over space and time the problem becomes a nonlinear version of the multi-marginal optimal transport (MOT) problem. To numerically solve this problem, we adopt the proximal gradient algorithm to sequentially linearize the nonlinear MOT and then take advantage of existing algorithms for MOT for each iteration. We further extend our method to the setting where multiple species are involved. Finally, in the linear quadratic setting where the dynamics is linear and the cost function is quadratic, we characterize the optimal solution via a coupled Riccati equation and obtain the closed-form solution.

The rest of the paper is organized as follows. In Section II we briefly introduce the several tools that will be used in this work. The main results on density control for interacting agent system are presented in Section III. An extension to density control problems involving multiple species is provided in Section IV. We investigate the problem in the linear quadratic setting in Section V and obtain a closed-form solution. Several numerical examples are presented in Section VI to illustrate the proposed framework. This is followed by a short concluding remark in VII.
II. BACKGROUND

In this section we introduce several mathematical tools on which our density control framework is based, including optimal transport and its generalizations, and the proximal gradient algorithm.

A. Optimal transport

Given two nonnegative measures \( \mu, \nu \) on \( \mathbb{R}^d \) having equal total mass (often assumed to be probability distributions), the Monge’s formulation of optimal transport seeks a transport map

\[
T : \mathbb{R}^d \rightarrow \mathbb{R}^d : x \mapsto T(x)
\]

from \( \mu \) to \( \nu \) in the sense \( T \mu = \nu \), that incurs minimum cost of transportation

\[
\int c(x, T(x))\mu(dx).
\]

Here, \( c(x, y) \) stands for the transportation cost per unit mass from point \( x \) to \( y \). The dependence of the total transportation cost on \( T \) is highly nonlinear, complicating early analyses to the point \[10\]. This problem was later relaxed by Kantorovich, where, instead of a transport map, a joint distribution \( \pi \) on the product space \( \mathbb{R}^d \times \mathbb{R}^d \) is sought. Let \( \Pi(\mu, \nu) \) be the set of joint distributions of \( \mu \) and \( \nu \), then the Kantorovich formulation of OT reads

\[
\inf_{\pi \in \Pi(\mu, \nu)} \int_{\mathbb{R}^d \times \mathbb{R}^d} c(x, y)\pi(dx,dy). \quad (1)
\]

Both the Monge’s and the Kantorovich’s formulations are “static” focusing on “what goes where.” It turns out that the OT problem can also be cast as a dynamical problem with a temporal dimension. In particular, when \( c(x, y) = \frac{1}{2} ||x-y||^2 \), OT can be formulated as a stochastic control problem

\[
\inf_{v} \mathbb{E} \left\{ \int_0^1 \frac{1}{2} \left( \|v(t, x^v(t))\|^2 dt \right) \right\}, \quad (2a)
\]

\[
x^v(0) = \mu, \quad x^v(1) = \nu. \quad (2b)
\]

Here \( V \) represents the family of admissible state feedback control laws. Note that this control problem \(2\) differs from standard ones in that the terminal constraint \( x^v(1) \sim \nu \), meaning \( x^v \) follows distribution \( \nu \), is unconventional. In \(2\), the goal is to find an optimal control policy to drive the system \( \frac{d}{dt}x(t) = v(t, x(t)) \) from an uncertain initial state \( x^v(0) \sim \mu \) to an uncertain target state \( x^v(1) \sim \nu \). The solution to \(2\) specifies how to move mass over time from configuration \( \mu \) to \( \nu \), providing more resolution to the optimal transport plan.

Assuming \( x^v(t) \) has an absolutely continuous distribution with density \( \rho_t \), \( \rho_t \) satisfies weak solution of the continuity equation

\[
\partial_t \rho_t + \nabla \cdot (v_t \rho_t) = 0, \quad (3)
\]

and the total transport cost becomes

\[
\mathbb{E} \left\{ \int_0^1 \frac{1}{2} \|v(t, x^v(t))\|^2 dt \right\} = \int_{\mathbb{R}^d} \int_0^1 \frac{1}{2} \|v(t, x)\|^2 \rho_t(x)dtdx.
\]

Thus, \(2\) is equivalent to \[30\]

\[
\inf_{v} \int_{\mathbb{R}^d} \int_0^1 \frac{1}{2} \|v(t, x)\|^2 \rho_t(x)dtdx, \quad (4a)
\]

\[
\partial_t \rho_t + \nabla \cdot (v_t \rho_t) = 0, \quad (4b)
\]

\[
\rho_0 = \mu, \quad \rho_1 = \nu. \quad (4c)
\]

The minimum is taken over all the pairs \( \rho, v \) satisfying \[35\] and some other technical conditions, see \[10\] Theorem 8.1, \[31\] Chapter 8.

Suppose we have a large number of individuals that share the same dynamics \[25\] but are independent to each other. Assume their initial states follow the same distribution \( \mu \), then \[4\] can be viewed as an density control problem for this group whose objective is to find a common control strategy for the group so that it would reach target distribution/configuration \( \nu \) at time \( t = 1 \). The solution to \(4\) is characterized by the coupled partial differential equations (PDEs)

\[
\partial_t \lambda + \frac{1}{2} \nabla \lambda^T \nabla \lambda = 0
\]

\[
\partial_t \rho_t + \nabla \cdot (\rho_t \nabla \lambda) = 0
\]

\[
\rho_0 = \mu, \quad \rho_1 = \nu.
\]

and the optimal control is \( v(t, x) = \nabla \lambda(t, x) \).

B. Schrödinger bridges

In 1931/32, Schrödinger \[32\], \[33\] posed the following problem: A large number \( N \) of independent Brownian particles in \( \mathbb{R}^d \) is observed to have an empirical distribution approximately equal to \( \mu \) at time \( t = 0 \), and at some later time \( t = 1 \) an empirical distribution approximately equal to \( \nu \). Suppose that \( \nu \) differs from what it should be according to the law of large numbers, namely

\[
\int q_n(0, x, 1, y)\mu(dx),
\]

where

\[
q_n(s, x, t, y) = (2\pi)^{-d/2}[t-s]^{-d/2} \exp \left( -\frac{\|x-y\|^2}{2(t-s)} \right)
\]

denotes the scaled Brownian transition probability density. It is apparent that the particles have been transported in an unlikely way. But of the many unlikely ways in which this could have happened, which one is the most likely?

This problem can be understood in the modern language of large deviation theory as a problem \[34\] of determining a probability law \( \mathcal{P} \) on the path space \( \Omega = C([0,1], \mathbb{R}^d) \) that minimizes the relative entropy (a.k.a., Kullback-Leibler divergence)

\[
\text{KL}(\mathcal{P}||\mathcal{Q}) := \int \log \left( \frac{d\mathcal{P}}{d\mathcal{Q}} \right) d\mathcal{P}. \quad (5)
\]

Here \( \mathcal{Q} \) is the probability law induced by the Brownian motion and \( \mathcal{P} \) is chosen among probability laws that are absolutely continuous with respect to \( \mathcal{Q} \) and have the prescribed marginals. The solution to this optimization problem is referred to as the Schrödinger bridge. Existence and uniqueness of the minimizer have been proven in various degrees of generality by Fortet \[35\], Beurling \[36\], Jamison \[37\], Föllmer \[34\].

It has been shown that the above Schrödinger’s problem can be reformulated as the stochastic control problem \[38\]

\[
\inf_{v} \mathbb{E} \left\{ \int_0^1 \frac{1}{2} \|v_t(X_t)\|^2 dt \right\}, \quad (6a)
\]

\[
dX_t = v_t(X_t)dt + \sqrt{\epsilon}dB_t, \quad (6b)
\]

\[
X_0 \sim \mu, \quad X_1 \sim \nu. \quad (6c)
\]

Here \( V \) is the class of finite energy Markov controls. This reformulation of the Schrödinger problem relies on the fact that the

\[\frac{dP}{dQ}\] denotes the Radon-Nikodym derivative between \( \mathcal{P} \) and \( \mathcal{Q} \).
relative entropy between distributions induced by the controlled and uncontrolled processes is
\[
\text{KL}(P \| Q) = \mathbb{E} \left\{ \int_0^1 \frac{1}{2} \| v(t, X_t) \|^2 dt \right\}.
\]
The proof is based on Girsanov theorem, see [39], [40]. It is easy
to see that (5) has the following density control reformulation [41],
\[\begin{align}
\inf_{\rho \in \mathcal{P}(\mathbb{R})} & \int \int_0^1 \frac{1}{2} \| v(t, x) \|^2 \rho(t) dt dx, \\
\Delta \rho_t + \nabla \cdot (v(t, x) \rho(t)) - \frac{\epsilon}{2} \Delta \rho_t &= 0, \\
\rho_0 &= \mu, \quad \rho_1 = \nu,
\end{align}\]
where the infimum is over smooth fields \(v\) and \(\rho\) that solve weakly
of the corresponding Fokker-Planck equation (7b).

Formulation (7) resembles the OT problem (4) except for the
presence of the Laplacian in (7b). It has been shown [43], [44], [45];
that the OT problem is, in a suitable sense, indeed the limit of the
Schrödinger problem when the diffusion coefficient \(\epsilon\) of the reference
Brownian motion goes to zero. On the other hand, the Schrödinger
bridge can be viewed as a regularized version of OT. Similar to (4),
the solution to (7) is characterized by the coupled PDEs
\[\begin{align}
\partial_t \lambda &= \frac{1}{2} \nabla \lambda^2 \nabla \lambda + \frac{\epsilon}{2} \Delta \lambda = 0, \\
\partial_t \rho_t + \nabla \cdot (\rho_t \nabla \lambda) - \frac{\epsilon}{2} \Delta \rho_t &= 0, \\
\rho_0 &= \mu, \quad \rho_1 = \nu,
\end{align}\]
and the corresponding optimal control policy is \(v(t, x) = \nabla \lambda(t, x)\).

C. Multi-marginal optimal transport

In this section we introduce discrete OT where the supports of
the marginal distributions are discrete sets. In this discrete setting,
the marginals \(\mu_1 \in \mathbb{R}^d_+, \mu_2 \in \mathbb{R}^d_+\) are nonnegative vectors with
equal sum. The transport cost function can be rewritten in the matrix
form \(C(x_1, x_2) \in \mathbb{R}^{d \times d}\) where \(C(x_1, x_2)\) represents the
transport cost of moving a unit mass from point \(x_1\) to \(x_2\). Similarly,
a transport plan is encoded in a joint probability matrix
\(B = \{B(x_1, x_2)\} \in \mathbb{R}^{d \times d}\) of \(\mu_1, \mu_2\). The total transport cost
is \(\sum_{x_1, x_2} C(x_1, x_2) B(x_1, x_2) = \text{Tr}(C^T B)\) and the OT problem
becomes
\[\min_{B \in \mathbb{R}^{d \times d}} \text{Tr}(C^T B) \quad \text{subject to} \quad B 1 = \mu_1, \quad B^T 1 = \mu_2, \quad (9)\]
where 1 denotes a vector of ones of proper dimension. The constraints
are to enforce that \(B\) is a joint distribution of \(\mu_1\) and \(\mu_2\).

Multi-marginal optimal transport (MOT) extends OT to the
setting involving multiple distributions. In particular, in MOT, one
seeks a transport plan among a set of marginals \(\mu_1, \ldots, \mu_J\)
with \(J \geq 2\). In the discrete setting, the transport cost is
encoded in a tensor \(C(x_1, x_2, \ldots, x_J) \in \mathbb{R}^{d \times d \times \cdots \times d}\) where
\(C(x_1, x_2, \ldots, x_J)\) denotes the unit cost associated with
\((x_1, x_2, \ldots, x_J)\), and the transport plan is described by a tensor
\(B \in \mathbb{R}^{d \times d \times \cdots \times d}\). For a transport plan \(B\), the total cost is
\[\langle C, B \rangle = \sum_{x_1, x_2, \ldots, x_J} C(x_1, \ldots, x_J) B(x_1, \ldots, x_J)\]. Thus, similar
\(\text{to} \quad C\), MOT has a linear programming formulation
\[\min_{B \in \mathbb{R}^{d \times \cdots \times d}} \langle C, B \rangle \quad \text{subject to} \quad P_j(B) = \mu_j, \quad j \in \Gamma, \quad (10)\]

where \(\Gamma \subseteq \{1, 2, \ldots, J\}\) is an index set specifying which marginal
distributions are given, and the projection on the \(j\)-th marginal of \(B\)
is defined by
\[P_j(B) = \sum_{x_1, \ldots, x_{j-1}, x_{j+1}, \ldots, x_J} B(x_1, \ldots, x_{j-1}, x_j, x_{j+1}, \ldots, x_J). \quad (11)\]

A popular method to solve the OT problem is entropy regularization,
which adds an entropy term
\[\mathcal{H}(B) = - \sum_{x_1, \ldots, x_J} B(x_1, \ldots, x_J) \log B(x_1, \ldots, x_J) \quad (12)\]
to (10), resulting in the strictly convex optimization problem
\[\min_{B \in \mathbb{R}^{d \times \cdots \times d}} \langle C, B \rangle - \epsilon \mathcal{H}(B) \quad \text{subject to} \quad P_j(B) = \mu_j, \quad j \in \Gamma \quad (13)\]
with \(\epsilon > 0\) being a regularization parameter. Invoking Lagrangian
duality, one can show that the optimal solution to (13) is
\[B = K \circ U, \quad (14)\]
where \(\circ\) denotes element-wise multiplication,
\[K = \exp(-C/\epsilon), \quad (15)\]
and \(U = u_1 \circ u_2 \circ \cdots \circ u_J\) with the vectors \(u_j \in \mathbb{R}^{d_j}\) being
associated with the Lagrange multipliers.

The Sinkhorn algorithm [46], [47], [48] iteratively updates the
vectors \(u_j\) according to
\[u_j \leftarrow u_j \circ \mu_j / P_j(K \circ U), \quad (16)\]
for all \(j \in \Gamma\). Here \(\circ\) denotes element-wise division. The Sinkhorn
algorithm (Algorithm 1) has a global convergence guarantee [49],
[50]. Moreover, it has a linear convergence rate [51], [26].

Regardless the rapid developments of OT algorithms, computation
remains a major problem preventing OT, in particular MOT,
from widely used in applications. Although Algorithm [1] is easy to
implement and considerably faster than generic linear programming
solving, its complexity still scales exponentially as \(J\) grows. The
computational bottleneck of it lies in the calculation of the projections
\(P_j(B)\), \(j \in \Gamma\) in (11).

Recently it was discovered that the computation of MOT can
be greatly accelerated if the cost tensor \(C\) has a graphical structure
[27], that is, the cost tensor \(C\) can be decomposed as
\[C(x) = C(x_1, x_2, \ldots, x_J) = \sum_{(i,j) \in E} C_{ij}(x_i, x_j), \quad (17)\]
where \(E\) denotes the set of edges of an undirected graph \(G = (V, E)\).
An important instance of this graphical OT is the Barycenter problems
[52], [53], [54] where the cost \(C\) can be decomposed into the sum of
 pairwise costs between the target distribution and each given marginal
distribution; the cost thus corresponds to a star-shaped tree.

The marginal constraints \(P_j(B) = \mu_j\) for the graphical OT
problem can be imposed on any variable node \(j \in V\). Figure [1]
depicts a graph with 7 nodes. The shaded nodes in the figure correspond
to marginal constraints, thus, in this example, \(\Gamma = \{1, 2, 3\} \subseteq V = \{1, 2, \ldots, 7\}\).

Consider the entropy regularized MOT problem (13). When the
cost \(C\) has form (17), \(K\) in (15) equals
\[K = [K(x)] = [ \prod_{(i,j) \in E} K_{ij}(x_i, x_j) ]\]
Algorithm 1 Sinkhorn Algorithm for MOT

1. Compute $K = \exp(-C/\epsilon)$
2. Initialize $u_1, u_2, \ldots, u_J$ to 1
3. while not converged do
   4. for $j \in \Gamma$ do
      5. Compute $U = u_1 \otimes u_2 \otimes \cdots \otimes u_J$
      6. Update $u_j$ as $u_j \leftarrow u_j \odot \mu_j / F_j(K \otimes U)$
   7. end for
4. end while

The (generalized) proximal gradient algorithm has nice convergence properties. When both $F$ and $G$ are convex, the algorithm is guaranteed to converge to the global minimum with rate $O(1/k)$ [28].

For more general graphical structures, we can convert it into a tree first using the junction tree algorithm [55] and then apply the Sinkhorn belief propagation algorithm on the resulting junction tree. The complexity of the algorithm depends on the node size of the junction tree, which scales exponentially as the treewidth of the graph. For graphical structure with small tree width, this algorithm is still efficient.

D. Proximal gradient algorithm

The proximal gradient algorithm [29] is an popular algorithm for the composite optimization

$$\min_{y \in \mathcal{Y}} F(y) + G(y),$$

where $\mathcal{Y}$ denotes the feasibility set. The function $F$ is assumed to be smooth. The function $G$ is usually a regularizer that is possibly nonsmooth. The algorithm reads

$$y^{k+1} = \arg\min_{y \in \mathcal{Y}} G(y) + \frac{1}{2\eta} \left\| y - (y^k - \eta \nabla F(y^k)) \right\|^2$$

$$= \arg\min_{y \in \mathcal{Y}} G(y) + \frac{1}{2\eta} \left\| y - y^k \right\|^2 + \langle \nabla F(y^k), y - y^k \rangle$$

where $\eta > 0$ is the stepsize. One advantage of the proximal gradient algorithm is that it only evaluates the gradient of $F$ and doesn’t require $G$ to be differentiable. In many applications, $G$ is a regularizer of simple form, e.g., 1-norm, and the minimization [22] can be implemented efficiently.

The proximal gradient algorithm has been generalized to the non-Euclidean setting. It is built upon the mirror descent method [28], [29]. Let $D(\cdot, \cdot)$ be a Bregman divergence, then the generalized non-Euclidean proximal gradient algorithm reads

$$y^{k+1} = \arg\min_{y \in \mathcal{Y}} G(y) + \frac{1}{\eta} D(y, y^k) + \langle \nabla F(y^k), y - y^k \rangle$$

A popular choice of $D(\cdot, \cdot)$ is the Kullback-Leibler divergence $\text{KL}(\cdot | \cdot)$, which is suitable for optimization over probability vectors/distributions.

The (generalized) proximal gradient algorithm has nice convergence properties. When both $F$ and $G$ are convex, the algorithm is guaranteed to converge to the global minimum with rate $O(1/k)$ [28].

When $F$ is nonconvex, one can only expect for convergence to local solutions. It turns out that objective function $F(y) + G(y)$ is monotonically decreasing along the updates, and the updates converge...
to some stationary points with sublinear rate $O(1/k)$ with respect to some suitable criteria [57].

III. DENSITY CONTROL OF INTERACTING AGENT SYSTEMS

Consider a collection of dynamical systems

$$dX^i_t = -\frac{1}{N} \sum_{j=1}^{N} \nabla W(X^i_t - X^j_t) dt + u^i_t dt + \sqrt{\epsilon}dB^i_t, \quad i = 1, \ldots, N,$$

where $X^i_t \in \mathbb{R}^d$, $u^i_t \in \mathbb{R}^d$ denote the state and control of agent $i$ respectively. The disturbance is modeled by a standard Wiener process $B_t$. The $N$ agents interact with each other through an interaction potential $W$, which is assumed to be continuously differentiable and symmetric, i.e., $W(x) = W(-x), \forall x$. Clearly, $\nabla W(0) = 0$. The Hessian of $W$ is assumed to be bounded, from both above and below. We are interested in controlling the collective dynamics of the individuals [54]. Our goal is to find a common feedback strategy for the $N$ agents to steer them from an initial group configuration to a target configuration over a finite time interval $[0, T]$ with minimum effort. Let $\xi(t)$ be the feedback strategy of the agents, meaning $u^i_t = \xi_t(x^i_t)$. The cost function to minimize is the average quadratic control effort

$$\mathbb{E} \left\{ \int_0^T \frac{1}{2N} \sum_i ||\xi_t(x^i_t)||^2 dt \right\}.$$ 

In the mean field limit as $N \rightarrow \infty$, the group behavior can be captured by a probability distribution

$$\rho_t \approx \frac{1}{N} \sum_{i=1}^{N} \delta_{X^i_t}$$

with $\delta_t$ denoting the Dirac distribution, and this density evolves according to the McKean-Vlasov equation [3]

$$\partial_t \rho_t + \nabla \cdot (\rho_t (-\nabla W \ast \rho_t + \xi_t)) - \frac{\epsilon}{2} \Delta \rho_t = 0. \quad (25)$$

The average control effort is approximately $\int_0^1 \int_{\mathbb{R}^d} \frac{1}{2} ||\xi_t(x)||^2 \rho_t(x) dx dt$. The initial and target configurations can both be modeled by probability distributions. Thus, in the mean field limit, our density/distribution problem can be formulated as

$$\inf_{\rho_0, \xi} \int_0^1 \int_{\mathbb{R}^d} \frac{1}{2} ||\xi_t(x)||^2 \rho_t(x) dx dt$$

$$\partial_t \rho_t + \nabla \cdot (\rho_t (-\nabla W \ast \rho_t + \xi_t)) - \frac{\epsilon}{2} \Delta \rho_t = 0 \quad (26a)$$

$$\rho_0 = \mu, \quad \rho_1 = \nu. \quad (26b)$$

We use the unit time interval $[0, 1]$ to simplify the notation. A general time interval can be transformed into $[0, 1]$ by rescaling.

One can view this as an optimal control problem for a dynamical system over the space of probability distributions with $\rho_t$ being the state. The dynamics is (26a) with state $\rho_t$ and control $\xi_t$. The constraints (26b) specify the initial and terminal states. We seek an optimal strategy with minimum control effort to steer the agents from an initial distribution $\mu$ to a target distribution $\nu$.

Using the Lagrangian duality method, one can derive a characterization of the solutions to (26). In particular, the optimal solution to (26) can be characterized by the coupled PDEs

$$\partial_t \lambda + \frac{1}{2} \nabla \lambda^T \nabla \lambda - \nabla \lambda^T \nabla W \ast \rho_t = 0$$

$$- \int_{\mathbb{R}^d} \rho_t(y) \nabla W(y - x) dy + \frac{\epsilon}{2} \Delta \lambda = 0 \quad (27a)$$

$$\partial_t \rho_t + \nabla \cdot (\rho_t (-\nabla W \ast \rho_t + \nabla \lambda)) - \frac{\epsilon}{2} \Delta \rho_t = 0 \quad (27b)$$

$$\rho_0 = \mu, \quad \rho_1 = \nu, \quad (27c)$$

where $\lambda$ is the Lagrange multiplier associated with the continuity constraint (26b). The optimal control policy is a state feedback

$$\xi_t(x) = \nabla \lambda(t, x).$$

There are several potential approaches to compute an optimal solution to the density control problem (26). For instance, the optimality condition (27) can be viewed as the Pontryagin’s principle for (26) when (26) is treated as an optimal control problem with state $\rho_t$ [88]. The multiplier $\lambda$ then becomes the costate in the Pontryagin’s principle [59], [60]. To get a solution to (27), one can use indirect method such as shooting method [59], [60] that is widely adopted for optimal control problems. However, due to the coupling between the state $\rho_t$ and the costate $\lambda$, and more importantly the fact that they are of infinite dimension, the shooting method maybe unstable and is not guaranteed to converge. Next we present a completely different approach to solve (26) based on a reformulation.

A. Reformulation and Discretization

For a given feedback policy $\xi_t$, in the mean field limit, the distribution $\rho_t$ of the individuals follows the McKean-Vlasov equation (25) and is deterministic. Moreover, the interaction between agents is of the form $-\frac{1}{N} \sum_{j=1}^{N} \nabla W(X^i_t - X^j_t) \approx -\nabla W \ast \rho_t$, which only depends on the group behavior. Thus, when $N$ is sufficiently large, the interactions between an agent with other agents becomes the interaction between the agent and the deterministic group distribution $\rho_t$. By the theory of propagation of chaos [61], the $N$ agents become effectively independent to each other and each of them follows the same stochastic dynamics

$$dX^i_t = -[\nabla W \ast \rho_t](X^i_t) dt + \xi_t(X^i_t) dt + \sqrt{\epsilon}dB^i_t. \quad (28)$$

Algorithm 2 Sinkhorn Belief Propagation (SBP) Algorithm

Initialize the messages $m_{j \rightarrow i}(x_j)$ to be $1$

Let $j_1, j_2, \ldots$ be a sequence taking values in $\Gamma$ in cyclic order

while not converged do

Update $m_{j \rightarrow i}(x_j), i \in N(j_k)$ using

$$m_{j \rightarrow i}(x_j) \propto \sum_{x_j} K_{ij}(x_i, x_j) \frac{\mu_j(x_j)}{m_{i \rightarrow j}(x_j)}, \quad \forall x_j \quad (20a)$$

Update the rest of messages on the path from node $j_k$ to node $j_{k+1}$ according to

$$m_{i \rightarrow j}(x_j) \propto \sum_{x_i} K_{ij}(x_i, x_j) \prod_{k \in N(i) \setminus j} m_{k \rightarrow i}(x_i), \quad \forall x_j \quad (20b)$$

end while
Denote by $\mathcal{P}$ the distribution induced by (25) over the path space $\Omega = C([0,1],\mathbb{R}^d)$, and by $Q(\mathcal{P})$ be distribution induced by the process
\[
dX_t = -\nabla W \ast \rho_t dt + \sqrt{d} \text{d}B_t,
\]
then by the Girsanov theorem \([60],[40]\), following a similar argument as in the Schrödinger bridge problem \([5]-[7]\), we obtain
\[
KL(\mathcal{P} \| Q(\mathcal{P})) = \int_0^1 \int_{\mathbb{R}^d} \frac{1}{2\varepsilon} \| \xi_t(x) \| ^2 \rho_t(x) dx dt.
\]
Note that we used $Q(\mathcal{P})$ to emphasize the fact that $Q$ depends on the marginal flow of $\mathcal{P}$, denoted by $(X_t) \mathcal{P} = \mu$.

Consequently, the density control problem (26) can be reformulated as
\[
\min_{\mathcal{P}} \quad KL(\mathcal{P} \| Q(\mathcal{P})) \\
(0) \quad (X_0) \mathcal{P} = \mu, \quad (X_1) \mathcal{P} = \nu.
\]
This formulation (30) coincides with the mean field Schrödinger bridge problem \([24]\). The equivalence between (26) and (30) is rigorously justified in [24], extending the large deviation theory to interacting systems. The major difference between (30) and the standard Schrödinger bridge problem \([5]\) lies in the fact that the prior distribution $Q$ in the former depends on the solution $\mathcal{P}$, rendering a nonconvex optimization, in general, over the space of path distributions.

The optimization variable $\mathcal{P}$ of (30) is of infinite dimension. To develop an implementable algorithm for (30), we first discretize the problem in time $t_i = i/T$, $i = 0, 1, \ldots, T$ as well as in space over a grid. With this discretization, the path distribution $\mathcal{P}$ becomes a $(T + 1)$-dimensional tensor $M$ with $M(x_0, x_1, \ldots, x_T)$ representing the probability of the process $\mathcal{P}$ goes through a neighborhood of $(X_0 = x_0, X_{1/T} = x_1, \ldots, X_1 = x_T)$. In terms of $M$, the objective function $KL(\mathcal{P} \| Q(\mathcal{P}))$ becomes
\[
\langle C(M), M \rangle + \epsilon \langle M, \log M \rangle
\]
where
\[
\langle M, \log M \rangle = \sum_{x_0, x_1, \ldots, x_T} M(x_0, x_1, \ldots, x_T) \log M(x_0, x_1, \ldots, x_T),
\]
and $C(M(x_0, x_1, \ldots, x_T))$ is the minimum control effort to drive the deterministic version ($\epsilon = 0$) of (28) to go through the state $x_0, x_1, \ldots, x_T$.

More explicitly, when the discretization grid is sufficiently fine,
\[
C(M(x_0, x_1, \ldots, x_T)) = \sum_{i=0}^{T-1} \frac{T}{2} ||x_{i+1} - x_i||^2 + \frac{1}{T} \langle \nabla W * P_i(M) \rangle ||x_i||^2,
\]
where $P_i(M)$ denotes the marginal of $M$ over $x_i$ and, by abuse of notation, $\nabla W * P_i(M)$ is a discretization of the convolution.

Thus, after discretization, (30) becomes
\[
\min_{\mathcal{M}} \quad \langle C(M), M \rangle + \epsilon \langle M, \log M \rangle \\
(0) \quad \mathcal{M}(0) = \mu, \quad \mathcal{M}(T) = \nu.
\]
Here $\mu$ and $\nu$ denote the discretized version of $\mu$ and $\nu$ respectively. This formulation \((31)\) is akin to the MOT problem except that the unit transport cost tensor $C$ now depends on the optimization variable $M$. This difference excludes the possibility of applying the Sinkhorn type algorithm directly to solve \((31)\). Next we develop an algorithm to compute the solution to \((31)\) by sequentially linearizing $\langle C(M), M \rangle$ and then solving the resulting MOT problems.

### B. Proximal Sinkhorn Belief Propagation Algorithm

Denote $\Pi(\mu, \nu)$ the set of $M$ that is consistent with the marginals $\mu, \nu$ and $F(M) = \langle C(M), M \rangle$ then (31) reads
\[
\min_{M \in \Pi(\mu, \nu)} F(M) - \epsilon H(M).
\]
This is a composite optimization over the probability simplex. We can thus apply the generalized proximal gradient descent algorithm to solve it. Surprisingly, when the Bregman divergence in \((23)\) is chosen to be the Kullback-Leibler divergence, each iteration of the algorithm on the problem \((32)\) takes the form
\[
M_{k+1} = \operatorname{argmin}_{M \in \Pi(\mu, \nu)} \langle \nabla F(M_k), M \rangle + \frac{1}{\eta} KL(M \| M_k) - \epsilon H(M)
\]
where $\eta > 0$ is the step size. Expanding the KL divergence term, the above becomes
\[
M_{k+1} = \operatorname{argmin}_{M \in \Pi(\mu, \nu)} \langle \nabla F(M_k) - \frac{1}{\eta} \log M_k, M \rangle - \epsilon H(M)
\]
which is a standard entropy regularized multi-marginal optimal transport problem \((13)\) with cost tensor $\nabla F(M_k) - \frac{1}{\eta} \log M_k$.

**Proposition 1.** The gradient of $F(M) = \langle C(M), M \rangle$ is
\[
\nabla F(M) = C(M) + E(M)
\]
where $E(M)(x_0, x_1, \ldots, x_T) = \sum_{i=0}^{T-1} E_i(x_i)$ with
\[
E_i(y) = \sum_{x_{i+1}} \nabla W(x_i - y)^T [x_{i+1} - x_i + \frac{1}{T} \nabla W * P_i(M)]
\]
\[
P_{i+1}(M)(x_i, x_{i+1}).
\]

**Proof.** By definition,
\[
F(M + \delta M) - F(M) \approx \langle \nabla F(M), \delta M \rangle.
\]
It follows that
\[
\langle \nabla F(M), \delta M \rangle = \langle C(M), \delta M \rangle + \sum_{i=0}^{T-1} \frac{T}{2} \langle \nabla W * P_i(\delta M) \rangle (x_{i+1} - x_i) + \frac{1}{T} \nabla W * P_i(M), M \rangle
\]
and,
\[
\sum_{i=0}^{T-1} (\langle \nabla W * P_i(\delta M) \rangle (x_{i+1} - x_i) + \frac{1}{T} \nabla W * P_i(M), M \rangle)
\]
where $E_i$ is as in (35). Hence,
\[
\langle \nabla F(M), \delta M \rangle = \langle C(M), \delta M \rangle + \langle E(M), \delta M \rangle,
\]
with $E(M)(x_0, x_1, \ldots, x_T) = \sum_{i=0}^{T-1} E_i(x_i)$, and therefore
\[
\nabla F(M) = C(M) + E(M).
\]
This completes the proof. \(\square\)

Plugging (35) into (34) yields the proximal gradient iteration
\[
M_{k+1} = \operatorname{argmin}_{M \in \Pi(\mu, \nu)} \langle C(M_k) + E(M_k) - \frac{1}{\eta} \log M_k, M \rangle - \epsilon H(M).
\]
Note that both $C(M_k)$ and $E(M_k)$ have a graphical structure associated with the line graph (Figure 2). Thus, assuming $M_k$
the same graphical structure, the solution $\mathbf{M}_{k+1}$ to (27) also has a graphical structure corresponding to the line graph. Therefore, with proper initialization, each iteration (27) can be solved efficiently using the Sinkhorn Belief Propagation algorithm (Algorithm 2). We thus establish our Proximal Sinkhorn Belief Propagation algorithm (Algorithm 3) to solve (31).

More specifically, following that (32), the complexity of the Sinkhorn Belief Propagation is

$$\mathcal{O}(\mathcal{D}^2T).$$

In the above discussions, to better illustrate our density control attention to the simple dynamics (24). Now we extend this framework to more general dynamics$^\dagger$. Let $b(\cdot) \in \mathbb{R}^d$ be a continuous drift term and $g \in \mathbb{R}^{d \times p}$ is the input matrix, and more general cost function

$$\int_0^1 \int_{\mathbb{R}^d} \left(\frac{1}{2} ||\xi_t(x)||^2 + V(x)\right) \rho_t(x) dx dt.$$

In the mean field limit, the density control problem can be formulated as

$$\inf_{\rho \in \xi} \int_0^1 \int_{\mathbb{R}^d} \left(\frac{1}{2} ||\xi_t(x)||^2 + V(x)\right) \rho_t(x) dx dt$$

(38a)

$$\partial_t \rho_t + \nabla \cdot (\rho_t (-\nabla W \ast \rho_t + \nabla \lambda (t, \cdot))) - \epsilon \Delta \rho_t = 0.$$

(38b)

$$\rho_0 = \mu, \quad \rho_1 = \nu$$

(38c)

where $a = \sigma \sigma^T$. The optimal strategy of (39) is

$$\xi_t(x) = \sigma^T \nabla \lambda (t, x)$$

where $\lambda$ solves the PDEs

$$\partial_t \lambda + \frac{1}{2} \nabla \lambda^T a \nabla \lambda - V + \nabla \lambda^T b - \nabla \lambda^T \nabla W \ast \rho$$

$$- \frac{1}{2} \rho(y) \nabla (y)^T \nabla W (y - x) dy + \frac{\epsilon}{2} \text{Tr}(a \nabla^2 \lambda) = 0$$

(40a)

$$\partial_t \rho_t + \nabla \cdot (\rho_t (-\nabla W \ast \rho_t + a \nabla \lambda)) - \frac{\epsilon}{2} \sum_{i,k} \frac{\partial^2 (a_{ik} \rho_t)}{\partial x_i \partial x_k} = 0$$

(40b)

$$\rho_0 = \mu, \quad \rho_1 = \nu$$

(40c)

Following similar arguments as before we obtain an alternative formulation

$$\min_{\mathcal{P}} \epsilon \text{KL}(\mathcal{P} | Q(\mathcal{P})) + \int V d\mathcal{P}$$

(41a)

$$\langle X_0 \rangle_\mathcal{P} = \mu, \quad \langle X_1 \rangle_\mathcal{P} = \nu.$$ (41b)

where $Q(\mathcal{P})$ is the distribution over the path space associated with the diffusion process

$$dX_t = -\nabla W \ast \mathcal{P}_t dt + b(X_t) dt + \sqrt{\epsilon} dB_t.$$ (42)

The same as (31), after discretization over space and time, the problem can be written as

$$\min_{M \in \mathbb{M}(\mu, \nu)} \langle C(M), M \rangle + \epsilon \langle M, \log M \rangle,$$ (43)

but with a slightly different cost tensor

$$C(M)(x_0, x_1, \cdots, x_T) = \frac{1}{T} \sum_{i=0}^{T-1} V(x_i)$$

$$+ \frac{1}{2} \sum_{i=0}^{T-1} \sum_{i=0}^{T-1} \frac{T}{2} ||x_{i+1} - x_i + \frac{1}{T} \nabla W \ast P_i(M) - \frac{1}{T} b(x_i)||^2.$$ (44)

Let $F(M) = \langle C(M), M \rangle$, then the above becomes a composite optimization (32) and can be solved using the proximal gradient algorithm. The derivation is similar to that of Proposition 1 and is omitted.

$\dagger$The dependence of $b, \sigma$ over time is suppressed to simplify the notation.
Algorithm 3 Proximal Sinkhorn Belief Propagation algorithm

Input: cost tensor $C$, regularization $\epsilon$, stepsize $\eta$, number of iterations $K$
Initialize $M_1$ to be a uniform probability vector
for $k = 1, 2, 3, \ldots, K$ do
  Compute $C(M_k) + E(M_k) = \frac{1}{2} \log M_k$
  Solve (47) using the Sinkhorn Belief Propagation algorithm to obtain $M_{k+1}$
extend for

Proposition 2. The gradient of $F(M) = \langle C(M), M \rangle$ with $C$ in (44) is

$$\nabla F(M) = C(M) + E(M)$$

where $E(M)(x_0, x_1, \ldots, x_T) = \sum_{i=0}^{T-1} E_i(x_i)$ with

$$E_i(y) = \sum_{x_i, x_{i+1}} \nabla W(x_i - y)^T [x_{i+1} - x_i] + \frac{1}{T} \nabla W * P_i(M)(x_i, x_{i+1}).$$

The proximal Sinkhorn belief propagation algorithm can be applied directly to solve (43) with a small modification on the expression of $E(M)$ as in Proposition 2.

IV. DENSITY CONTROL WITH MULTIPLE SPECIES

In this section, we extend our density control framework to account for the collective dynamics with multiple species. Consider a group of individuals comprised of $L$ species and each has $N$ agents. The dynamics of the $i$-th agents in the $\ell$-th species is

$$dX_{i,\ell,t} = -\frac{1}{N} \sum_{m=1}^{L} \sum_{j=1}^{N} \nabla W_{\ell m}(X_{i,\ell,t} - X_{m,i,t})dt + b_{\ell}(X_{i,\ell,t})dt + \sigma(a_{i,k} + \sqrt{\epsilon} B_{i,k}), \quad i = 1, \ldots, N,$$

where $X_{i,\ell,t}$ and $u_{i,\ell,t}$ denote the state and control of the $i$-th agents in the $\ell$-th species respectively. The interaction potential between species $\ell$ and species $m$ is assumed to be continuously differentiable and symmetric in the sense $W_{\ell m}(x) = W_{m\ell}(-x) = W_{\ell m}(x)$. We seek $L$ feedback policies, one for each species, such that, when they are adopted by the individuals, the group would be transformed from one configuration to another.

In the mean field region, denoting the initial distribution/configuration of species $\ell$ by $\mu_\ell$, and its target distribution by $\nu_\ell$, this density control problem can be formulated as

$$\inf_{\rho_{1,\ell}, \ldots, \rho_{L,\ell}} \sum_{\ell=1}^{L} \int_{\mathbb{R}^T} \int_0^1 \frac{1}{2} \left| \xi_\ell(x,t) \right|^2 + V_{\ell}(x) \rho_{\ell,t}(x)dxdt \tag{45a}$$

$$\partial_t \rho_{\ell,t} + \nabla \cdot \left( \rho_{\ell,t} \left( - \sum_m \nabla W_{\ell m} * \rho_{m,t} + b_{\ell} + \sigma \xi_{\ell,t} \right) \right) = 0, \quad \ell = 1, 2, \ldots, L \tag{45b}$$

$$\rho_{\ell,0} = \mu_\ell, \quad \rho_{\ell,1} = \nu_\ell, \quad \ell = 1, 2, \ldots, L \tag{45c}$$

where $\rho_{\ell,t}$ denotes the distribution of the $\ell$-th species. The constraints (45b) is a generalization of (39b) to the multi-species setting describing the distribution evolution of each species. The optimal solution to (45) can be characterized by the PDEs

$$\partial_t \lambda_\ell + \frac{1}{2} \nabla \lambda_\ell^T \alpha \nabla \lambda_\ell - V_\ell + \nabla \lambda_\ell^T b_\ell - \nabla \lambda_\ell^T \sum_m \nabla W_{\ell m} * \rho_{m,t} \tag{46a}$$

$$-\sum_m \int \rho_{m,t}(y) \nabla \lambda_m(y)^T \nabla W_{\ell m}(y - x)dy + \frac{\epsilon}{2} \text{Tr}(\alpha \nabla^2 \lambda_\ell) = 0$$

$$\partial_t \rho_{\ell,t} + \nabla \cdot \left( \rho_{\ell,t} \left( - \sum_m \nabla W_{\ell m} * \rho_{m} + b_{\ell} + \alpha \nabla \lambda_\ell \right) \right) = 0 \tag{46b}$$

$$\rho_{\ell,0} = \mu_\ell, \quad \rho_{\ell,1} = \nu_\ell, \quad \ell = 1, 2, \ldots, L \tag{46c}$$

for all $\ell = 1, 2, \ldots, L$. Here $\lambda_1, \lambda_2, \ldots, \lambda_L$ are Lagrange multipliers associated with the constraints (45b) for $\ell = 1, 2, \ldots, L$. The corresponding optimal control policy for the $\ell$-th species is

$$u_{\ell,t} = \sigma^T \nabla \lambda_\ell(t, X_{\ell,t}).$$

To develop an efficient algorithm for (45), we reformulate it as an optimization over the path measures. More specifically, denote by $P^\ell$ the distribution on the path space induced by species $\ell$, then following a similar argument as before, we obtain the following reformulation

$$\min_{P^1, \ldots, P^L} \sum_{\ell=1}^{L} \left\{ \epsilon \text{KL}(P^\ell || Q^\ell(P^1, \ldots, P^L)) + \int V_\ell dP^\ell \right\} \tag{47a}$$

$$(X_0)P^\ell = \mu_\ell, \quad (X_1)P^\ell = \nu_\ell, \quad \ell = 1, 2, \ldots, L \tag{47b}$$

Here the distribution $Q^\ell$ is induced by the diffusion process

$$dX = -\sum_m [\nabla W_{\ell m} * P^\ell_m](X)dt + b_{\ell}(X)dt + \sqrt{\epsilon} \sigma dB_t,$$

which clearly depends on $P^1, P^2, \ldots, P^L$.

Discretizing the problem over space and time, the optimization variables become $L$ tensors $M^\ell, \ell = 1, 2, \ldots, L$ and the optimization problem becomes

$$\min_{M^1, \ldots, M^L} \sum_{\ell=1}^{L} \left\{ \langle C^\ell(M^1, \ldots, M^L), M^\ell \rangle + \epsilon \langle M^\ell, \log M^\ell \rangle \right\} \tag{48a}$$

$$P_0(M^\ell) = \mu_\ell, \quad P_1(M^\ell) = \nu_\ell, \quad \ell = 1, 2, \ldots, L \tag{48b}$$

where the cost tensor for the $\ell$-th species is

$$C^\ell(M^1, \ldots, M^L)(x_0, x_1, \ldots, x_T) = \sum_{i=0}^{T-1} \frac{1}{T} V_\ell(x_i)$$

$$+ \frac{1}{2} \sum_{i=0}^{T} \left\| x_{i+1} - x_i + \frac{1}{T} \sum_m \nabla W_{\ell m} * P_i(M^m) - \frac{1}{T} b_{\ell}(x_i) \right\|^2.$$

A more compact form of the above problem can be obtained by combining the $L$ optimization variables $M^1, M^2, \ldots, M^L$ into a single variable $M$. More precisely, we denote by $M$ the $T + 2$
Proof. The gradient of $F(M) = \langle C(M), M \rangle$ with $C$ in (49) is
\[
\nabla F(M) = C(M) + E(M) \tag{52}
\]
where $E(M)(\ell, x_0, x_1, \ldots, x_T) = \sum_{i=0}^{T-1} E_i(\ell, x_i)$ with
\[
E_i(\ell, y) = \sum_{m, x_i, x_{i+1}} \nabla W_{em}(x_i - y)^T [x_{i+1} - x_i + \frac{1}{T} \sum_n \nabla W_{en} * P_{-1,i}(M) - \frac{1}{T} b_i(x_i)] P_{-1,i, i+1}(M)(\ell, x_i, x_{i+1}).
\tag{53}
\]

Proposition 3. The gradient of $F(M) = \langle C(M), M \rangle$ with $C$ in (49) is
\[
\nabla F(M) = C(M) + E(M) \tag{52}
\]
where $E(M)(\ell, x_0, x_1, \ldots, x_T) = \sum_{i=0}^{T-1} E_i(\ell, x_i)$ with
\[
E_i(\ell, y) = \sum_{m, x_i, x_{i+1}} \nabla W_{em}(x_i - y)^T [x_{i+1} - x_i + \frac{1}{T} \sum_n \nabla W_{en} * P_{-1,i}(M) - \frac{1}{T} b_i(x_i)] P_{-1,i, i+1}(M)(\ell, x_i, x_{i+1}).
\tag{53}
\]

The second term on the right hand side equals
\[
\sum_{i=0}^{T-1} \langle \sum_n \nabla W_{em} * P_{-1,i}(\delta M) \rangle^T (x_{i+1} - x_i + \frac{1}{T} \sum_n \nabla W_{en} * P_{-1,i}(M)) - \frac{1}{T} b_i(x_i), M).
\]

The second term on the right hand side equals
\[
\sum_{i=0}^{T-1} \langle \sum_n \nabla W_{em} * P_{-1,i}(\delta M) \rangle^T (x_{i+1} - x_i + \frac{1}{T} \sum_n \nabla W_{en} * P_{-1,i}(M)) - \frac{1}{T} b_i(x_i), M).
\]

Remark 3. In the multi-species setting, the SBP algorithm is applied to the graphical OT in Figure 3. The computation complexity for each outer iteration becomes $\mathcal{O}(D^2LT)$. The proof follows from the properties of the OT problem.

Remark 4. Even though in (55) the cost is decoupled into $L$ separate terms, each corresponds to one species, it is straightforward to generalize the method to include cost such as $\int_0^T \int V(x) \rho_\ell dx dt$ that depends on the group behavior of all the individuals.

V. LINEAR QUADRATIC CASES

A special case of particular interest is the linear quadratic density control problem where the dynamics of the individuals are linear and the costs are quadratic. That is, in the linear quadratic setting, $b_i, W_{em}, V_i$ are of the form
\[
b_i(x) = A_{\ell,x}, \tag{55a}
\]
\[
W_{em}(x) = \frac{1}{2} x^T A_{em} x, \quad \text{with } A_{m,t} = A_{m,t}^T = A_{t,m}, \tag{55b}
\]
and
\[
V_i(x) = \frac{1}{2} x^T Q_i x. \tag{55c}
\]

rendering linear dynamics for each individual
\[
dX_{i,t} = - \frac{1}{N} \sum_{m} \sum_{j} A_{\lambda} (X_{i,j} - X_{m,j}) dt + A_{i} X_{i,t} dt + \sigma(u_{i,t} dt + \sqrt{\epsilon} B_{\ell,t}), \quad i = 1, \ldots, N, \tag{56}
\]
and quadratic cost in the mean field limit
\[
\int_{t=1}^{L} \int_0^T \int_{\mathbb{R}^d} \frac{1}{2} \|\xi_{\ell,t}(x)\|^2 + \frac{1}{2} x^T Q_i x \rho_{\ell,t}(x) dx dt. \tag{57}
\]

When the feedback strategies $\xi_{\ell,t}$ are linear and the initial distributions are Gaussian, the distribution $\rho_{\ell,t}, \ell = 1, \ldots, L$ of the populations remain Gaussian all the time. Thus, we assume the marginal distributions are Gaussian, denoted by
\[
\mu_\ell = \mathcal{N}(m_\ell^i, \Sigma_\ell^i), \quad \nu_\ell = \mathcal{N}(m_\ell^i, \Sigma_\ell^i), \quad \ell = 1, \ldots, L.
\]
When there is no interaction between the individuals, the problem reduces to the covariance control problem \cite{14}. The coupling of the agents introduces extra complexities. Recently, the linear quadratic density control problem for one species \((L = 1)\) has been addressed in \cite{62}.

We next present the solution when multiple species are involved. To this end, we parametrize the Gaussian distributions \(p_\ell\) by
\[
p_\ell(t) = \mathcal{N}(m_\ell(t), \Sigma_\ell(t)).
\]
Just as standard linear quadratic optimal control, the Lagrange multipliers \(\lambda_1, \lambda_2, \ldots, \lambda_L\) in \cite{55} are quadratic, denoted by
\[
\lambda_\ell(t,x) = \frac{1}{2} x^T \Pi_\ell(t)x + n_\ell(t)^T x + c_\ell(t).
\]
Plugging \cite{55}, \cite{58} and \cite{59} into the optimality condition \cite{46} yields a coupled equation system (for all \(\ell = 1, 2, \ldots, L\))
\[
\dot{\Pi}_\ell - \Pi_\ell \sigma^T \Pi_\ell \sigma + Q_\ell + (A_\ell - \sum_m \hat{A}_{\ell m})^T \Pi_\ell + \Pi_\ell (A_\ell - \sum_m \hat{A}_{\ell m}) = 0
\]
\[
\dot{\Sigma}_\ell - (A_\ell - \sum_m \hat{A}_{\ell m} - \sigma^T \Pi_\ell) \Sigma_\ell - \Sigma_\ell (A_\ell - \sum_m \hat{A}_{\ell m} - \sigma^T \Pi_\ell)^T = 0
\]
\[
\dot{\Pi}_\ell(0) = \Sigma_{\ell 0}^T, \quad \dot{\Sigma}_\ell(0) = \Sigma_{\ell 1}^T.
\]

Assume \cite{61} is controllable, then the above Riccati equation system allows a unique solution in closed-form. We refer the reader to \cite{13} for the exact expression for the closed-form solution.

Once \(\Pi_\ell, \Sigma_\ell\) are computed, we can plug them into \cite{60a}-\cite{60d} to solve for \(n_\ell, m_\ell\). These are standard linear equations and can be solved efficiently. Once the solution to \cite{60a}-\cite{60d} is obtained, we can recover the optimal control as
\[
\xi_\ell(x) = -\sigma^T \Pi_\ell(t)x + \sigma^T n_\ell(t),
\]
which is a linear state feedback.

VI. NUMERICAL EXAMPLES

In this section we provide several numerical examples to illustrate the proposed framework on density control of interacting agent systems. In the first example, we demonstrate the solution to the density control problem in the linear quadratic setting for both single species and multiple species can steer the agents to target distributions. In the second example, we illustrate how a general interacting particle system evolve from an initial configuration to a target configuration.

A. Linear quadratic density control

We first consider \(N\) agents of the same species interacting with each other through the dynamics \cite{56} with
\[
A_1 = \begin{bmatrix} 0 & 1 \\ 0 & 0 \end{bmatrix}, \quad \hat{A}_{11} = \begin{bmatrix} 0 & 0 \\ 0 & 0.5 \end{bmatrix},
\]
and \(\sigma = [0 \ 1]^T\). Each agent alone has a trivial second order dynamics. The choice of \(A_{11}\) corresponds to an interacting potential that synchronizes the velocities of the agents. The noise intensity \(\epsilon\) is set to be 1 and we choose \(Q_1 = I\). Our goal is to find a global feedback policy so that the distribution of the agents is transformed from
\[
\mu_1 = \mathcal{N}(\begin{bmatrix} 1 \\ 1 \end{bmatrix}, \begin{bmatrix} 0.25 & 0 \\ 0 & 0.25 \end{bmatrix})
\]
to
\[
\nu_1 = \mathcal{N}(\begin{bmatrix} 1.5 \\ 0.8 \end{bmatrix}, \begin{bmatrix} 0.5 & 0 \\ 0 & 0.1 \end{bmatrix}).
\]
Figure \ref{fig:3} depicts the 3-\(\sigma\) confidence level of the Gaussian distribution of the agents. The states of the agents should be inside this envelope with probability 99.73\%. We also plot several typical trajectories of the agents, which stay inside the envelope as expected.

We next add another species to it. Let
\[
A_2 = \begin{bmatrix} 0 & 1 \\ 0 & 0 \end{bmatrix}
\]
The choice of \( \bar{A}_{12} \) imposes a repulsive potential between the agents of the two species in position. Set \( Q_2 = I \). The two marginal distributions of the second species is set to be

\[
\mu_2 = \mathcal{N}\left(\begin{bmatrix}-2 \\ -2\end{bmatrix}, \begin{bmatrix}0.25 & 0 \\ 0 & 0.25\end{bmatrix}\right)
\]

and

\[
\nu_2 = \mathcal{N}\left(\begin{bmatrix}-1 \\ -0.8\end{bmatrix}, \begin{bmatrix}0.25 & 0 \\ 0 & 0.1\end{bmatrix}\right).
\]

As before, we show the 3 – \( \sigma \) confidence envelope of the distributions of both species in Figure 5 together with some typical trajectories of the agents. It is clear from Figure 5 that the behavior of the first species is affected by the second one with the tendency to stay away from the second species.

### B. Density control for general dynamics

In this example we consider \( N \) agents in one dimensional space whose dynamics are described by (38) with

\[
W(x) = \frac{\beta}{|x|^\alpha}, \quad b(x) = 0, \quad \sigma = 1, \quad \epsilon = 0.1.
\]

That is, each agent alone is a first order integrator but they are affected by each other through the repulsive potential \( W \). Our goal is to steer the distribution of the agents from

\[
\mu = \mathcal{N}(-0.4, 0.2)
\]

to

\[
\nu = \mathcal{N}(0.4, 0.2)
\]

in some optimal way. For simplicity, we set \( V(\cdot) \equiv 0 \). Thus the objective function is the total control effort.

The evolution of the agent distribution under optimal control policy is depicted in Figure 6 for different values of \( \alpha \) and \( \beta \). When there is no interaction (\( \beta = 0 \)) among the agents, the solution (Figure 6) corresponds to a standard Schrödinger bridge problem as expected. As we increase the repulsive potential (increase \( \alpha \) or \( \beta \)), the agents spread out more quickly in between due to the repulsive force.

![Fig. 6: Density evolution under optimal control with \( \beta = 0 \)](image)

The evolution of the agent distribution under optimal control policy is depicted in Figure 7 for different values of \( \alpha \) and \( \beta \). When there is no interaction (\( \beta = 0 \)) among the agents, the solution (Figure 7) corresponds to a standard Schrödinger bridge problem as expected. As we increase the repulsive potential (increase \( \alpha \) or \( \beta \)), the agents spread out more quickly in between due to the repulsive force.

![Fig. 7: Density evolution under optimal control with \( \alpha = 0.15, \beta = 1 \)](image)
Fig. 8: Density evolution under optimal control with $\alpha = 0.15, \beta = 2$

Fig. 9: Density evolution under optimal control with $\alpha = 0.2, \beta = 1$

Fig. 10: Density evolution under optimal control with $\alpha = 0.2, \beta = 2$

VII. CONCLUSION

We studied a swarm control problem for a large group of agents that are constantly interacting with each other. We considered the problem in the mean field and formulate it as a density control problem. We further reformulated it as a nonlinear multi-marginal optimal transport problem with proper discretization. Leveraging the proximal gradient framework, we were able to compute the solution via iteratively linearizing the problem and solving the linearized problems with the Sinkhorn belief propagation algorithm. We extended our framework to account for swarm control with multiple species. Finally, we provided a closed-form solution to the density control problem in the linear quadratic setting. In this work, we assume the total cost is the summation of the cost of each individual and is thus linear over the state distribution $\rho$. In the future we plan to extend our method to deal with cost that is a nonlinear function of $\rho$.
